Aluminum honeycomb assemblies have experienced serious in-service durability problems, the most severe being moisture migrating inside the assemblies and causing corrosion of the aluminum core cells. Honeycomb suppliers have responded by producing corrosion-inhibiting coatings that have improved durability. A typical corrosion-inhibiting arrangement is shown in Fig. 12. The core foil is first anodized with phosphoric acid and

then coated with a corrosion- inhibiting primer. However, corrosion can still be a serious issue with aluminum honeycomb assemblies, and proper sealing methods are imperative. It should also be noted that the freeze/ thaw cycles encountered during a typical aircraft flight can cause skin-to-core delaminations if liquid water is present in the honeycomb cells.

Honeycomb Processing

Honeycomb processing before adhesive bonding includes: perimeter trimming, mechanical forming, heat forming, core splicing, contouring, and cleaning.

Trimming. The four primary tools used to cut honeycomb to plan dimensions are serrated knife, razor blade knife, band saw, and a die. The serrated and razor edge knives and die cutter are used on light-density cores; white heavy-density cores and complex-shaped cores are usually cut with a band saw.

Forming. Metallic, hexagonal honeycomb can be roll- or brake-formed into curved pans. The brake-forming method will crush the cell walls and densify the inner radius. Overexpanded honeycomb can be formed to a cylindrical shape on assembly. Flexcore usually can be shaped to compound curvatures on assembly.

Nonmetallic honeycomb can be heat formed to obtain curved parts. Usually the core slice is placed in an oven at high temperature for a short period of time. The heat softens the resin and allows the cell walls to deform more easily. Upon removal from the oven, the core is quickly placed on a shaped tool and held there until it cools.

Splicing. When large pieces of core are required, or when complex shapes dictate, smaller pieces can be spliced together to form the finished part. This is usually accomplished with a foaming adhesive, as shown in Fig. 13. Core splice adhesives normally contain blowing agents that produce gases (e.g., nitrogen) during heat-up to provide the expansion necessary to fill the gaps between the core sections. Different core types, cell sizes, or densities can be easily interconnected in this manner.

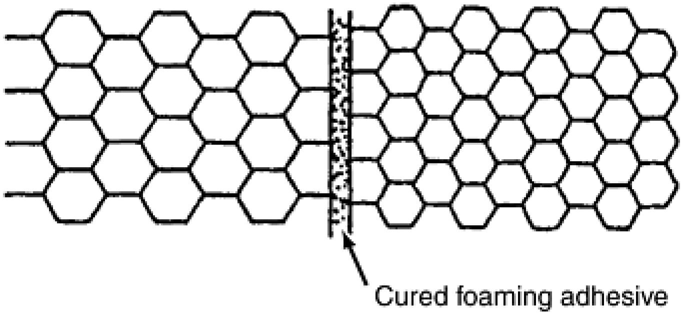

Fig. 13 Core splicing

Machining. In many sandwich panel applications, such as air foils, honeycomb must have its thickness machined to some contour (Fig. 14). This is normally accomplished using valve- stem-type cutters on expanded core. Occasionally, the solid honeycomb block is machined using milling cutters. Typical machines used for contour machining (carving) are gantry, apex, three-dimensional tracer, or numerically controlled (NC) five-axis. With five-axis NC machining, the cutting head is controlled by computer programs, and almost any surface that can be described by *x*, *y*, and *z* coordinates can be produced. These machines can carve honeycomb at speeds of up to 1.27 m/s (50 in./s) with extreme accuracy. A standard contour tolerance of an NC machine is ±0.13 mm (±0.005 in.).

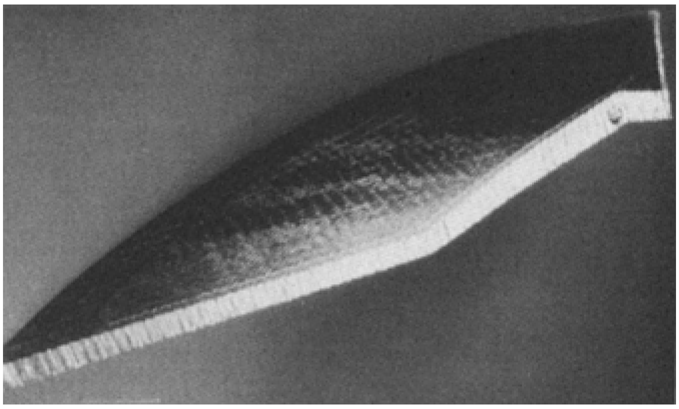

Fig. 14 Machined honeycomb parts

Cleaning and Drying. It is preferable to keep honeycomb core clean during all manufacturing operations prior to adhesive bonding; however, aluminum honeycomb core can be effectively cleaned by solvent vapor degreasing. Nonmetallic core, such as Nomex or Korex (aramid), fiberglass, and graphite core, readily absorbs moisture from the atmosphere. Similar to composite skins, nonmetallic core sections should be thoroughly dried prior to adhesive bonding. A further complication is that since the cell walls are relatively thin and contain a lot of surface area, they can reabsorb moisture rather rapidly after drying.

Flake C. Campbell, The Boeing Company—St. Louis

Syntactic Core

Syntactic core is sometimes used as an alternate to honeycomb core. Syntactic core consists of a matrix (e.g., epoxy) that is filled with hollow spheres (e.g., glass or ceramic microballons). Syntactic cores are generally much higher in density than honeycomb, with densities in the range of 482 to 1284 kg/m^3 (30–80 lb/ft^3). They are used to make sandwich panels over a wide thickness range, including much thinner than is practical for honeycomb. They can also be used as fillers in honeycomb to increase local compression strength and as edge stiffening prior to machining core. When cured against precured composite details, syntactics do not need an

adhesive. However, if the syntactic core is already cured and requires adhesive bonding, it should be scuff sanded and then cured with a layer of adhesive.

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Foam Core

A third type of core material frequently used in adhesively bonded structure is foam core. The material is usually supplied in block form that is easily cut or machined to shape. Sections may be bonded together using either two-part paste adhesives or adhesive films. Both open- and closed-cell materials are available; however, closed-cell materials are normally used for bonded structure. Sections can also be heat formed to contour using procedures similar to those for nonmetallic honeycomb core. Core densities normally range from about 48 to 642 kg/m^3 (3–40 lb/ft^3). A wide range of materials is available made from resins such as polymethylacrylimide, polyvinyl chloride, polyurethane, and polyisocyanurate. Depending on their chemistry, these core materials can be used in the temperature range of 66 to 204 °C (150–400 °F).

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Adhesive-Bonding Process

The basic steps in the adhesive-bonding process are:

1. Collection of all the parts in the bonded assembly, which are then stored as kits
2. Verification of the fit-to-bondline tolerances
3. Cleaning of the parts to promote good adhesion
4. Application of the adhesive
5. Mating of the parts and adhesive to form the assembly
6. Application of a force to produce a good fit
7. Application of force concurrent with application of heat to the adhesive to promote a chemical reaction, if needed
8. Inspection of the bonded assembly

Prekitting of Adherends. Many adhesives have a limited working life at room temperature, and adherends, especially metals, are contaminated by exposure to the environment. Thus, it is normal practice to kit the adherends so that application of the adhesive and buildup of the bonded assemblies can proceed without interruption. The kitting sequence is determined by the product and production rate.

Bondline Thickness Control. Controlling the thickness of the adhesive bondline is a critical factor in bond strength. This control can be obtained by matching the quantity of available adhesive to the size of the gap between the mating surfaces under actual bonding conditions (heat and pressure). Higher applied loads during bonding tend to reduce bondline thickness. A slight overfill is usually desired to ensure that the gap is totally filled. Conversely, if all the adhesive is squeezed out of a local area due to a high spot in one of the adherends, a disbond can result.

Fortunately, most bonds do not require optimal strength and can tolerate some local disbonds. For these bonds, an attempt should be made to produce faying parts to a tolerance of 0.8 mm (0.03 in.), and enough adhesive

should be applied to fill the gap. The use of excess adhesive adds weight and unnecessary material cost: it also increases cleanup costs. However, these negative factors must be tolerated in order to avoid disbonds during service.

Some of the most critical structural bond applications are found in highly loaded aircraft structures. For these applications, the adhesive used is in the form of a calendered film with a thin fabric layer. The fabric maintains the bondline thickness by preventing contact between the adherends. In addition, the carrier acts as a corrosion barrier between graphite skins and aluminum honeycomb core. Voids are not usually permitted. In the most common case, the bondline can vary from 50 to 230 μm (2–9 mils). Extra adhesive can be used to handle up to 510 μm (20 mils) gaps. Larger gaps must be accommodated by reworking the metal parts; tolerances are achieved by reworking of the various details so that they fit as required.

Prefit Evaluation. A prefit-checking fixture is often used in high-precision bonding. This fixture simulates the bond by locating the various parts in the exact relationship to one another as they will appear in the actual bonded assembly (see Fig. 15). For high-value assemblies, a verifilm operation is frequently conducted. The bondline thickness is simulated by placing a vinyl plastic film or the actual adhesive encased in plastic film in the bondlines. The assembly is then subjected to the heat and pressure normally used to chemically react the epoxy adhesive to form the bond. The parts are disassembled, and the vinyl film or cured adhesive is then visually or dimensionally evaluated to see what corrections are required. These corrections can include sanding the parts to provide more clearance, reforming metal parts to close the gaps, or applying additional adhesive (within permissible limits) to particular locations in the bond.

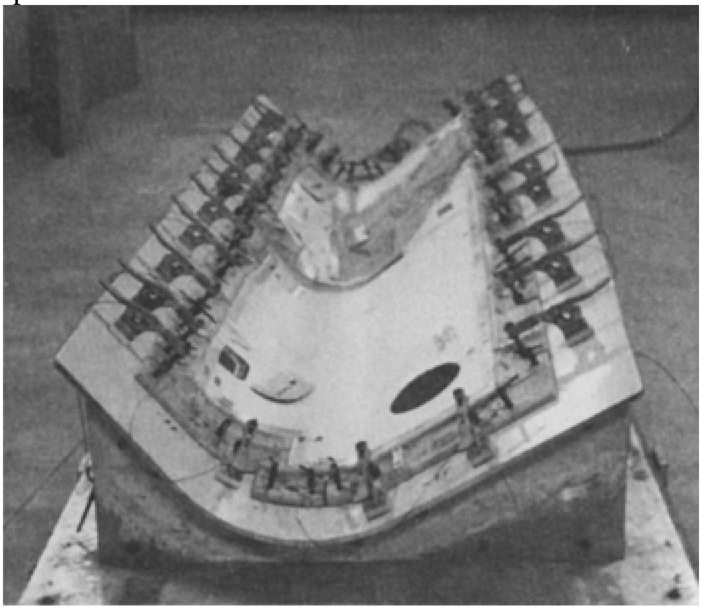

Fig. 15 Prefit fixture used for a complex-contour aircraft door

Verification of bondline thickness may not be required for all applications. However, the technique can be used to validate the fit of the mating parts prior to the start of production or to determine why large voids are produced in repetitive parts. When using paste adhesives, the adhesive thickness can be simulated by encasing the adhesive in plastic film (as mentioned previously) or aluminum foil. Once the fit of mating parts has been evaluated, the necessary corrections can be made. For cases in which the component parts can be dimensionally corrected, it is much more efficient to make the correction than risk having to scrap the parts or having them fail in service.

Flake C. Campbell, The Boeing Company—St. Louis

Adhesive Application

The application of adhesives and the accuracy of the application have a major impact on cost and quality. Enough adhesive must be applied to form an acceptable joint, but any excess represents wasted material. The labor and equipment costs should also be kept to a minimum. The method of application is a function of the physical form of the adhesive. The choice of method is also influenced by the volume and sophistication of the work.

The most commonly used adhesives are supplied as liquids, pastes, or prefabricated films. The liquid and paste systems may be supplied as one- or two-part systems. The two-part systems must be mixed before use and thus require scales and a mixer. The amount of material to be mixed should be limited to the amount needed to accomplish the task. The larger the mass, the shorter the pot or working life of the mixed adhesive. To prevent potential exotherm conditions after application, excess mixed material should be removed from the container and spread out in a thin film. This will prevent the risk of mass- related heat buildup and the possibility of a fire or the release of toxic fumes.

The storage facility plays a vital role in a production bonding operation. Many one-part adhesives and film adhesives must be stored at temperatures below ambient. Adhesives containing organic solvents must be segregated to reduce the risk of fire, and others containing polymers and solvents must be shaken periodically to prevent settling or gelation.

One factor that must be considered in adhesive application is the time interval available between adhesive preparation and final assembly of the adherend. This factor, which is referred to as pot, open, out-time, or working life, must be matched to the production rate. Obviously, materials that are ready to bond quickly are needed for high- rate applications, such as those found in the automotive and appliance industries. It should be noted that many two-part systems that cure by chemical reaction often have a limited working life before they become too viscous to apply.

Application of liquid adhesives can be accomplished using brushes, rollers, manual sprays, or robotically controlled sprays. A robot (Fig. 16) can apply tightly controlled quantities of adhesive to specific areas. Solvated two-part systems are sprayed using equipment with two pumps; preset quantities of each component are pumped through the spray head where they are blended into a single stream. Of course, many plants use several different application systems simultaneously for their various job shop requirements.

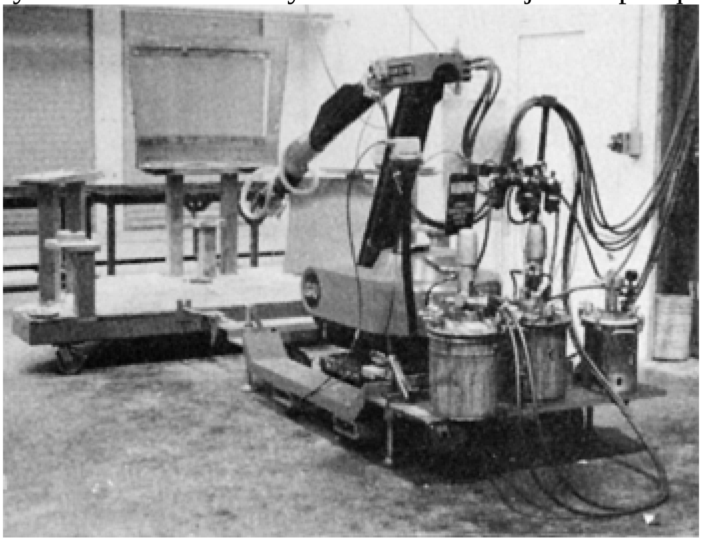

Fig. 16 Robot used for spraying adhesive

Application of paste adhesives can be accomplished by brush, by spreading with a grooved tool, or by extrusion from cartridges or sealed containers using compressed air. For the latter, the combination of the orifice diameter and the applied pressure controls the size of the bead applied to the work. Robots can move the application head in a constant path at a repetitive surface speed to enhance the accuracy of bead placement and size. The use of robots to apply paste adhesive is analogous to their use to locate spot welds. In the automotive industry, several vans with plastic skins bonded to a steel structural frame are assembled using paste adhesives applied by robots.

Film adhesives are costly and thus are used mainly in aircraft applications. They consist of an epoxy, bismaleimide, or polyimide resin film and a fabric carrier. The fabric guarantees a bondline because it prevents contact of the adherends. These adhesives are manually cut to size, usually with knives, and placed in the bondlines.

Tooling

Adherends must be in the specified relationship to one another during bond formation. Slippage of one of the constituents of the bonded assembly will result in a need for costly reworking, or the entire assembly might be scrapped. When a paste or liquid adhesive is used, it is usually helpful to have a load applied to the joint to deform the adhesive to fill the bondline. In applications such as aircraft parts, higher pressures are used to force the adherends to fit to within small tolerances. The adhesives used in high-pressure bonding typically do not have a high flow; they contain a thin scrim fabric to ensure that a bondline is maintained. Fixtures can be used to maintain part alignment, or fixtureless concepts can be used in which some other method provides the required alignment.

Fixtures. Bonding fixtures can represent a large investment in tooling and have a significant impact on cost. Every time they are used, they must be loaded with parts, unloaded, cleaned, and maintained. Fixtures can be used for both high- and low-rate production. A bonding fixture contains several basic elements:

- A tooling surface matching the contour of the bonded panel (face sheet)
- A series of jig points, side rails, and pressure blocks as needed
- A support structure to prevent warpage of the face sheet for contoured tools
- A dolly or removable wheels to permit moving the fixture if needed

Press-Bonding Fixtures. Many flat panels are bonded in press-bonding fixtures. The face sheet of the fixture is flat, and the alignment rails are usually thinner than the thickness of the structural panel. For very thin panels, the rails may be higher than the panel to ensure that alignment is maintained. In this type of fixture, a pressure plate is used to take up the space between the panel and the top of the rails. The pressure plate fits within the alignment rails (see Fig. 17). Often, press-bonding tools are made to standard thickness so that several tools can be placed in the press cavity at the same time.

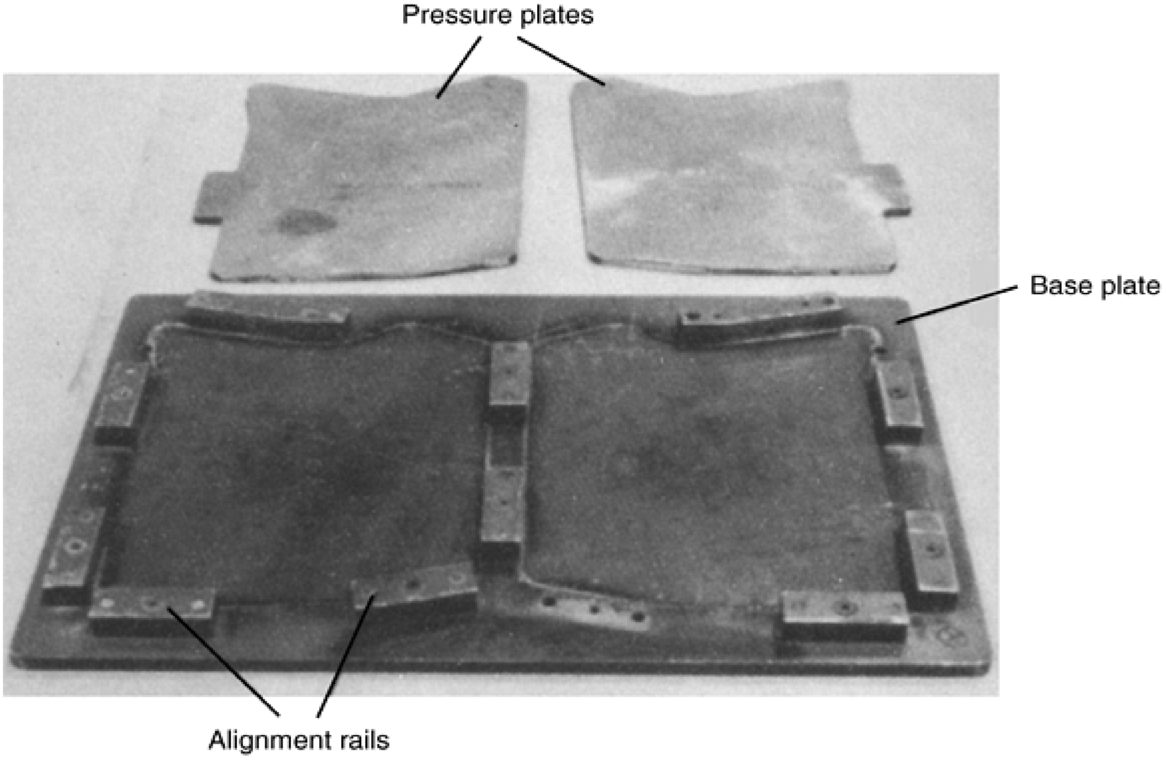

Fig. 17 Press-bonding fixture

Pressure Bag Fixtures. Parts with significant contour must be bonded using a pressure bag process, because the thickness of the tooling needed for the parallel flat surfaces of press- bonding fixtures is excessive for these parts. Also, the extra thickness causes problems with thermal uniformity, tool cost, and handling.

In the pressure bag process, a plastic-film bag, usually a modified nylon for temperatures up to 190 °C (375 °F), is attached to the face sheet of the tool and sealed in place. The air under the bag is evacuated by a vacuum pump to produce a pressure of 96 kPa (14 psi). The heat required to chemically react the adhesive is provided by an oven. If higher pressure is needed, the tool is placed in a heated pressure vessel called an autoclave. The additional pressure required to obtain a good bond is obtained by pressurized air or an inert gas. As the pressure is applied, the vacuum under the bag is vented to prevent damage to the honeycomb assembly from entrapped vacuum.

Additional vacuum ports must be provided to evacuate the vacuum bag. Typically, two holes are drilled in the face sheet and tapped with pipe thread. A pipe sealed with Teflon tape is mounted in each hole. Quick-disconnect fittings and hoses are used to connect the tool to the vacuum systems in the oven or autoclave. One port is used to apply vacuum, and the second is connected to a recorder that monitors the pressure under the bag.

The rails are pinned to the face sheet so that they stay in place despite the side loads produced by the applied pressure. If the rails were to move, damage to the panel would result.

Panels with straight edges can be bonded using only the edge rails. However, many panels have one skin that projects beyond the core and second skin. Usually, the central core is enclosed by Z-shape members that are bonded to both the larger external skin and the smaller internal skin. The bonding fixture for these panels is configured to place the larger skin next to the face sheet of the tool. The rails surround the larger skin. The space between the rail and the vertical edge of the Z-shape member is filled with removable pressure blocks. Wedges are placed between the side rails and pressure blocks to force the blocks inward to ensure good contact with the Z-shape member. Blocks are also required when a space is needed between the skins for attachment of a fitting (see Fig. 18).

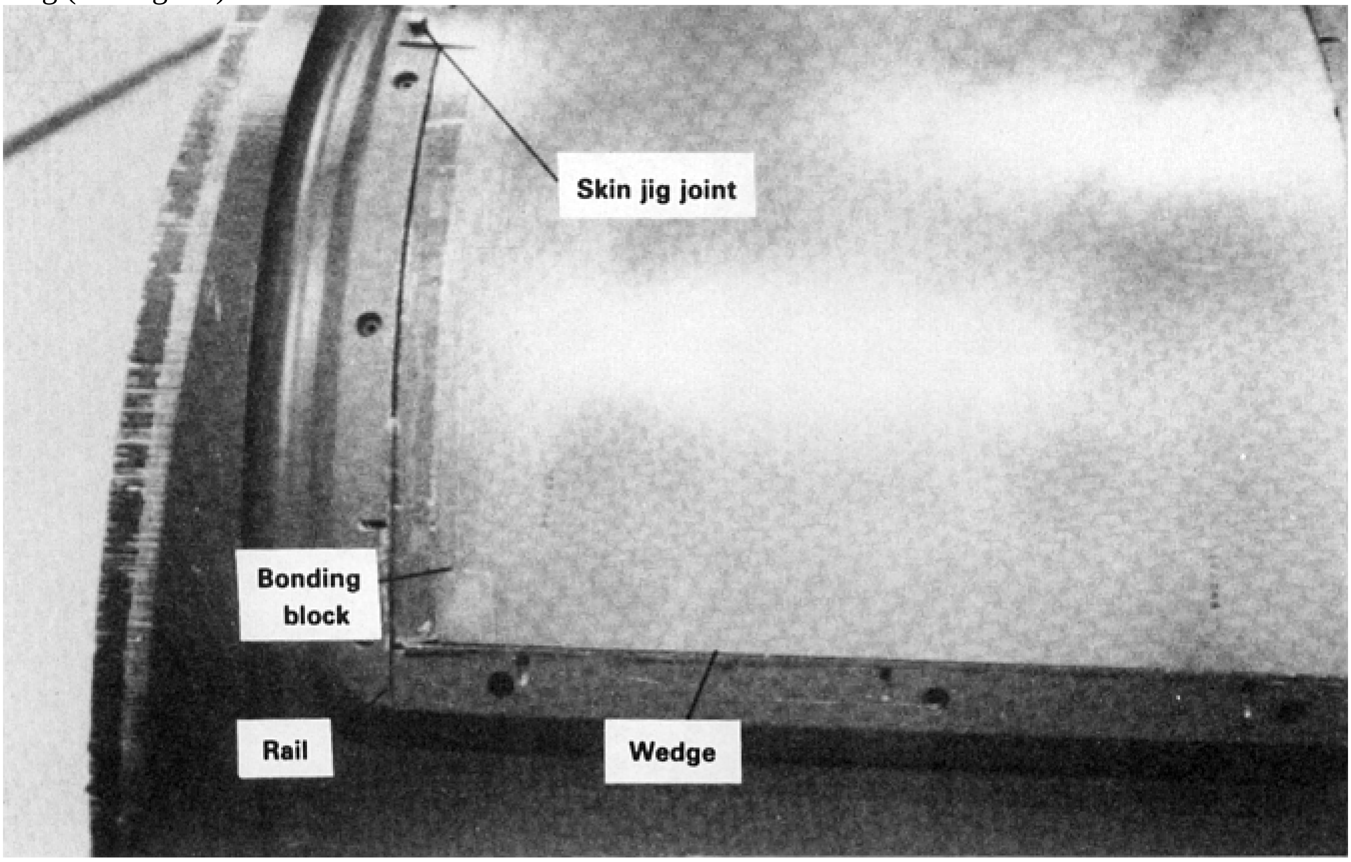

Fig. 18 Detail of a pressure bag bonding fixture

Pressure bag fixtures (Fig. 19) are more complex than press-bonding fixtures. These fixtures are fitted with a base to support the tooling surface in the proper contour. The base must contain provisions for moving the tools, such as removable wheels or hoist points for lifting the tool on the dolly or platens for positioning the tool in the autoclave (Fig. 20) or an oven. Flat tables are often used because they can accept tools of any

configuration, provided there are several flat areas in the tool base. To prevent warpage, the base must be configured to maximize airflow under the face sheet.

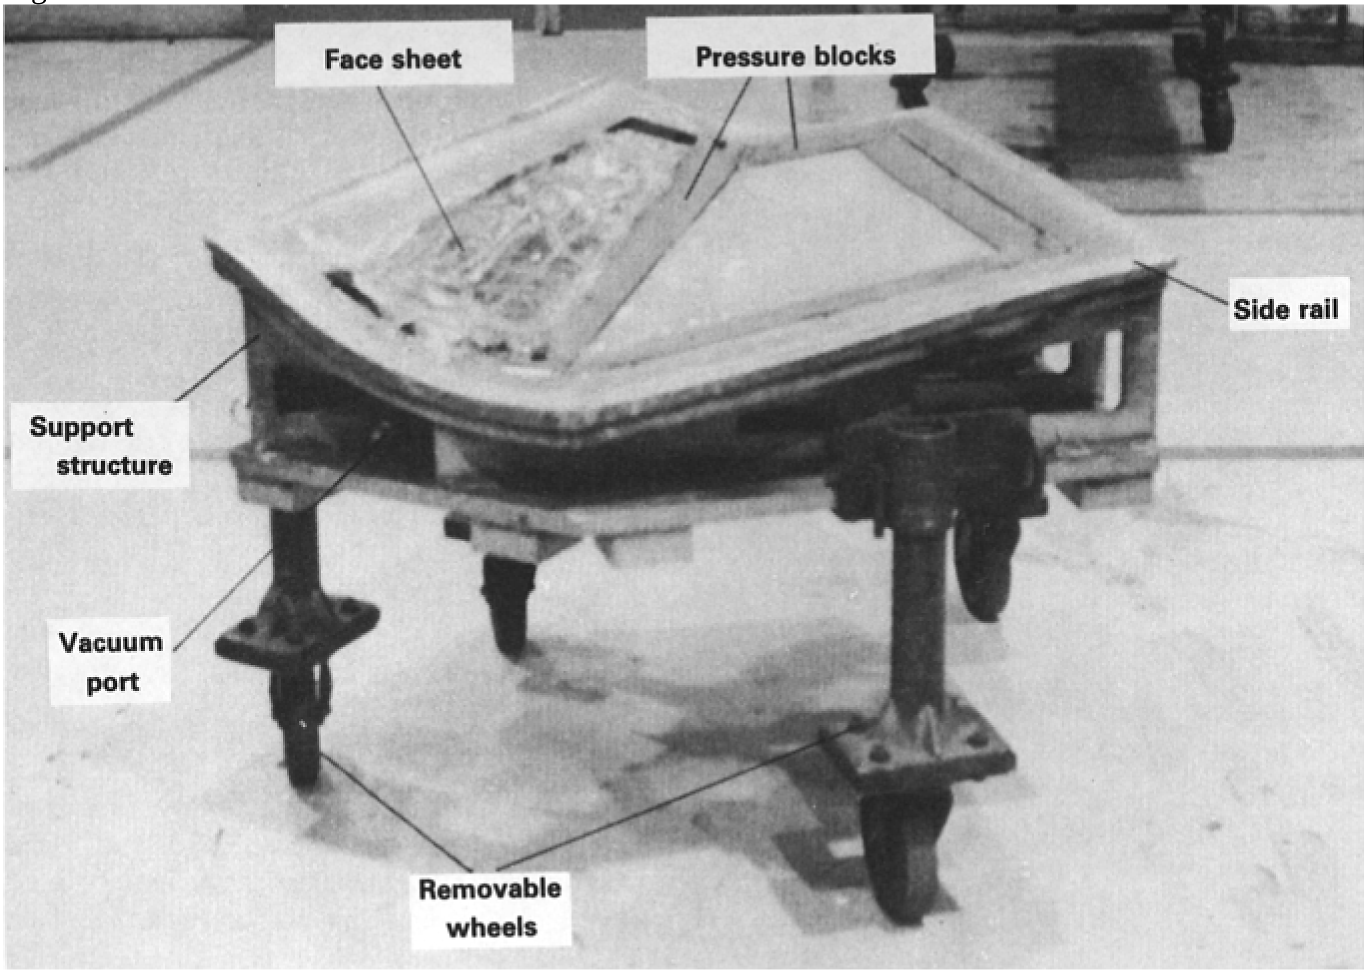

Fig. 19 Autoclave bonding fixture

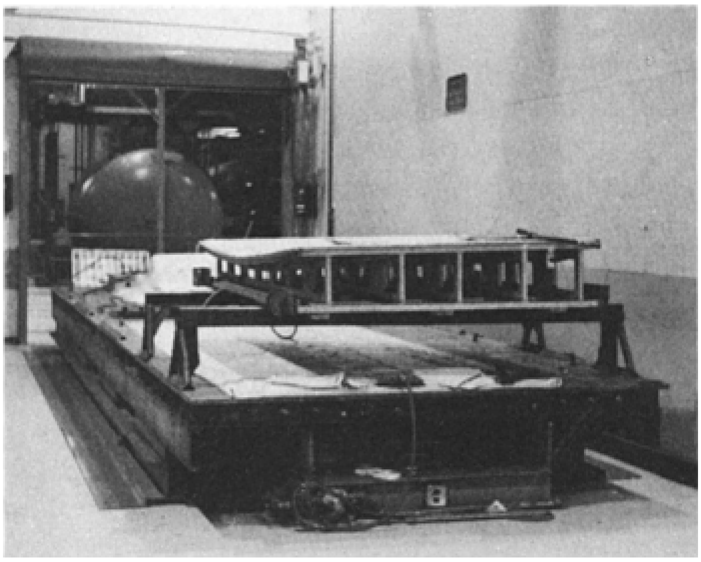

Fig. 20 Flat and contoured bonding fixtures mounted on a platen

Fixture Design. Several secondary rules apply to the design of a successful bonding fixture:

- The tooling surface must be precisely machined to the desired contour so that the skin fits well into the cavity produced by the face sheet and the rails.
- The face sheet must be free of nicks and gouges that could damage the skin.
- The side rails must be easily detachable from the face sheet; this can be accomplished by using pins or screws to attach the rails.

- The bonding fixture should be coated with Teflon to prevent adhesion before the tool is used for the first time.
- Mold release or fluorocarbon film must be applied before each use to prevent sticking of the blocks to the adhesive squeeze-out.

Including tapped, threaded holes in the bonding blocks to permit the use of a “T” wrench will simplify block removal. Also, jig points, locating blocks, or precisely located alignment pins must be provided for each major solid detail located within the honeycomb. These devices ensure that the parts are always in the same location so that the prefit operation performed before the panel is disassembled for cleaning will be valid for the panel when it is reassembled with adhesive after cleaning.

The coefficient of thermal expansion of the face sheet of the fixture and that of the panel skins should match so that the relative position of the tooling and skins is maintained during elevated-temperature curing of the adhesive. This is especially important for a sandwich structure. Both bonds of such a structure should be formed by chemical reaction within a narrow temperature range. As soon as one skin is bonded to the core, the relative positions of these bond constituents are locked in. As the assembly is heated further, the skins and core continue to expand thermally until the second skin is bonded. Because the second skin has expanded more than the first skin prior to bond formation, the panel has thermally induced warpage when cooled to ambient.

The solution to this problem is to use a fixture of minimum mass and provide a uniform flow of heated air above and below the tool surface. Typically, aluminum panels are bonded in aluminum fixtures and composite panels are bonded on composite, steel, or Invar fixtures. Composite tools for composite parts have the closest match in thermal expansion; however, composite tools are not as durable as metal tools for large production runs. Therefore, Invar or steel fixtures can be used to replace composite fixtures because the coefficients of thermal expansion of the two materials are closely matched; electroformed nickel tools are the next best choice.

Because the fixtures for large panels are heavy, handling equipment is required in a production bonding area. Cranes or forklifts are needed, and the tools must be fitted with the proper hoist points. Because the tools must be moved from the clean room (where the adhesive is applied to the individual parts) to the curing equipment, dollies or removable wheels must be provided. Some fabricators use permanently attached steel wheels to move the tools. If large platens are used, steel tracks in the floor and steel wheels on the platen are needed to move the plate in and out of the curing equipment.

Fixtureless Bonding. Alternatives to the use of fixtures are desirable for both high- and low- rate production. One method involves using the fully assembled part as the fixture, as in the case of some metallic automotive panels. Once the adhesive is applied to the edge of the internal skin and the external skin is folded over, the skins are locked into position and cannot move relative to each other. Another example is the various forms of insert bonding used to assemble electronic connectors and circuit boards.

Another fixtureless method for maintaining alignment of the adherends during bonding involves drilling precision alignment holes in the workpiece, applying the adhesive, and installing temporary fasteners. The fasteners are coated with mold release to prevent them from bonding to the assembly. The fasteners also apply force to the joint to produce adhesive flow. However, excessive clamp-up force with temporary fasteners can result in resin-starved bondlines in the vicinity of the fastener. A similar concept is used to mate the decks and hulls of small fiberglass boats. After bonding, the alignment holes are often enlarged to receive structural fasteners.

Pressure Applicators. A common approach for applying bonding pressure involves using clamping devices, such as C-clamps or woodworker's clamps, to hold the adherends in place. A fiberglass panel bonded with C-clamps is shown in Fig. 21.

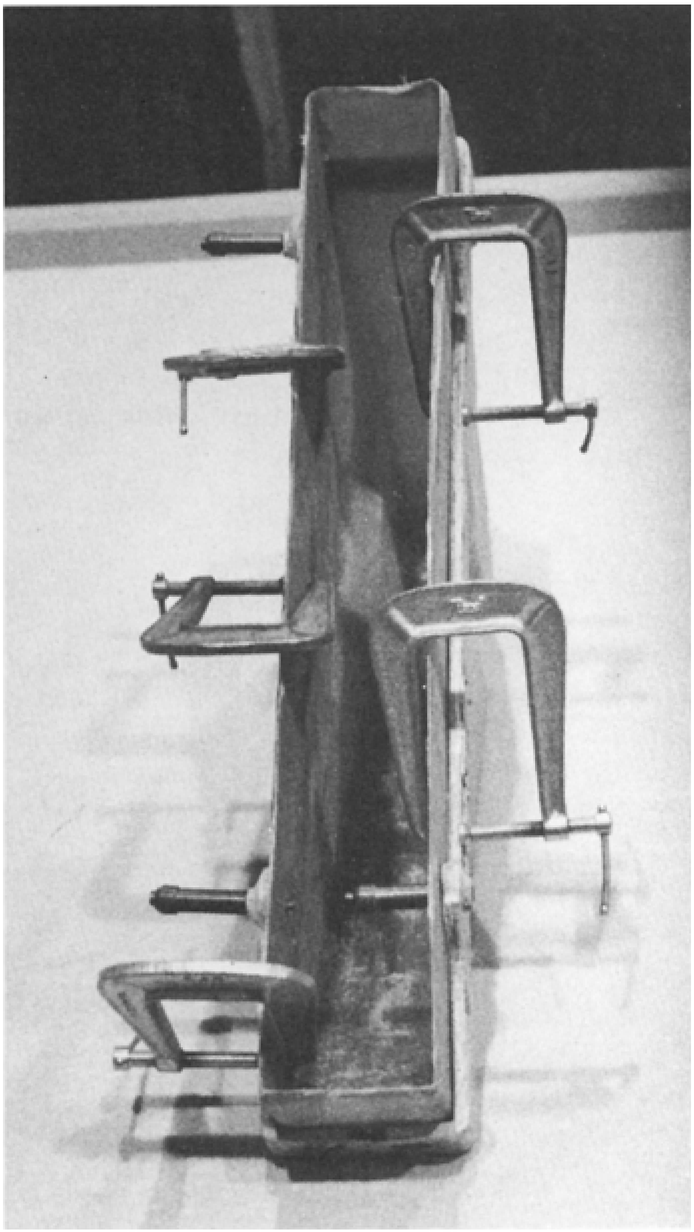

Fig. 21 Fiberglass assembly bonded using clamps and temporary fasteners

Spring-loaded clamps that are similar to old- fashioned laundry clamps are also used for certain bonding applications because they can be installed and removed rapidly. One patented type of clamp has one movable surface and one fixed surface; the adjustable clamps are permanently attached to a base, and the movable jaws open and close as required. In high-rate production, pneumatically actuated clamps are used to accelerate the loading of parts or the removal of the assembly from the fixture.

Mechanical screw jacks can also be used to apply load and align adherends. For example, blocks of honeycomb material are often spliced in the vertical direction with a foaming adhesive that expands to fill the space between mating blocks. The operation is done in a fixture that defines the horizontal surface of the assembly. Pressure plates, strong backs, and screw jacks are used to push the core blocks toward the horizontal surface as the adhesive is cured in an oven (see Fig. 22).

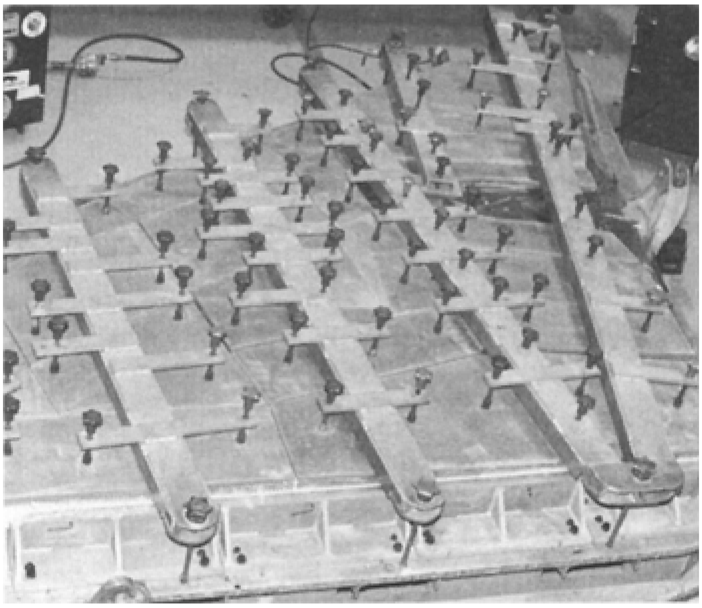

Fig. 22 Honeycomb splicing fixture using screw jacks to apply load

Curing Equipment. Various types of curing equipment are used for adhesives requiring heat for polymerization. Conventional ovens and full or partial vacuum are used for lightweight assemblies with thin skins. A variation of this concept is used in the automotive industry: heated tunnels concurrently cure adhesives and exterior paint in automobile bodies. Multicavity platen presses (Fig. 23) are used to bond flat panels under heat and pressure. In the aircraft industry, most panels have a complex geometry and are bonded by the pressure bag technique. The bond may occur in an oven or an autoclave.

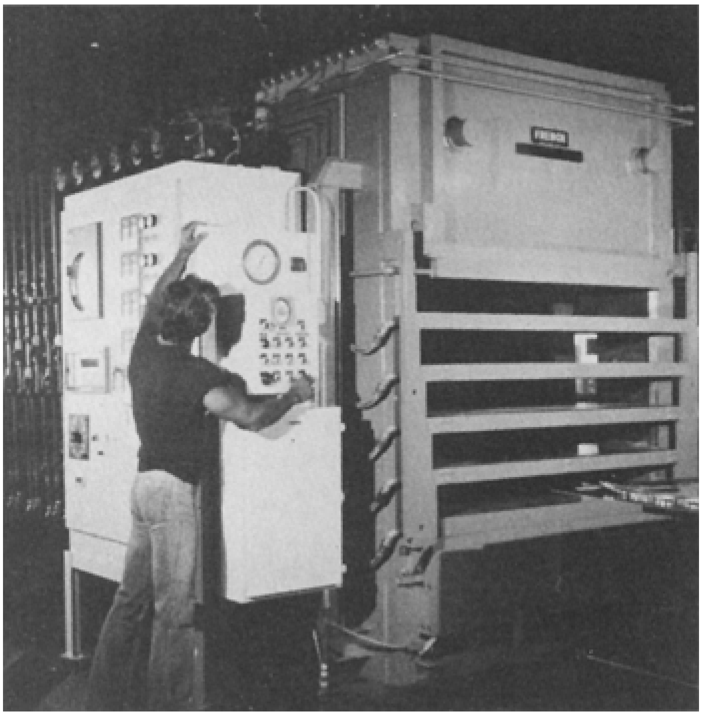

Fig. 23 Flat-panel bonding press. Courtesy of M.C. Gill Corporation

Inspection

Adhesively bonded joints and assemblies are normally nondestructively inspected after all bonding operations are completed. Radiographic and ultrasonic inspection methods are typically used to look for defects in both the bondlines and the honeycomb core portions of the assemblies. For a description of these test methods, as well as others, refer to the article “Repair Applications, Quality Control, and Inspection” in this Volume. In addition to these methods, it is quite common practice to leak check honeycomb-bonded assemblies by immersing the assembly for a short time in a tank of hot water (e.g., 66 °C, or 150 °F). The hot water heats the residual air inside the honeycomb core, and any leaks can be detected by air bubbles escaping from the assembly.

Processing and Joining of Thermoplastic Composites

Douglas A. McCarville and Henry A. Schaefer, Boeing Military Aircraft & Missile Systems

Introduction

THE SPORTING GOODS, medical, automotive, chemical, and aerospace industries have applications that require materials with good combinations of impact resistance, fracture toughness, and elevated temperature endurance. Advanced thermoplastic composites (ATPCs)— meltable engineering resin/fiber mixes typically containing approximately 60 vol% continuous carbon, glass, quartz, and so on—possess these properties, and because of their melt-fusible nature, lend themselves to low-cost rapid thermoforming and joining methods.

Economic Considerations

In an effort to meet requirements on future aircraft such as the F-22 Raptor, X-33 Reusable Launch Vehicle, V-22 Osprey, and Joint Strike Fighter, the aerospace industry has been the primary driver for advanced high strength composite product forms (Ref 1, 2). Emphasis on weight minimization as a means of enhancing aircraft performance and reducing life cycle cost has pushed the use of composites in lieu of heavier, but in general, lower manufacturing cost, metals. Automated processes such as pultrusion, fiber placement, filament winding, and contoured tape laying have systematically reduced the cost of fabricating parts using traditional thermoset (TS)—materials that undergo chemical reaction during cure—resin systems. There remain, however, pocket applications that require better target properties (i.e., use temperatures greater than 105 °C, or 220 °F, enhanced environmental resistance or improved damage tolerance) than TS materials can deliver. In response,

various combinations of high-performance thermoplastic (TP) matrix resins (Table 1) and continuous fiber reinforcements (Table 2) have been offered to the industry.

Table 2 Thermoplastic resin/fiber mix options

Product form	Description
Postimpregnated[(a)]	
Film stacked	**Alternating sheets of fiber and resin film stacked and melt fused together**
Co-woven	**Narrow slit film woven with fibers**
Co-mingled	**Fine resin filaments interwoven with fibers**
Powder coated	**Resin powder attached to fiber tows**
Dry preimpregnated[(b)]	
Tape	**Boardy unidirectional fiber form typically 15 or 30 cm (6 or 12 in.) wide**
Slit tape	**Tape that is slit to width**
Slit woven	**Slit tape woven into rattanlike broadgood rolls to improve drapability**
Wet preimpregnated[(c)]	
Tape	**Tacky unidirection fiber**
Slit tape	**Tape that is slit to width**
Tow	**Yarnlike fiber bundles**
Fabric	**Woven tow**

(a) Fiber and resin placed in physical contact then fused together during processing.
(b) Fibers completely preimpregnated with resin, melt fusible.
(c) Pseudothermoplastics with tack and drape, chemistry advances during processing.

Advanced TP resins have relatively high molecular weights and, hence, melt viscosities (10^3 to 10^6 Pa · s), and are typically more challenging to prepreg than TSs (Ref 4). This means that, in small lots, TP raw materials are typically 2 to 5 times more expensive than mass produced TSs and 10 to 50 times more expensive than metals. In large production lots (i.e., thousands of kg/ year), this cost difference between TPs and TSs can be negated, but to date, ATPC use remains low (a few percent of the U.S. advanced composite market) and said economies of scale remain unrealized.

Further impeding the penetration of TPs into the aerospace market are costs associated with creating allowable databases. Before a manufacturer can certify a new material for flight hardware, millions of dollars must be spent on element tests covering all conceivable operating environments (i.e., moisture soak, hot/wet

temperature, fuel/solvent resistance, fatigue, etc.). This data must not only be based on the specific resin/fiber mix undertaken but must also be generated using any equipment developed or specifically modified to take advantage of the rate- independent processing parameters associated with melt-fusible TPs.

To avoid the cost of developing unique manufacturing equipment and methods specifically for converting dry TP material forms, many companies have chosen to direct their efforts toward assimilating pseudothermoplastics (PUTPs), such as Avimid K (E.I. DuPont de Nemours & Co. Inc., Wilmington, DE), Torlon (Amoco Performance Products Inc., Chicago, IL), or LARC- TPI (NASA Langley Research Center thermoplastic imide), into existing processes. These materials are prepreged as wet tacky broadgoods with the look and drapability of traditional TSs. Therefore, in theory, a fiber placement machine that is used one day to lay down epoxies could, with modifications to head pressure, backing removal, and heat application, be used later to place PUTPs. In practice, however, PUTPs are more sensitive than TSs to process variability and require much longer high-temperature cures; typically 10 to 24 h at 340 to 430 °C (645–805 °F), versus 4 to 8 h at 120 or 180 °C (250–355 °F). High raw material costs, tight process control requirements, the release of volatiles, extended cure cycles, and expensive shop expendables (autoclave bagging, breather, release, sealant, etc.), in general make PUTP parts cost two to four times that of equivalent TS or metal parts. In certain weight or performance critical applications (i.e., fighter wings, launch vehicle tanks, etc.), this cost difference is acceptable, but in others it has driven manufacturers to research potentially lower-cost dry TP processing options.

True (or dry) thermoplastics (TTPs), in which there are no chemical changes during processing, can be rapidly heated, remelted, shaped, consolidated, and cooled. These relatively rate-insensitive process parameters lend themselves to innovative lay-up, forming, and joining techniques that in certain applications slash process times from hours to minutes. Several industry and government-directed prototype efforts (Fig. 1) have been conducted that demonstrate the potential economic benefits of ATPC materials and methods, but full-up production of primary aircraft components has been hindered by the lack of long term, high-volume production contracts.

Material Options

Since ATPCs possess high melt viscosity resins and high volume fractions of continuous inelastic fibers, traditional thermoforming methods that rely on material flow during softening, such as injection molding, blow molding, compression molding, resin transfer molding, vacuum forming, and so on, cannot be used. Rather, these advanced material forms must either be placed directly to final shape or stacked in such a manner that individual plies can slip to shape during thermal forming. Further complicating manufacture is the fact that most TP parts are designed for weight-critical applications by tailoring thickness throughout to match loading requirements. Unlike metals, where material is machined or chemically milled away after processing to achieve a desired thickness, advanced composites require individual oriented plies to be cut to shape and sequentially stacked in precise locations (Fig. 2).

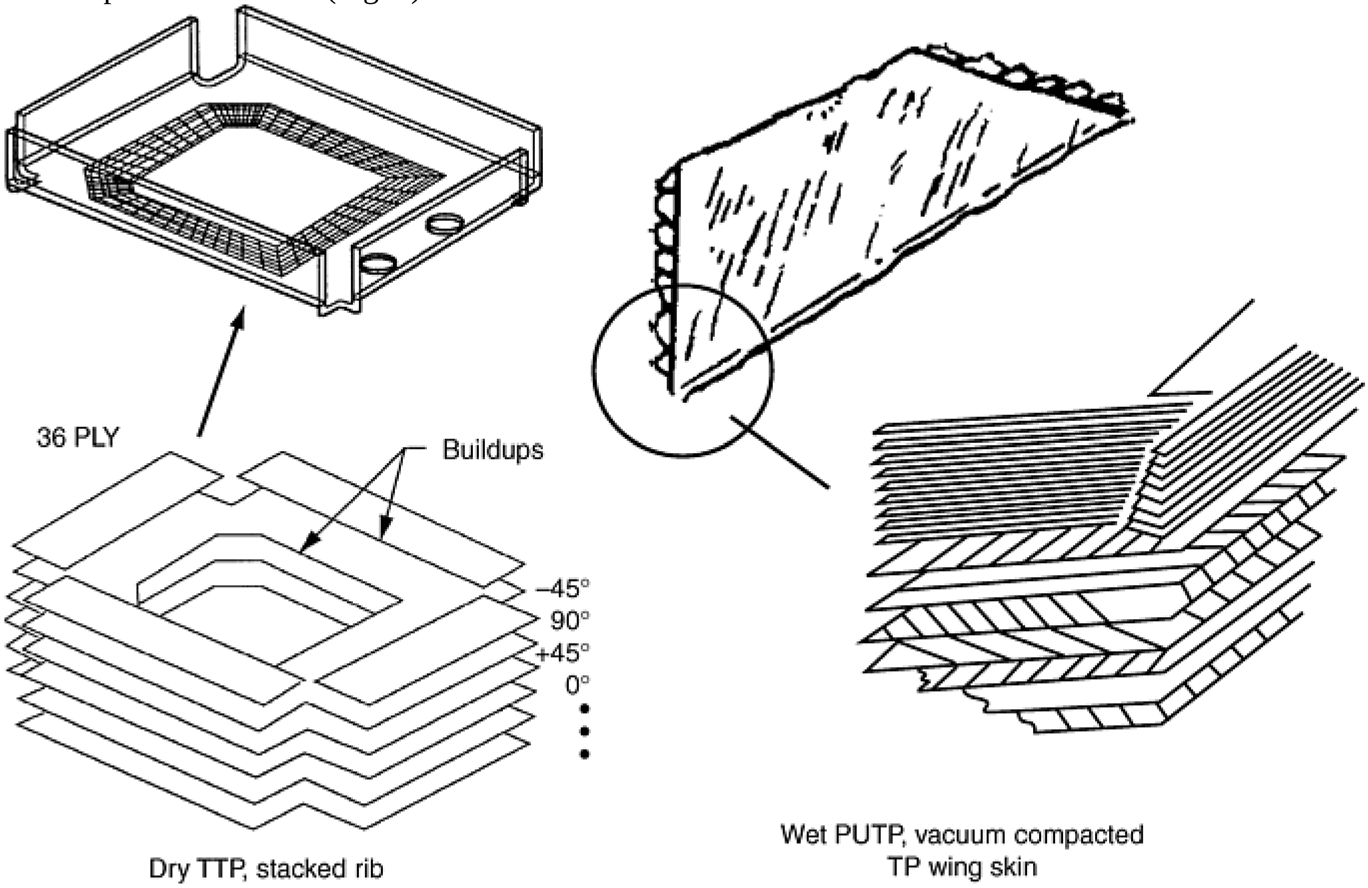

Fig. 2 Ply Stacking/orientating. TTP, true thermoplastic; PUTP, pseudothermoplastic; TP, thermoplastic

Pseudothermoplastics, or pseudo TPs, in which there are molecular-weight-increasing chemical reactions and volatile release during final processing, are preimpregnated in wet/tacky tape or fabric form similar to traditional TS materials. PUTPs are usually laid to shape by hand or with automated equipment (i.e., contoured tape lay-up machines or fiber placement machines). Individual full plies and partial padup plies (typically 0.14–0.30 mm, or 0.005–0.01 in., thick each) are sequentially placed on a shaped tool and vacuum compacted every 1 to 3 plies to reduce bulking. Once a layup is complete, it is vacuum bagged using high-temperature film and fiberglass breather to assist in the removal of solvents and volatiles (water, ethanol, etc.). PUTPs require slow controlled heat-up rates (0.5–1.6 °C/min to ~370 °C, or 1–3 °F/min to ~700 °F), extended holds (2 to 8 h), and precise pressure application (initial slight vacuum changing to ~1400 kPa, or ~200 psi, during hold) to achieve desired target properties. If a matched closed tool is used to make a tight tolerance part such as a rib or spar,

special provisions must be made for volatile removal to ensure porosity-free laminates (Ref 5). Due to the extended nature of these cures and the fact that PUTPs possess melt viscosities an order or two magnitude greater than dry melt fusible TPs, these materials do not lend themselves to rapid processing methods such as pultrusion, press, rolling, or diaphragm forming. Figure 3 illustrates typical manufacturing flows for PUTP processing.

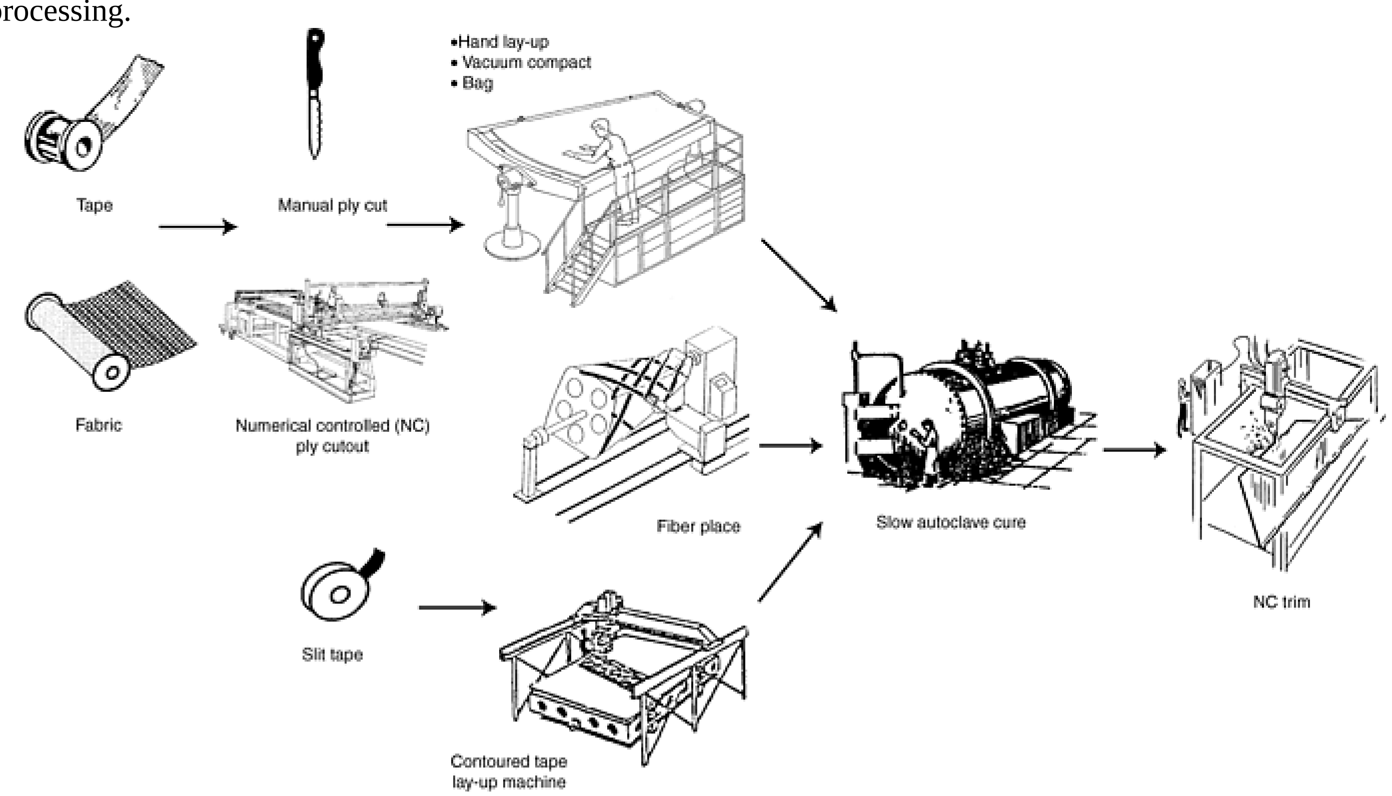

Fig. 3 Pseudothermoplastic processing

Postimpregnated thermoplastics (PITPs), in which the fiber and resin are placed in close physical contact then fused together during processing, are usually dry drapable fabric forms, similar to a burlap bag. Examples include commingled fabrics where both the reinforcement and resin are in fiber form, and powdered resin fabrics where resin powder is electrostatically deposited on the reinforcing fibers. PITPs lend themselves to layup directly on shaped consolidation tools. To achieve consistent fiber wetout, hence optimal structural properties, PITPs require longer fusion times and higher consolidation pressures than preimpregnated dry TPs. PITPs are compliant but cannot be vacuum compacted like wet composites. Therefore, precise ply cutout, kitting, and locating is somewhat labor intensive, and ramped plies have a tendency to shift during high-pressure thermal cycling. The PITP product form is most useful for making contoured constant thickness parts where slight variations in fiber/resin volume mix are acceptable. In these cases, short thermal cycles can be achieved and processing options include high temperature/pressure autoclaving (in the 370 °C, or 700 °F, 1400 kPa, or 200 psi, range), extended hold pressing, or diaphragm consolidation. Another PITP product form that circumvents lay-up difficulties is woven, or braided, tow shapes (Tee, J, C, etc.), which can be consolidated in heated, matched metal molds (Ref 6).

True (or dry) thermoplastics (TTPs), in which the continuous fiber reinforcement is completely wetted with a linear chain polymer resin that does not require further chemical reaction during processing, are preimpregnated as 150 or 300 mm (~6 or 12 in.) wide boardy tape rolls. This tape can be slit, slit woven, or seamed together to create product forms that lend themselves to rapid automated processing methods. Unlike TSs and PUTPs, dry thermoplastic raw material forms have indefinite shelf life at room temperature and do not require refrigeration. Further, processing parameters (heatup rate, hold during high-pressure thermal forming, and cooldown rate during consolidation) are mostly rate insensitive and rapid forming cycle times as low as 10 min are achievable. An exception is when slow cool-down rates are required to control crystallinity in a semicrystalline resin such as PEEK (polyetheretherketone) and transcrystallinity, which enhances resin adhesion to reinforcing fibers. Heating to above melt temperature can be accomplished by traditional methods such as two-sided infrared, convection, conducting platens, and so on. Shaping can be accomplished using a wide variety of modified TS or metal-forming methods such as hand layup, autoclaving, pultrusion, laminating, press forming, diaphragm

forming, roll forming, and hydroforming. Laying up TTPs on compound curved tools is more difficult than with TSs because of the “boardy” nature of TTP prepregs and lack of tack. Secondary thermoforming equipment can be used to convert flat material layups to shaped parts via the following mechanisms:

- Moving the inelastic reinforcing fibers to shape without wrinkling or excessive waviness (the main forming mechanisms include interply slip, which occurs above the resin melt temperature, and intraply slip where fibers slide relative to one another)
- Applying adequate consolidation pressure (typically 700 to 7000 kPa, or 100 to 1015 psi)
- Cooling the material at a slow enough rate to avoid part warpage and also a rate that supports construction of the desired morphology in semicrystalline materials such as PEEK (polyetheretherketone) and PPS (polyphenylene sulfide).

Processing Methods

Pseudothermoplastics require extended cure cycles that allow time for matrix resin advancement and volatile removal. Therefore, PUTPs almost always are processed in an autoclave where the heat can be precisely controlled and byproducts can be removed with a vacuum system.

Postimpregnated thermoplastics usually are stacked constant thickness (possibly to shape) and consolidated in a manner so that the resin has sufficient time above melt temperature to fully wet the fibers (i.e., extended-hold autoclave, press, or diaphragm).

The objective when processing TTPs is to use the materials melt fusible characteristics to automate ply handling and forming. Tight tolerance ply locating is required for weight-critical aerospace designs, and parts usually are created by sequential placement of oriented (within ± 5° of desired) full plies intermixed with structure-enhancing pad-up plies. For example, a 2.54 mm (0.1 in.) thick laminate with stiffening might consist of a series of full tape plies at +45°, 90°,–45°, 0°, +45°,–45°,–45°, +45°, +45°, 0°, 90°,–45°, +45°, and 0° mixed with 3.8, 3.9, 4.0, and 4.1 cm (~1.5 in.) wide pad-up plies. Table 3 lists equipment prevalent in the industry for accomplishing such tasks as:

- Modifying incoming dry TP tape rolls to more useable product forms
- Placing or forming plies to shape
- Providing final consolidation heat and pressure

Table 3 Thermoplastic processing equipment

Process	Description
Raw material modification	
Weaving	**Tape is slit to 0.3 to 0.6 cm (0.1–0.2 in.) wide then woven to create a semidrapable form.**

Hand seaming/tacking	**Tape is butted together and seam welded to wider widths with a handheld iron. Also, ply stacks can be tack melted together.**
Automated seaming	**Equipment takes multiple 30 cm (12 in.), 0° tape rolls and butt seams them to wide (i.e., 300 cm, or 118 in.) 0° or 45° roll stock.**
Sheet consolidating	**Wide roll 0° and 45° roll stocks are stacked together and melt fused into sheet stock.**
Autoclave	**Material is laid to shape, vacuum bagged; autoclave heats TP to melt, applies pressure, and cools to consolidate.**
Continuous processes	
Pultrusion	**Slit tape stacks are pulled through a heated pressure die to generate continuous cross section Ts, Js, etc.**
Roll forming	**Similar to pultruding, but uses rollers to shape, consolidate, and cool the material**
Fiber laminating (FL)	**0.5 cm (0.2 in.) wide slit tape rolls are placed and melt fused to prior layers on a contoured mold tool (may autoclave after to get full compaction).**
Contoured tape laminating	**Similar to FL, but uses wider slit tape (7 cm, or 2.75 in.), better for large gentle contour parts such as wing skins**
Thermoforming	
Press	**Sheet or tack seamed stacks are heated in an oven, shuttled into a matched die, then formed/cooled under pressure.**
Hydro	**Similar to press, but hydrostatic fluid replaces one die half**
Diaphragm	**Sheet or tack seamed stacks are placed between extendable plates or bagging, heated in a one-sided die, and pressure blown to shape.**
Induction	**Similar to diaphragm, but an electromagnet field is used to heat the extendable plates, not the tool, thereby reducing cycle time**

TP, thermoplastic.

Weaving. Because of the high viscosity, high- temperature conditions required to melt impregnate true thermoplastics, it is difficult to prepreg TTP fabric forms directly. An alternative to using PUTP or PITP fabrics is to create a dry TP fabric by first slitting unidirectional prepeg tape then weaving it into wider roll stock. In this manner, 30 cm (12 in.) wide tape rolls can be converted into a semidrapable 300 cm (120 in.) wide mat amenable to automated ply cutout methods using dies, ultrasonic knives, water jets, and so on.

Seaming. Weaving reduces the load-carrying capability of unidirectional tape. An alternative width-increasing method is to butt weld or seam multiple tape rolls side by side. This can be done by hand with hot irons (400 to 600 °C, or 750 to 1110 °F) during prototyping efforts and in production with automated seaming equipment. There are 0° seamers that pull, guide, and seam up to five tape rolls at a time at rates as high as 20 m/min (65 ft/min) rolls 300 cm (118 in.) wide made in this fashion can then be cut into 0° or 90° plies using automated cutting equipment. Since 45° oriented plies are typically combined with 0° and 90° plies to create a layup, seamers have been made that repeatedly pull out a length of tape, butt seam it to a 45° oriented roll start, cut the new seamed section, and advance the section onto a roll. Throughput on these 45° seamers is slower, and the controls required to align, seam, and advance the tape are more complex than those of a 0° seamer. Therefore, in most cases, other than extremely high-volume efforts, it is cheaper to take 0° roll material and cut it to ±45° orientation during kitting.

Autoclaving. Other than considerations for higher temperatures (340–430 °C, or 645–805 °F) and pressures (700–2100 kPa, or 100–305 psi), laid-to-shape TPs can be consolidated in an autoclave using thermoset cure methods. The autoclave serves as a heated pressure vessel where vacuum, heatup, cooldown, and pressure application can be controlled to within precise limits. These high temperatures and pressure runs require the use of costly shop expendables (bagging, breather, release, and bag sealant), and the risk of a bag failure is greater than that of 180 °C (355 °F) cure TSs.

Preconsolidation. Within broad limits (each material has a specified process window developed by the supplier), most TPs can be heated and cooled repeatedly without affecting final component morphology. Thermoforming equipment (roll, press, and diaphragm formers) rely on ply and fiber slippage as the mechanisms for converting flat ply stacks into formed components. In most cases, this stack can be either loose (with spot seams to hold sequential plies relative to one another), fully preconsolidated (already melt fused into

a solid stack), or some combination of a preconsolidated base with loose stack padups. Using preconsolidated planks eliminates manual ply-by-ply stackup and can dramatically cut costs during high-volume production. Preconsolidation can be accomplished using a laminator, press, autoclave, or a roll consolidator. The roll consolidator is an efficient way to make constant thickness sheet stock. In this apparatus, TP tape is pulled directly off preseamed, to width and orientation, rolls, heated in an infrared, conductive, or convective oven, and consolidated and cooled under a series of pinch rolls. The material often is contained within rigid metal plates as it passes under the rolls to ensure consistent pressure application and to avoid fiber distortion. In most cases, since the material will be subsequently thermoformed, only partial compaction is required, and rates of 1.5 to 3 m/min (5 to 10 ft/min) are achievable (rates are limited by how fast the composite can be heated and cooled).

Roll Consolidation. Unlike TSs and PUTPs, which can be compacted to within 5 to 15 % of their final cured thickness, dry, boardy thermoplastics cannot be vacuum compacted to remove bulk. Typically, spot seamed and stacked TPs exhibit bulk factors 2 to 4 times final consolidated part thickness. Therefore, hand laying up thick, highly padded parts, such as a wing skins or large cylinders, is impractical. One option for placing such components is to use modified thermoset fiber placement equipment. Fiber placement combines the differential tow payout of filament winding and the compaction and cut-restart capabilities of automatic tape laying (Ref 10). As shown in Fig. 4, TTP lamination (melt fusion on the fly) can be accomplished by feeding slit tape or tow from creel rolls onto a lay-up mandrel, heating the tape to above melt temperature, and cooling and consolidating the new layer to the previously placed stack with a pressure roller. This process sometimes is called in-situ consolidation and uses hot gas or a sweeping laser beam as the heat source. On flat parts, high fiber placement rates (several cm/s) and low void content (less than 1%) can be achieved. On highly contoured parts or parts with extensive ply drops, however, it is best to count on the laminator to only partially compact the stack (to within a 5% void content) and to subsequently achieve full consolidation by running the part through a high pressure/temperature autoclave cycle.

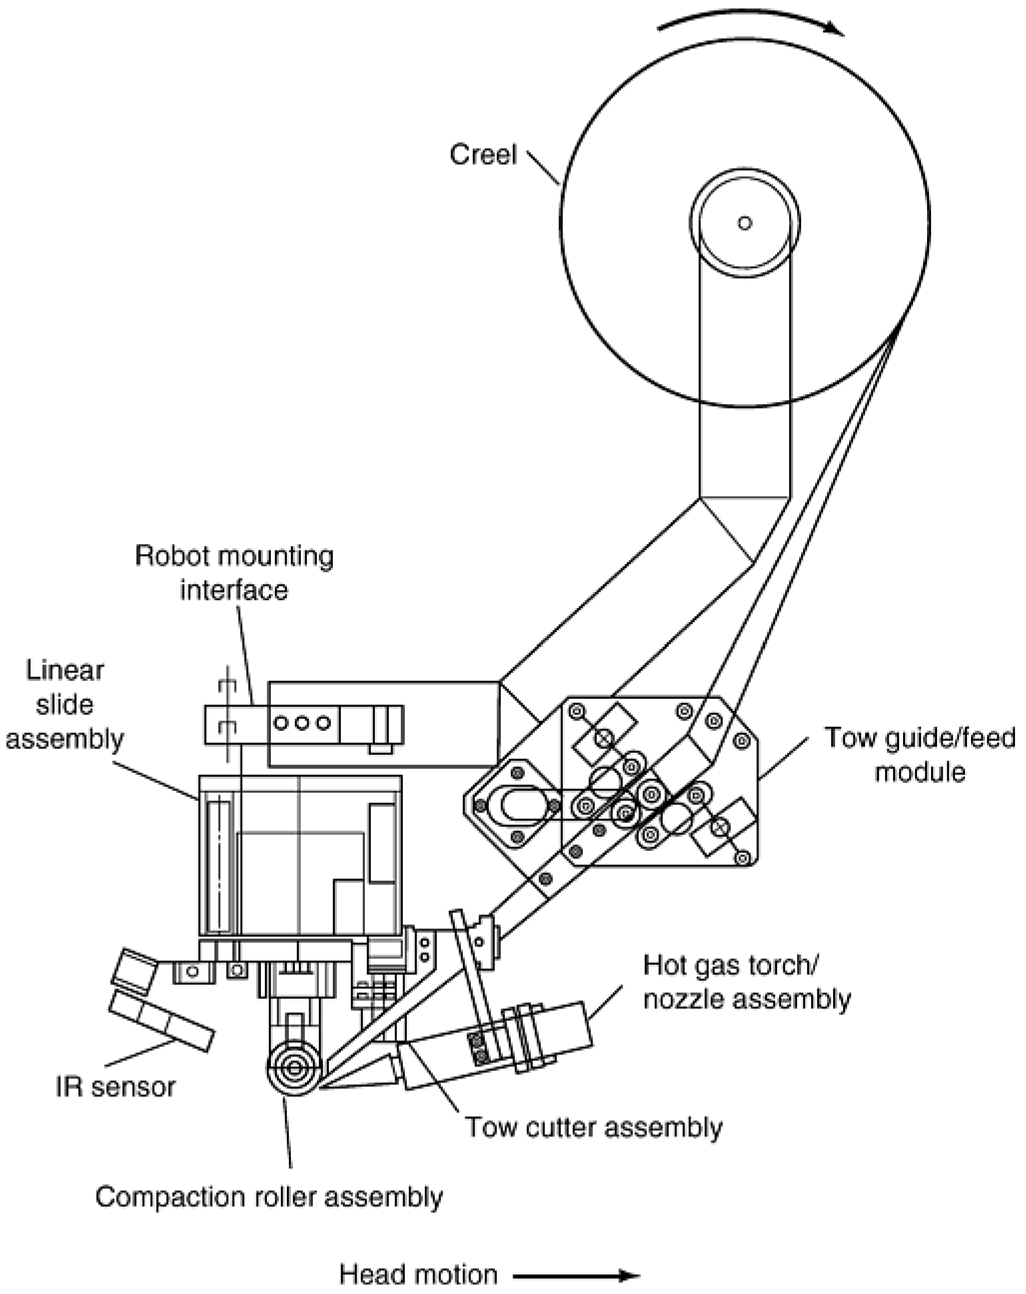

Fig. 4 Thermoplastic laminating. IR, infrared. Source: Ref 10

Roll Forming/Pultruding. Constant cross- section TP components (Tees, Js, Cs, Zs, or hats) can be made by pultruding or roll forming. A roll former operates in the same manner as the roll consolidator described previously. But, instead of using wide roll stock and flat rollers, it uses slit tape or narrow sheet stock and shaped roller dies. Typically, it is desired to fully consolidate during roll forming, so higher pressures and slower feed rates are used versus roll consolidation.

A pultruder uses a gradually changing cross section heated die through which tape stacks can be pulled, heated, formed to shape, and cooled. The die must contain a zone that allows the material to be heated to above melt temperature prior to forming and a subsequent zone that cools the laminate to shape under pressure. Because TP prepreg fibers are incompressible and there is minimal flow with high molecular weight TP resins, the die must have built-in gap width compliance in order to maintain compaction pressures of 700 kPa (100 psi) or greater. The roll and pultrusion processes can produce laminate at rates from 0.2 to 0.6 m/min (0.7 to 2 ft/min), which generally is slower than TS pultrusion. This factor combined with the fact that most aircraft components are weight optimized (composed of thickness variations) and contain compound contours has limited the infiltration of TP pultrusion and roll forming as a means of fabricating production hardware (Ref 11).

Thermoforming. In TP thermoforming processes (press, diaphragm, hydro, and induction), loose stack plies or preconsolidated sheet stock are formed and consolidated to shape in a single step. With TTPs, process heatup and cooldown rates have minimal effect on final part morphology; therefore, cycle times are far shorter than

those used when autoclaving (Fig. 5). But in full- up production, thermoforming throughputs can be duplicated with an autoclave by loading several rate tools into a single run. Hence, rapid cycle times are not the primary driver for using thermoforming processes. Rather, the time saved by placing material flat versus laying it to shape is the main economic contributor (Fig. 6).

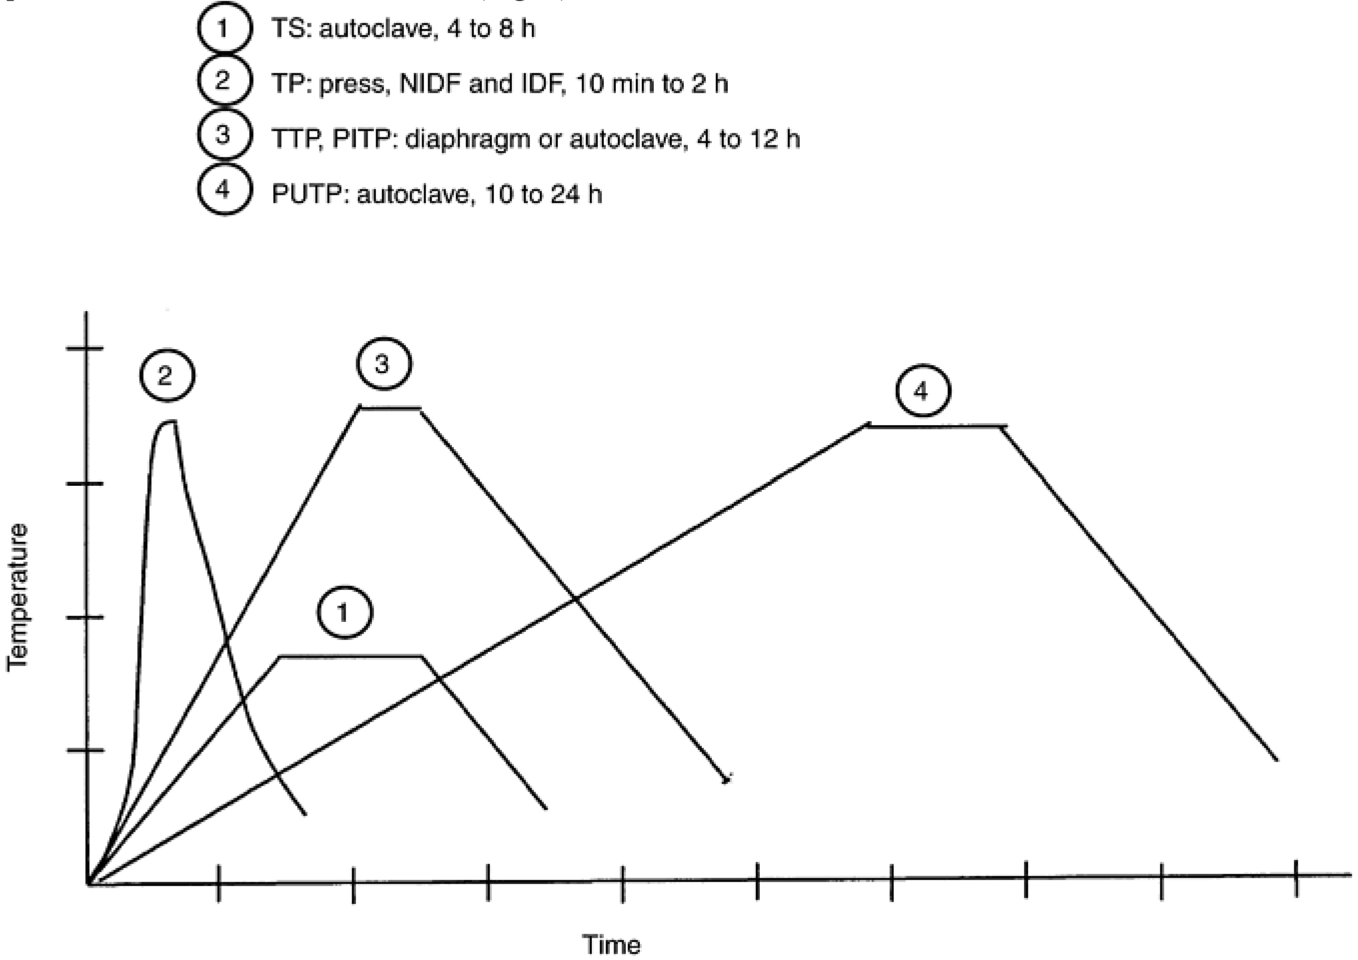

Fig. 5 Thermoplastic cycle times. TS, thermoset; TP, thermoplastic; NIDF, nonisothermal diaphragm forming; IDF, induction diaphragm forming; TTP, true thermoplastic, PITP, postimpregnated thermoplastic; PUTP, pseudothermoplastic

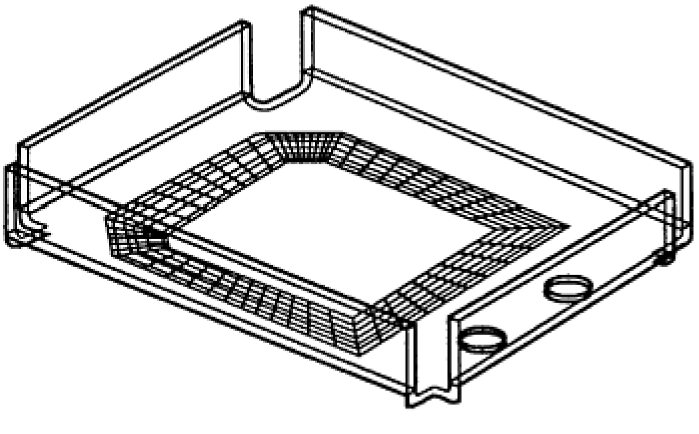

Fig. 6 Wing rib production cost comparison

Press. During the press forming process (Fig. 7), flat stacked TP prepreg is heated to above melt temperature (340 to 430 °C, or 645 to 805 °F) in an oven, rapidly (within 1 to 10 s) shuttled to a forming die, pressed to shape, and consolidated and cooled under pressure (700 to 7000 kPa, or 100 to 1000 psi). In production, press forming dies usually are matched male-female sets constructed of steel or aluminum. But, during prototyping, rubber, wood, phenolics, and so on can be used. The die set can be maintained at room temperature throughout the forming/consolidation cycle. But, the use of a hot die (between 120 and 200 °C, or 250 to 390 °F) allows

control of the cooldown rate (avoiding part warpage and controlling morphology in semicrystalline TPs such as PEEK and PPS) and extends the forming window, promoting better ply slip. The main disadvantage with this method is that the press only applies pressure in one direction, and hence, it is difficult to make complex shaped (i.e., beads, closed corners, etc.) parts or parts with legs that approach vertical. Since the temperature of the die set need not be cycled with each part, rapid forming times of between 10 min and 2 h are achievable with press forming (Ref 12).

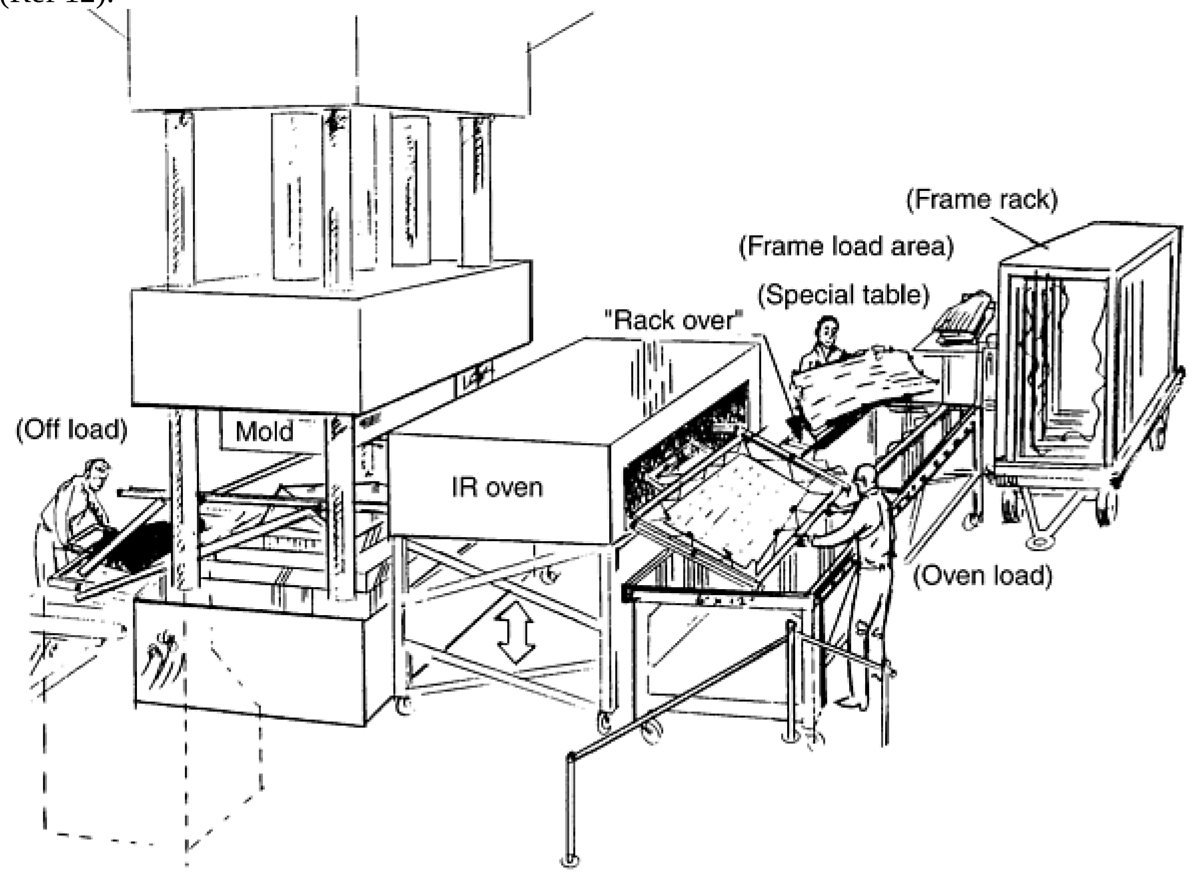

Fig. 7 Thermoplastic press forming

Hydroforming. Hydroforming is similar to press forming, except that one die side is replaced with a flexible fluid diaphragm. Similar to the press, this allows for heating the prepreg in a separate oven, shuttling it into the forming zone, and forming and consolidating in a die. Unlike the press, consistent hydrostatic pressures can be applied to all part surfaces, and complex shapes and vertical flanges are obtainable. The primary drawback with this apparatus is that it is costly to scale up high-pressure hydraulics and associated containment mechanisms.

Diaphragm forming can be used to create shapes (beads, compound contour, etc.) that would be labor intensive to layup or are beyond the formability limits of press forming. The process starts by placing loose stack plies or preconsolidated sheet stock between two aluminum sheets that can plastically deform or between two plastic films that can elongate at high temperature. This stackup is placed in a diaphragm former that consists of a one-sided metal die, a pneumatic pressure source, a means of evacuating the air from within the stackup, heating and cooling elements, and a clamping arrangement (Fig. 8). The stackup is heated and formed in place, and for sake of economy, an autoclave or press usually is used to apply heat and/or clamping pressure (Ref 13). Much like superplastic forming of aluminum sheet, diaphragm forming works by heating the material to above softening temperature while holding it under tension, then slowly applying pressure to one side to force it to take the shape of the forming mold. In TP diaphragm forming, the inelastic continuous reinforcement fibers prevent material stretching, but at forming temperature the stack becomes soft and pliable and can, for many geometries, be slipped into shape without wrinkling or splitting. In certain severe contours (beads, closed corners, etc.), this controlled reorganization will result in variations in laminate thickness. But unlike the press, pressure application is fluid and all laminate surfaces receive equivalent compaction force. The formation of wrinkles and splitting depends on process parameters and the properties of both the laminate and diaphragm materials. A slower forming rate can delay the onset of wrinkling by allowing viscous shear between fibers and plies to occur without fiber buckling. A stiffer diaphragm material can hinder out-of-plane buckling of the

laminate. Since the forming die must be heated and cooled from between 340 and 430 °C (645 and 805 °F) for each part, diaphragm forming typically requires 4 to 8 h.

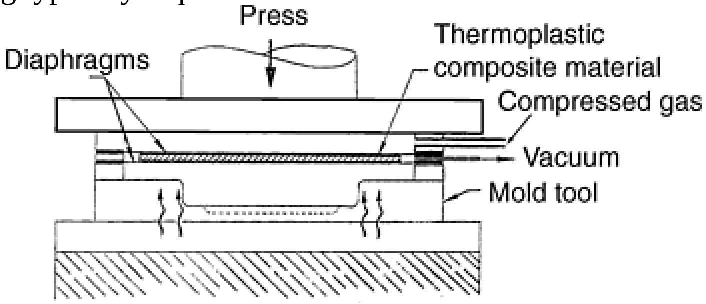

Fig. 8 Thermoplastic diaphragm forming

Rapid, Nonisothermal and Induction Diaphragm Forming. Diaphragm forming cycle times can be reduced either by heating the deformable stack in a separate oven and shuttling it to a cold forming die nonisothermal diaphragm forming, or NIDF, (Ref 14) or by using induction diaphragm forming (IDF). The NIDF process is similar to hydroforming except that the layup is contained in extendable silicone bagging, and forming pressures are exerted by pneumatics instead of hydrostatics. In the case of IDF, deformable aluminum sheets are made to serve as susceptors that can be heated directly by induction using electromagnetic forces generated within the press. A ceramic forming die can be used that remains at low temperatures below 90 °C (195 °F) throughout the forming cycle while the stackup is rapidly heated and cooled (Ref 9). By not heating the forming die, both NIDF and IDF can reduce cycle times from hours to minutes.

Joining

Although advanced composite process developments have made it possible to create one- piece, co-cured/co-consolidated structures with integral features not attainable or economically feasible with metals, secondary joining of individual components is still the prevalent means of creating complex assemblies. Mechanical fastening is a well understood and predictable way to join, but it involves undesirable drilling, and in some cases, countersinking operations, which are costly, cut continuous fibers, create stress concentrations, and degrade in-plane load-carrying capabilities. Consequently, manufacturers have pursued methods that replace traditional fastening techniques with noninvasive bonding and welding processes.

Within the aerospace industry, secondary bonding with 120 or 180 °C (250 or 355 °F) structural adhesives is the most used nonmechanical method for joining TS components. Well-characterized adhesives and surface treatments (to remove contaminants, increase contact area, and improve wetout) are used routinely to join large, highly loaded assemblies. Attempts to transition these methods to ATPCs, however, have been only marginally successful. Primarily, this is because thermoplastic substrate resins are relatively inert and do not lend themselves to the type of chemical attack required to facilitate a cohesive bond. Further, bonding adhesives in general have glass transition temperatures, fracture toughness, and environmental-resistive capabilities inferior to those of the TP components being assembled.

An attractive alternative for joining preconsolidated TP components is to melt fuse them together. Subsequently, manufacturers have pursued dual polymer bonding and co-consolidation methods, which seek to meld resin-rich TP surfaces together under heat and pressure. Surface treatment needs are limited to removing mold release contaminants and increasing bondline surface areas (i.e., by peel ply or mechanical abrading followed by a solvent wipe). This type of joining can be accomplished using various techniques, the more popular being autoclave, press, diaphragm, ultrasonic welding, resistance welding, and induction welding. Several manufacturers rely on these processes to join commodity grade thermoplastics, where consolidation pressures and temperatures are low compared with those of ATPCs. Widespread integration of these processes by the aerospace industry has been limited by a lack of production volumes and perceived risk levels associated with creating flawless, inspectable, durable bondlines.

Joint Types

Fastened. Since failure mechanisms are well understood and predictable, manufacturing methods are similar to those used on TS materials, and repair procedures exist, mechanical fastening is the most popular way to join TP aerospace components. Still, fastening is inherently costly. In general, drilled fastener holes are tightly spaced (approximately one every 3.8 cm, or 1.5 in.), require close diameter hole tolerances (±0.025–0.075 mm, or ±0.001–0.003 in., accomplished by step drilling and reaming), and necessitate two-sided installation and inspection access.

Since most aerospace grade ATPCs use abrasive continuous graphite fibers, short-duration expensive tungsten carbide or diamond grit drill bits are required to create precision fastener holes. Quality problems commonly associated with drilling TPs include surface delaminations, internal delaminations, fiber breakout, and degradation of the resin around the hole due to excessive heating. In response, several techniques and specialty bits have been developed to prevent such defects and to address specific applications such as drilling composite-metal stackups (Ref 15).

Equally important is fastener life cycle endurance. Traditional aluminum and steel fasteners do not work well in combination with graphite reinforcing fibers due to galvanic corrosion concerns. This problem necessitates the use of titanium, Inconel or austenitic alloys with graphite- compatible electromotive properties (Ref 16). During fastener installation, shank-to-hole interference fit must be maintained, and clamp-up loads must not exceed the compression strength of the composite materials being joined. Further, due to the sensitivity of graphite fiber to bearing loads, optimized countersinking configurations differ from those used on metal components (Ref 17).

Adhesive Bonded. Adhesive bonding offers inherent advantages over mechanical fastening since load-carrying fibers are not cut and smooth aerodynamic surfaces can be maintained. Consequently, manufacturers have used bonding extensively when assembling TS aerospace hardware. By far the most popular product form is thin film epoxy resin systems carried on scrim fiberglass reinforcement. The bonding scenario consists of preparing and cleaning the bond surfaces, applying adhesive film, bringing the surfaces together and curing the adhesive under heat and pressure (normally 120 or 180 °C and 315 to 595 kPa, or 250 or 355 °F and 45 to 85 psi). Properly bonded articles can have joint strengths as good or better than fastened assemblies, and long term hot/wet capabilities at a temperature of approximately 105 °C (220 °F) are achievable. Bondlines can be inspected using traditional nondestructive techniques, but underlying cohesive quality cannot be determined without the use of destructive testing. Therefore, manufacturers must rely on extensive allowable databases and rigid process controls to ensure part- to-part integrity.

A good structural bond starts with clean, suitable bond surfaces. To create a bond surface, the substrates must be roughened to increase bond area. This can be accomplished by mechanical abrading, but more commonly, a finely woven peel ply is consolidated with the part, which, when removed, provides a uniformly textured, contaminant-free bond surface. If abrading (by grit blasting, sanding, etc.) is used, the bond surfaces must be wiped clean with a solvent to remove contaminants (Ref 18). Another essential to creating a good bondline is to maintain compaction pressure between the bonding surfaces during the bond cure cycle. On small, simply shaped parts, mechanical clamping can be used, but with large complex parts autoclave fixturing may be required. Even under autoclave pressure tight radii, joggled areas, and so on are difficult to confine. Small misalignments can result in gaps in the bond surfaces, creating poor bonds and, in turn, premature structural failure.

Standard surface preparation methods normally are not enough to promote wet out and chemical bonding when using ATPC resin systems. Rather, to achieve a structural bond, the chemical makeup of the TP part surface must be altered. Various methods have been used to accomplish this task, including flame treatment, corona discharge, plasma activation, and chemical etching (Ref 19). These methods have shown promise in producing bonded elements with room temperature bond strengths equivalent to those of bonded TS composites (Ref 20, 21, 22, and 23), especially when combined with standard abrading practices (Ref 24). Because of additional surface treatment costs, inconsistent or unpredictable bond quality, and the reduction in environmental and fracture toughness properties associated with lower temperature capable TS adhesives, secondary bonding of ATCPs has yet to meet with wide scale production acceptance.

Dual Polymer Bonded. Dual polymer bonding provides a high use temperature alternative to adhesive bonding. In this case, a resin film with a melt temperature, or in the case of amorphous polymers, a glass transition temperature (T_g), less than that of the TP parts to be joined is placed at the bond interface instead of a TS adhesive film. Optimally, to circumvent surface preparation problems and to obtain maximum adhesion between the resin film and base laminate, this bonding polymer is adhered to the bond interface of each part during an initial preconsolidation cycle. Typically, the bond surfaces are placed in intimate contact, fixtured or bagged and heated to above the melt temperature of the bonding resin, but below that of the individual components while compaction pressure (typically 700 to 1400 kPa, or 100 to 200 psi) is maintained. The resin-rich mating surfaces are fused together creating a structural assembly. The major drawbacks to this joining method are that the properties of the assembly are reduced to those of the polymer used for bonding and that the entire assembly must be fixtured/heated within a narrow process window to achieve good structural results. If the parts get too hot, the preconsolidated laminates may deform or delaminate, and if they are not hot enough, they will not stick together.

Co-consolidated. Co-consolidation involves the melt fusion of individual TP articles into a one-piece assembly. In this case, the TP matrix resin provides the bond mechanism. Usually, to enhance flow and fitup, a layer of resin film is placed at the mating surfaces prior to consolidation. This process creates assemblies that have properties consistent to the base components, but like dual polymer bonding requires careful fixturing and heatup while maintaining consistent pressure.

Welded. TP welding is the joining of two or more parts wherein only the areas being fused together are heated. The weld mechanism can be either dual polymer bonding or co-consolidation, and process methods include ultrasonic (heating by rapid vibration), resistance (heating with electric current), or induction (heating with magnetic field). Welding can be used to join preconsolidated parts ranging from, hat stiffeners, I-beams, and so on to large panels such as wing skins. This method has an advantage over pressing, diaphragming, and autoclaving because the bulk of the surface area of the parts need not be heated, and lay-up mandrels and

fixture tooling materials are not limited to those compatible with the TPs at elevated temperatures. Figure 9 compares lap shear strengths reported for various bond types and methods, and Fig. 10 relates fracture toughness to lap shear strength. Table 4 summarizes the thermoplastic-joining techniques, indicating the relative advantages and disadvantages.

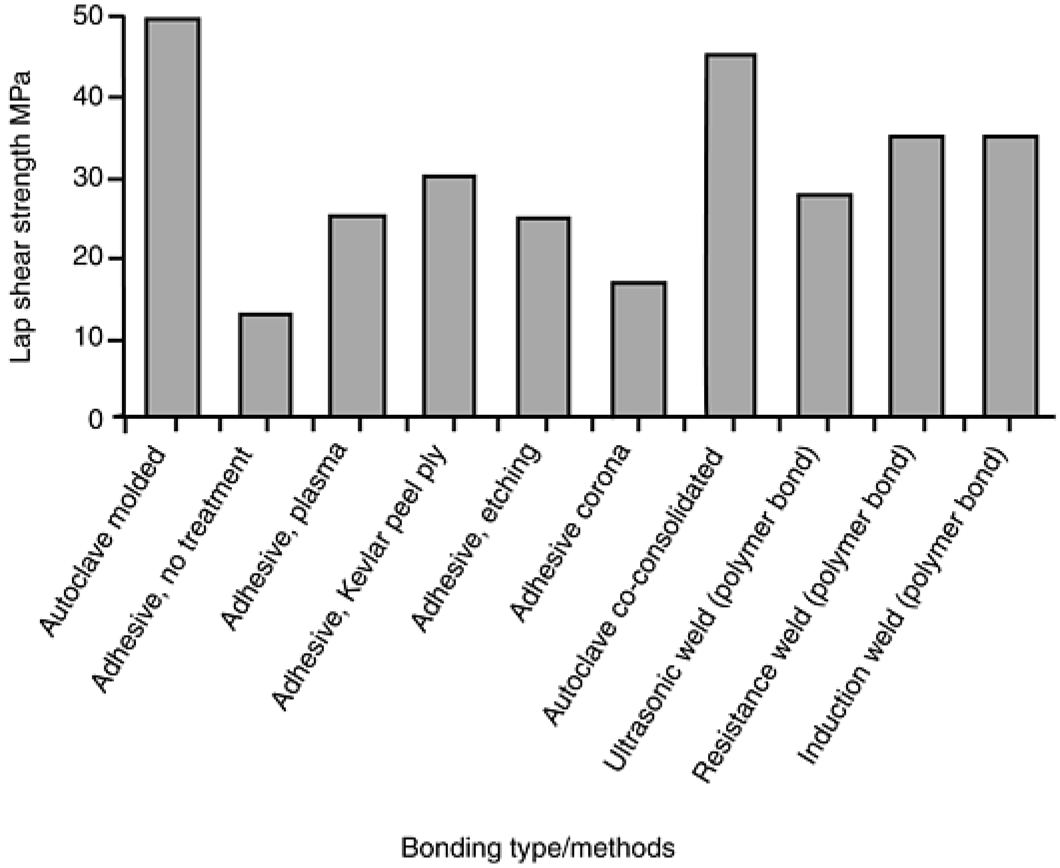

Fig. 9 Comparison of lap shear strength for various bond types/methods. Source: Ref 21, 23, 24, 25, 26, 27, 28, and 29.

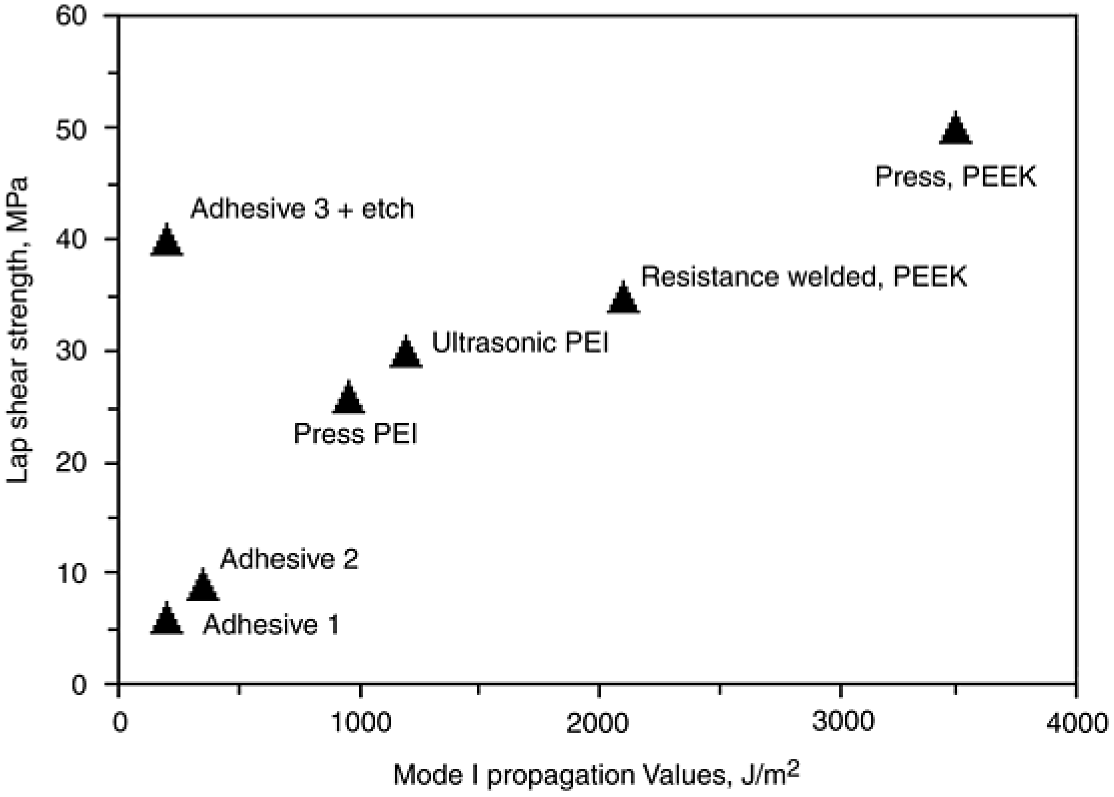

Fig. 10 Comparison of fracture toughness to lap shear strength for various bond types/methods. PEEK, polyetheretherketone; PEI, polyetherimide. Adhesive 1, Ciba Geigy AV138M, 100 °C (210 °F) cure; adhesive 2, Ciba Geigy AY103, 100 °C (210 °F) cure; adhesive 3, Ciba Geigy AV118, 180 °C (355 °F) cure. Source: Ref 25

Table 4 Comparison of selected thermoplastic-joining methods

Joining method	**Advantages**	Disadvantages
Press	Good for small, flat lap joints	**Only applies pressure in one direction. Requires heating of tool and entire part. Hard to scale up**
Diaphragm	Can apply fluid pressure. Can adapt to complex structures	**Requires heating of tool and entire part. Requires dedicated tool**
Autoclave	Even pressure throughout article Can adapt to complex structures	**Requires heating of tool and entire part. Long heatup and cool down**
Ultrasonic welding	Localized heating. Can use room temperature fixturing. Fast bond times (<10 s)	**Hard to scale up. Not practical on complex geometries**
Resistance welding	Localized heating. Can use room temp. fixturing. Good for 2–30 cm (0.75–12 in.) lap joints	**Foreign object in bondline. Inconsistent heating as length increases**
Induction welding	**Localized heating. Can use room temperature fixturing. Potential to make running long welds**	**Foreign object in bondline**

Joining Methods

Press, Diaphragm, and Autoclave. To facilitate a dual-polymer or co-consolidation TP bond, parts must be placed in intimate contact, heated to above melt temperature, and fused together under consolidation pressure (typically 700 to 1400 kPa, or 100 to 200 psi). Often the most difficult part of this process is to position and maintain the parts relative to one another while still allowing some degree of movement during the compaction/joining cycle. Simple lap shear specimens require this pressure and movement in only one direction and can be joined in a press using heated platens with stepped plates.

Complex contoured parts require fluid pressure application and are better joined in a diaphragm or autoclave. In these instances, locating dies can be used to hold the parts relative to one another and the entire assembly can be confined within a bag or bladder. For example, the V-22 Osprey aircraft landing gear door shown in Fig. 11 illustrates how a diaphragm former can be used to consolidate a base laminate, form a bead stiffened panel, and then join the two into an assembly via the dual polymer bonding process.

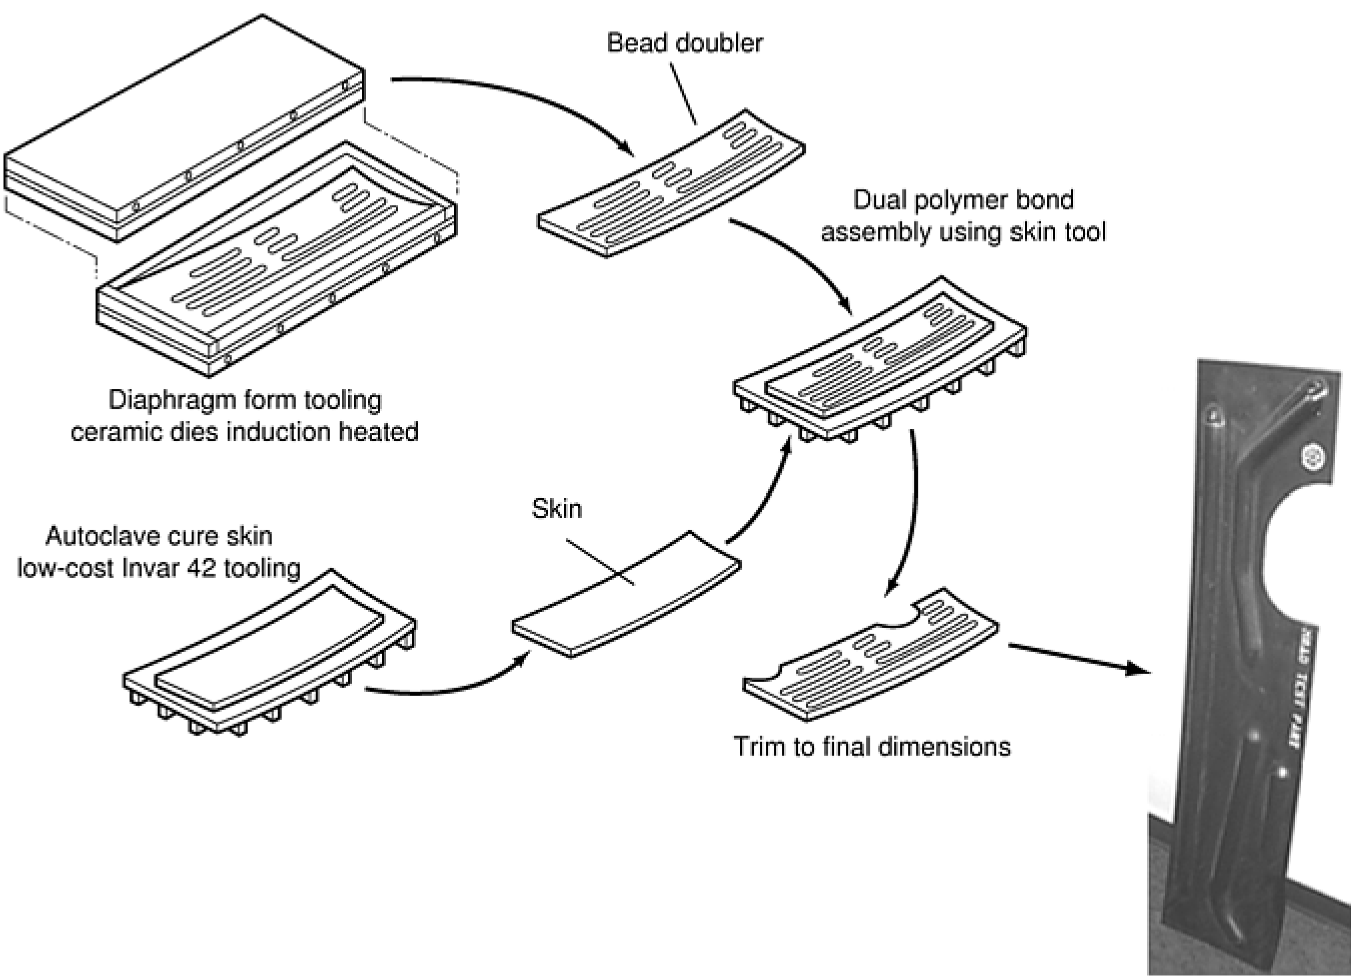

Fig. 11 Dual polymer bonded V-22 Osprey door

An autoclave is a large hollow pressure vessel that can in theory accommodate an infinite variety of dual polymer or co-consolidation assembly configurations. In practice, the constraining factor becomes the thermal expansion of the materials being bonded compared with that of the tooling being used to fixture the parts. Dual polymer bonding requires heatup from room temperature to approximately 230 °C (445 °F), and co-consolidation cycles go as high as 430 °C (805 °F). Over these temperature ranges aluminum and tool steels have incompatible coefficients of thermal expansion compared with those of the TP composites being joined. These temperatures limit tool choices to materials such as Invar 42 (an iron-nickel alloy), ceramic and monolithic graphite, which have coefficients of thermal expansion in the 4 to 5 μm/m/°C (2.2 to 2.8 × 10^{-6}in./in./°F) range over the range of the bonding cycle. Figure 12 displays an experimental cockpit floor co-consolidated in an autoclave.

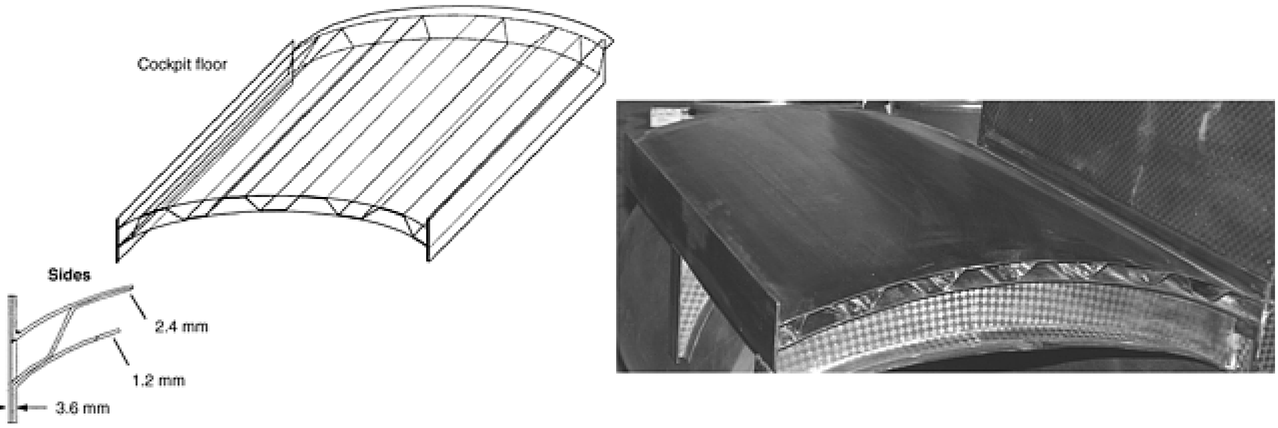

Fig. 12 Co-consolidated cockpit floor

Ultrasonic Welding. In ultrasonic welding vibration energy (typically 20–40 kHz) is used to heat the TP bondline. Figure 13 shows a schematic of an ultrasonic welder. During the welding process, the ultrasonic

machine converts electric power to mechanical vibration through a horn (or sonotrode), which is placed in physical contact with the back face of one of the TP components being joined. Vibration focused through the horn causes this component to rapidly move relative to another fixed component and the resultant friction generates heat at the joint interface. The objective is to focus the heat at the bondline and keep the remainder of the part interior and the heat-affected zone, or HAZ (the area next to the bond) from deconsolidating. Since this method only heats the parts in the area being bonded, pressure only needs to be maintained directly under the horn and any associated HAZs. Pressure between 500 and 1400 kPa (70 and 200 psi) must be maintained until the part has cooled to below the T_g of the matrix resin.

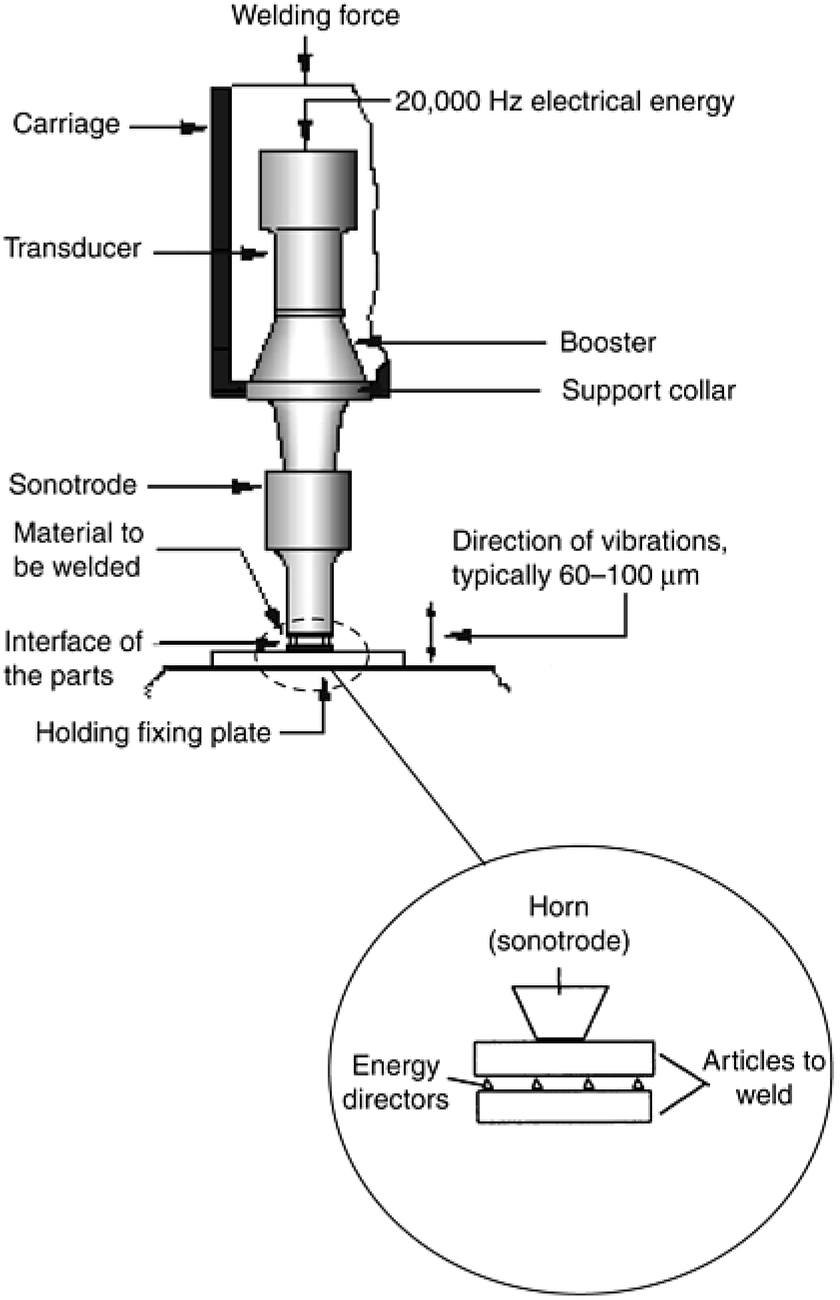

Fig. 13 Schematic for ultrasonic welder and multiunit weld machine. Source: Ref 30, 31

Ultrasonic welding (especially in spot applications) of unreinforced TPs is used widely in the automotive and medical industries, and total weld times of less than 10 s are achievable (Ref 32). With ATPC materials a resin rich layer usually is added to enhance the polymer film-to- laminate bond, decrease melt viscosity, and lower melt-temperature requirements at the bond interface. In addition, researchers have developed molded-in energy directors that make heat up more efficient (Ref 33). The weld time to get a sufficient bond is a function of pressure, vibration amplitude of the horn, and thickness of the material. Care must be taken not to have too great of a weld time since this could cause the interior of the laminate to heat to above melt temperature and excessive squeeze-out could result. Although ultrasonic is perhaps the fastest TP welding technique, lap shear

strengths (25–30 MPa, or 3625–4350 psi for PEEK components) are typically lower than for other methods, and it is difficult, if not impossible, to scale the process to complex and/or large geometries (Ref 25).

Resistance Welding. Figure 14 shows a schematic for the TP resistance welding process, in which electrical current is passed through conductive fibers or strands to create heat at the bond interface. This heating element (or susceptor) usually is made from metal (typically copper) or, preferably, graphite fibers identical to those used to reinforce the ATPC. The purpose of the susceptor is to focus heat locally at the bond interface, thereby minimizing laminate interior and adjacent bond area heating. As with ultrasonic welding, pressure must be maintained on the HAZ during part heat up and cooldown to avoid deconsolidation.

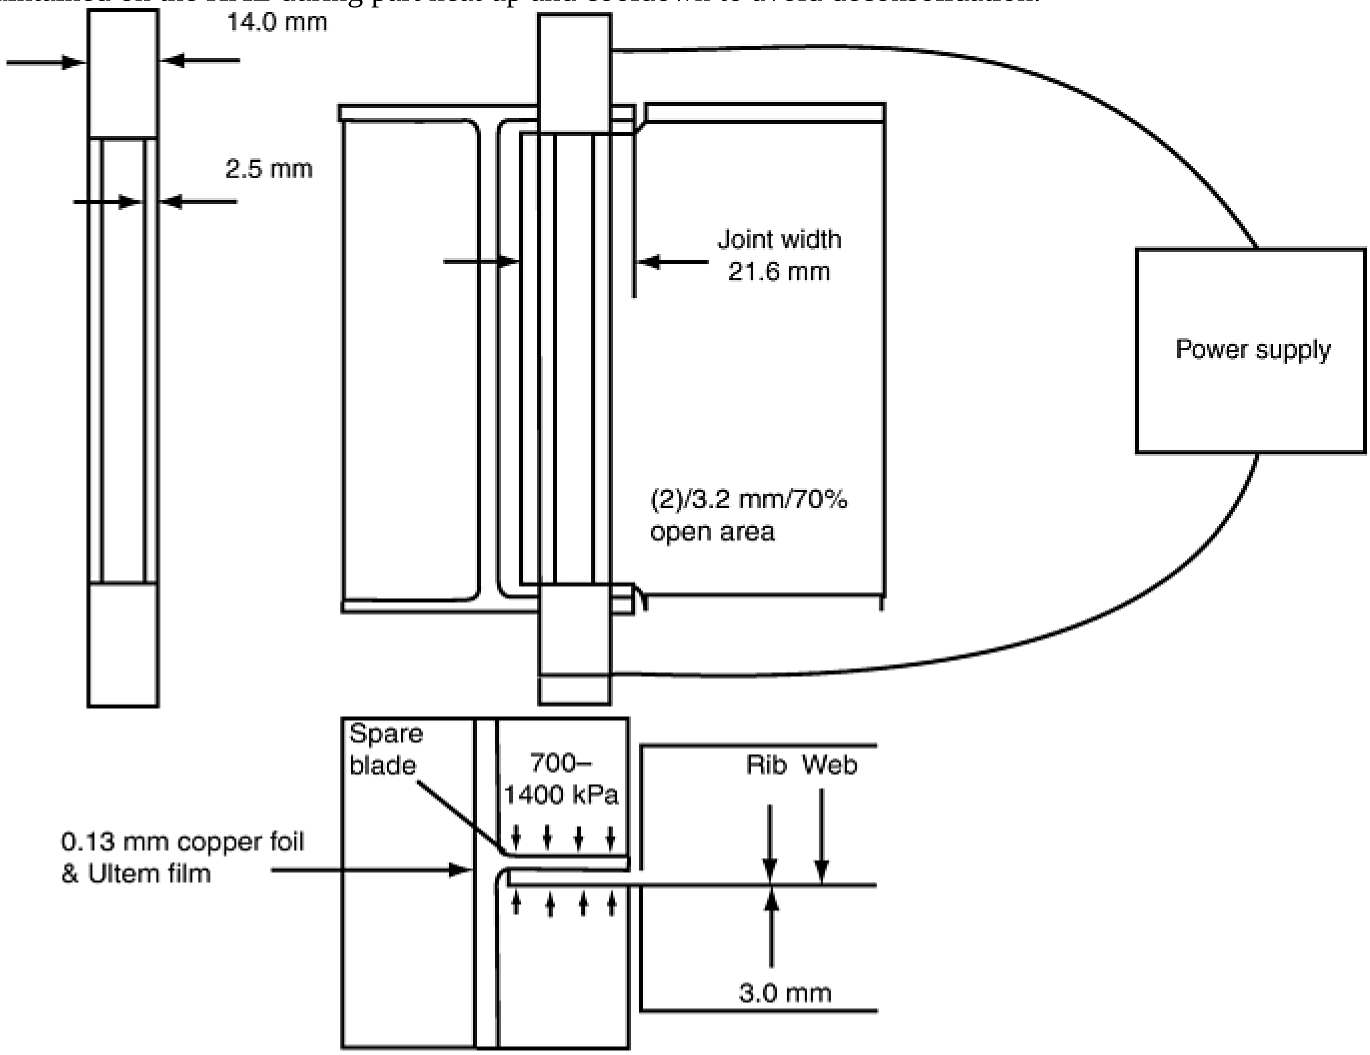

Fig. 14 Schematic for resistance weld of rib to spar

Weld times vary depending on the power supply and characteristics of the susceptor being used. But, total cycle times in the 30 s to 5 min range are achievable. Like most TP joining processes, resistance-welded parts usually have a resin-rich area at the bond interface. The process has been shown to be very efficient on small 2 to 30 cm (0.75–12 in.) flat joints and lap shear strengths for dual polymer resistance bonded articles can range from 30 to 35 MPa (4350–5075 psi), while strengths for co-consolidated resistance-welded articles are typically between 35 and 40 MPa (5075 and 5800 psi) (Ref 25, 26). As part length and curvature increases, differential edge and nonlinear heat-up effects often encroach. This phenomenon is less of a factor when dual polymer bonding, given the temperature required to fuse the bonding resin is lower than the T_g of the matrix resin. Scaling-up resistance welding to large aerospace structures is further complicated by the fact that consolidation pressures (700–1400 kPa, or 100–200 psi) must be maintained over the entire bond surface during heat up (Ref 34, 35). As shown in Fig. 15, however, wing tip substructure rib to spar joints lend themselves to resistance welding as long as joint length is relatively short and access for a pressure tool can be accommodated.

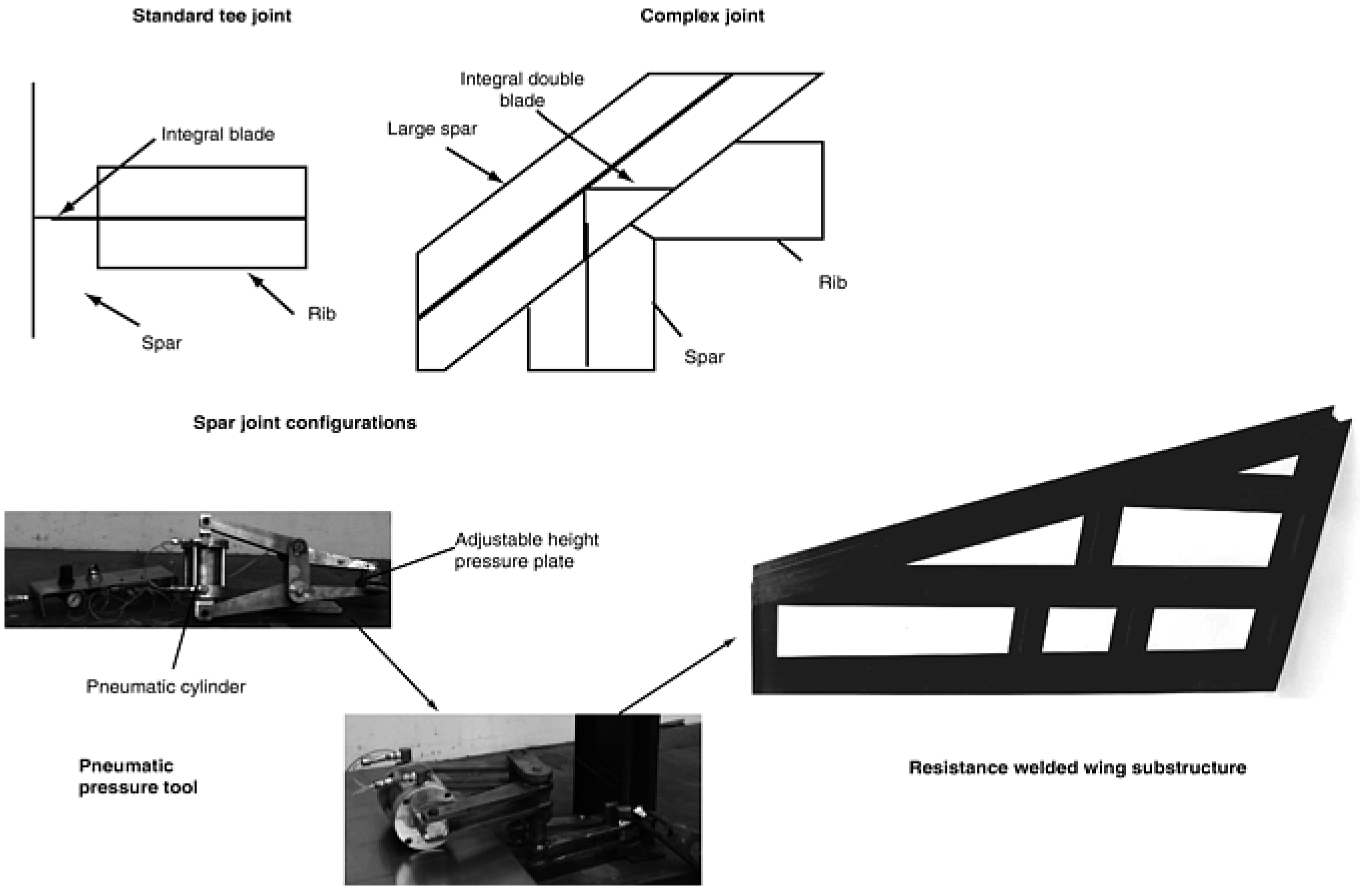

Fig. 15 Resistance welding wing substructure using copper foil and amorphous thermoplastic (Ultem, GE Company, Pittsfield, MA) resin

Induction Welding. Figure 16 shows the schematics of a moving head of an induction welder. During induction welding, the bond interface is heated by utilizing an electromagnetic field in conjunction with a susceptor embedded at the surface of one of the bond articles. Heating occurs, either by eddy current (EC) dissipation in an electrically conductive susceptor or by hysteresis losses in a magnetic susceptor, giving rise to particle interaction frictional heat. Since heating takes place only in the vicinity of the magnetic field, the HAZ and associated bond pressure can be focused exclusively on the area being joined. Early fabrication trials used thin magnetic/conductive metal susceptors (i.e., iron or nickel base) that provided rapid heatup, but graphite fibers (Ref 27, 28) and copper mesh also have been used to avoid corrosion concerns. In either case, a foreign material is being added to the bondline, and some degradation in structural properties compared with a co-consolidated joint is inevitable.

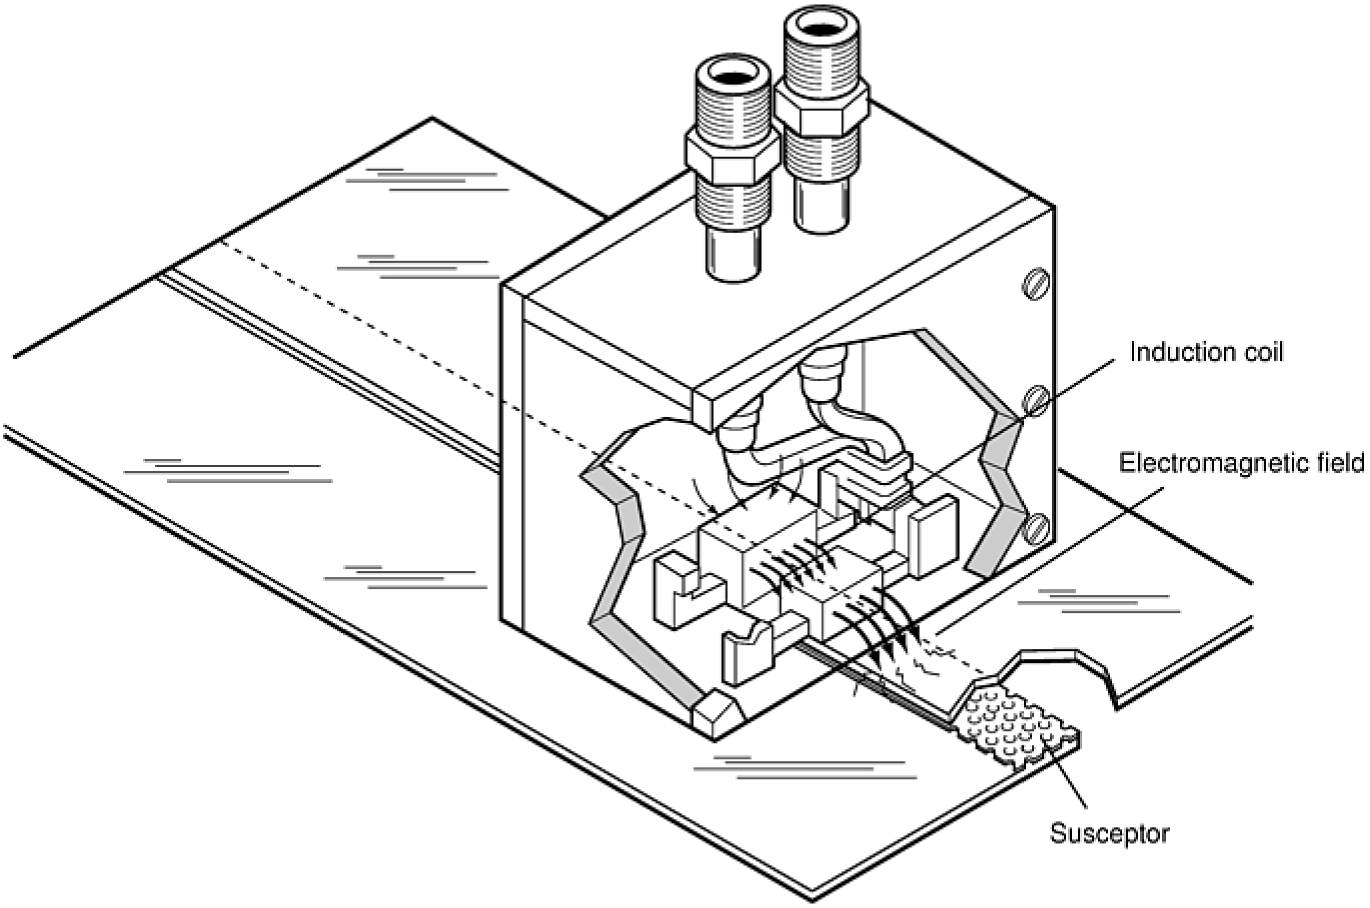

Fig. 16 Induction welder schematic

Typically, heat-up times (5 to 30 min) for induction welding are longer than either ultrasonic or resistance. Cycle times are dependent on the melt temperature one is trying to achieve, pressure applied (material contact as melt progresses improves conduction), input power, and susceptor type. As with all localized welding techniques, pressure on the part must be maintained above consolidation levels (350–1400 kPa, or 50–200 psi) to achieve good bond quality. Lap shear strengths between 30 and 35 MPa (4350 and 5075 psi) have been reported by a variety of research programs (Ref 25).

Induction welding has been widely pursued by the aerospace industry since it has potential for being adapted to long line weld applications, such as wing to spar or stiffener joints. Figure 17 displays a schematic of an induction welder used to bond sine wave spars to a fighter wing skin. Figure 18 shows an induction-welded article, consisting of a K3B skin and stringer. Like most TP process techniques, however, implementation of induction welding has been hindered by the lack of allowable databases, perceived life-cycle risks, and the lack of large-volume production contracts.

Hole Drilling in Polymer-Matrix Composites

Michael J. Paleen and Jeffrey J. Kilwin, The Boeing Company, St. Louis

Introduction

GOOD HOLE-DRILLING PROCESSES are key to joining composite parts with other composite parts or with metal parts. Poor hole quality can affect the strength and durability of structures. To consistently obtain good hole quality, it is important to identify four factors before selecting the optimal techniques, tools, and drill parameters. First, identify the material types in the assembly stack-up. For composite structures, the material type and fiber type must be known in addition to fiber orientation. For example, the hole preparation techniques and tools will differ between a carbon/epoxy composite part and an aramid fiber (Kevlar)/epoxy composite part. Also there may be different techniques and tools for unidirectional (tape) products and woven (cloth) products. When unidirectional carbon/epoxy materials are used on the part surface, the fibers are prone to splintering and fiber breakout from the hole-drilling process, especially if the surface is resin starved. This splintering or fiber breakout is much less of a problem with woven materials. Unidirectional fiber materials do offer some benefits over woven materials in their ability to be oriented in the direction of the structural load, which can keep weight to a minimum. Also unidirectional fiber materials typically have less waste than woven products, unidirectional products lend themselves to automated lay-up in tape-laying machines, and unidirectional products may provide a smoother aerodynamic external surface than woven products. It is not uncommon to mix composite types and fiber materials to better utilize the advantages of the materials. For example, composite structures can be a combination of unidirectional inner plies to keep weight to a minimum and woven surface plies for reduced impact damage or hole preparation damage, and the woven material adjacent to mating metal structure could be fiberglass to be more compatible with aluminum.

Any metallic structures in a joint must also be known. Often, the metallic structure serves as a backup for drilling and will help reduce or eliminate fiber breakout problems. Required hole size, hole tolerance, and the available equipment also influence hole-drilling process selection.

Part Fit-Up

Gaps detected between parts of an assembly must be evaluated to determine if they are acceptable "as is" or if they need to be shimmed. Gaps between mating parts may entrap drill chips and debris and also can allow fiber breakout and/or delaminations in the composite structure; this is discussed further in the Section "Hole Quality" in this article.

Shimming is the process of filling the gap between mating parts using either solid shims, liquid shim (moldable plastic), or a combination of both. Typically, engineering should evaluate an assembly to determine if some minor gaps can be tolerated and when shimming will be required. With this determined, additional guidelines may be established to identify when assembly personnel may automatically fabricate and install shims and when engineering is required to evaluate a gap. For example, in some aircraft assemblies, gaps up to 0.13 mm (0.005 in.) may be left unshimmed, gaps from 0.15 to 0.76 mm (0.006–0.030 in.) may be liquid (moldable plastic) shimmed, or a combination of a flat solid shim plus liquid shim may be used to accommodate tapered gaps. Gaps exceeding 0.76 mm (0.030 in.) require engineering evaluation. When determining if gaps are present, specific load application requirements must be specified in order to uniformly preload the parts to an acceptable level and not damage the parts. The amount of preload should be specified by engineering and may be limited to "thumb and forefinger" pressure, or the tightening of temporary fasteners or clamps to specified torque levels. Any gaps remaining after application of controlled preload are evaluated for shimming.

Solid shims can be fabricated from either solid metal, prelaminated metallic sheets, or from prefabricated laminated composite material. Assembly personnel must be given guidelines as to which materials will be acceptable. When specifying solid or laminated metallic materials, material compatibility must be considered to eliminate "built-in" corrosion problems. For example, aluminum shims should not be used if they will be in contact with carbon/epoxy composite structure. Since assembly personnel will be required to adjust the shim thickness if the gap is tapered, choose shim materials that can be easily shaped or cut in the production environment.

Liquid shim materials are often more advantageous than attempting to fabricate a complex tapered shim from solid materials. Assembly personnel fill gaps with the liquid shim, clamp the parts together under proper preload, and remove excess shim material squeezed from the joint. Since liquid shim materials are usually filled two-part epoxies, the elapsed time for the shimming operation may be as long as 8 to 24 h due to the cure time before additional assembly operations can continue.

When using solid or liquid shims, the shim material should be bonded to one surface of the mating parts. The key to good adhesion is surface preparation. Carefully follow the manufacturer's surface preparation procedures. Once shimming operations are completed, hole generation can begin.

Hole Drilling in Polymer-Matrix Composites

Michael J. Paleen and Jeffrey J. Kilwin, The Boeing Company, St. Louis

---

Drilling Considerations

Hole generation is very dependent on the materials in the joint and their stack-up. If the joint is all carbon/epoxy composite, special flat flute drills or similar four-flute drills have successfully produced quality holes in equipment operating from 2000 to 20,000+ rpm. Figure 1 shows a flat flute drill commonly used by hand- drilling techniques in 2000 to 3000 rpm drill motors. A four-flute drill used for hand drilling at 18,000 to 20,000 rpm usually with hard tooling is shown in Fig. 2. One key to successful hole drilling is feed control. If the cutters are hand fed through the materials with no controls, composite materials are susceptible to breakout damage and delaminations. Two methods to reduce this damage are: use of a hydraulic dash pot or control feed equipment (Fig. 3), which restricts the surging of the drill as it exits the composite material, and use of woven materials or barrier plies. One or two layers of woven material, which is less susceptible to breakout, can be designed into the part at its outer plies. If a composite part is in contact with a metallic part such as carbon/epoxy mated to aluminum, the woven ply on the composite part that mates the aluminum part can be a fiberglass ply, which provides corrosion protection in addition to reducing fiber breakout. For cases where no metallic structure provides backup support, it may be necessary to use a metallic plate or sheet as backup to

avoid breakout. Figures 4 and 5 show the effect of proper utilization of a metallic backup plate in reducing exit-hole breakout.

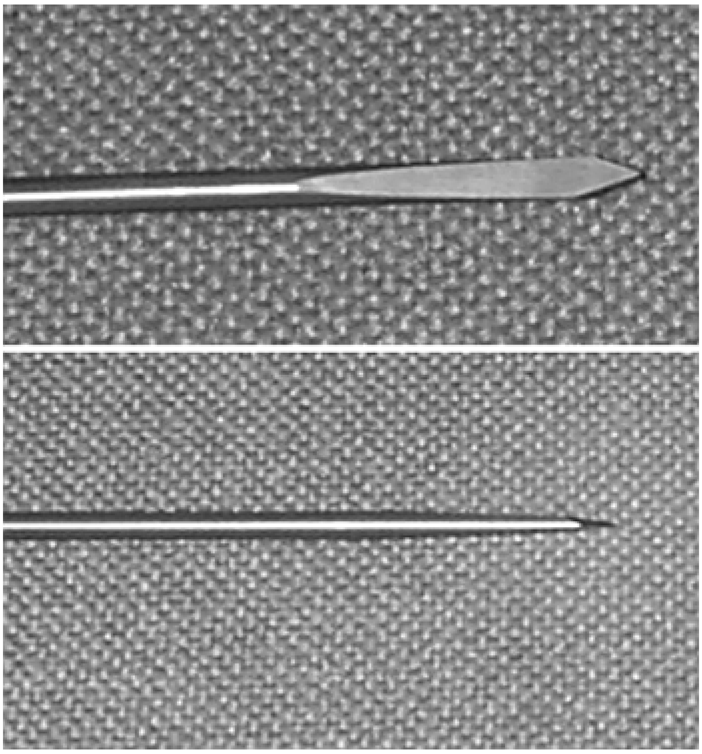

Fig. 1 A flat flute drill for drilling carbon/epoxy composites

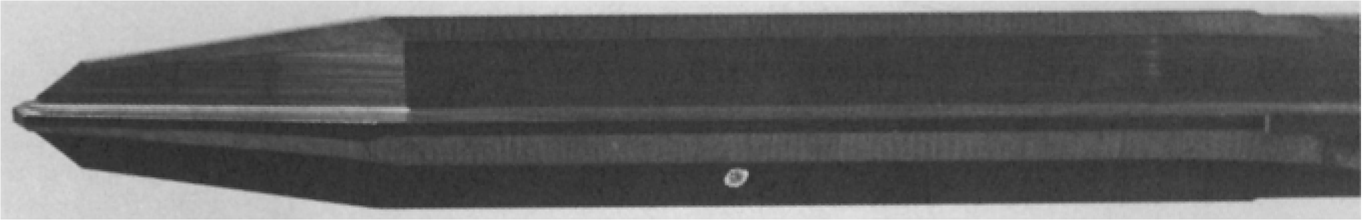

Fig. 2 Four-flute drilling/reaming cutter for carbon/epoxy composites

Fig. 3 Hand-feed drill motor with hydraulic dash pot for feed control

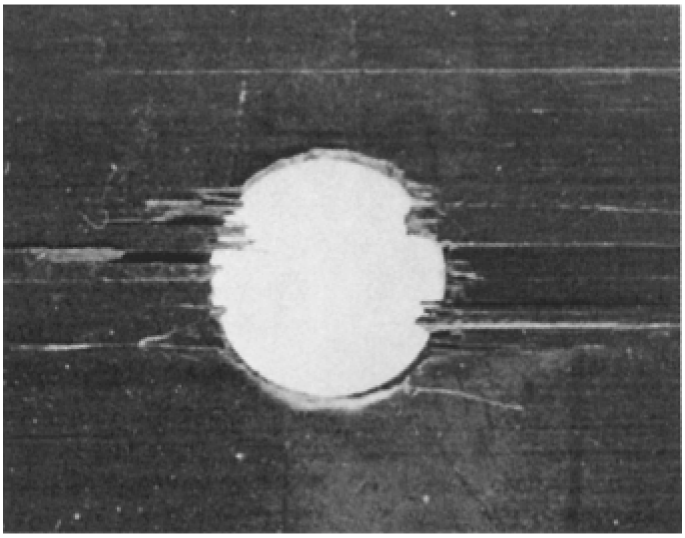

Fig. 4 Typical hole exit splintering damage from drilling without a backup

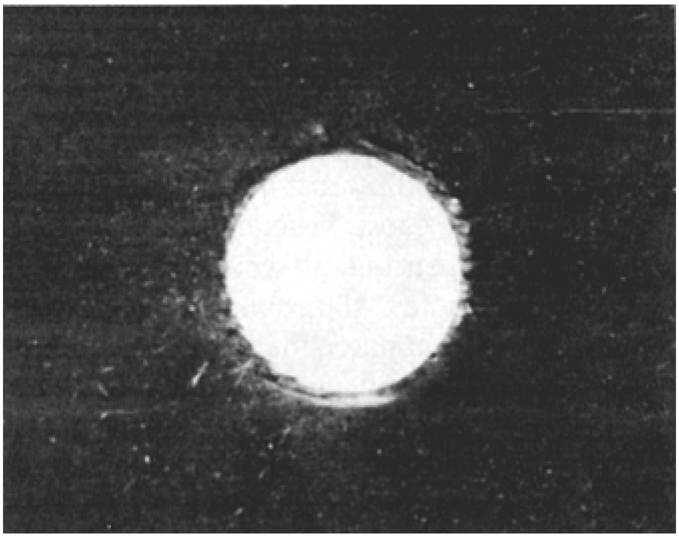

Fig. 5 Clean hole exit condition when using a backup

Back counterboring is a condition that can occur when carbon/epoxy parts mate metal substructure parts. The back edge of the hole in the carbon/epoxy part can be eroded or radiused by metal chips being pulled through the composite. The condition is more prevalent when there are gaps between the parts or when the metal debris is stringy rather than small chips. Back counterboring can be minimized or eliminated by changing feeds and speeds, cutter geometry, better part clamp-up, adding a final ream pass, using a peck drill operation, or combinations of these.

If a composite part is sandwiched between two metallic parts, minimal drilling difficulties should occur. When drilling combinations of composite parts with metal parts, the metal parts may govern the drilling speed. For example, even though titanium is compatible with carbon/ epoxy material from a corrosion perspective, slower drilling speeds (about 0.12 m/s, or 25 sfm) are required in order to ensure no metallurgical damage occurs to the titanium.

Carbon/epoxy is very abrasive to cutters, so carbide tools are a must for any significant drill life. Small diameter high-speed steel (HSS) drills, such as No. 40 drills used to manually drill pilot holes, are typically used because carbide drills are relatively brittle and are easily broken. The relatively low cost of these small HSS drills offsets the limited life expectancy. High-speed steel drills may last for only one hole. The most common problem with carbide cutters used in hand-drill operations is handling damage (chipped edges) to cutters. A sharp drill with a slow constant feed can produce a 0.1 mm (0.004 in.) tolerance hole through carbon/epoxy plus thin aluminum, especially if a drill guide is used. With hard tooling, tighter tolerances can be maintained. When the structure under the carbon/epoxy is titanium, drills can pull titanium chips through the carbon/epoxy and enlarge the hole. In this case, a final ream operation may be required to hold tight-hole tolerances.

Aramid fiber (Kevlar)/epoxy composites are difficult to drill unless special cutters are used because the fibers tend to fray or shred unless they are cut clean while embedded in the epoxy. Thus, drills with special “clothes pin” points and “fish tail” points have been developed that slice the fibers prior to pulling them out of the drilled hole. If the Kevlar/epoxy part is sandwiched between two metal parts, standard twist drills can be used.

Use of power-feed drill motors with hard tooling (Fig. 6) is very beneficial for drilling holes in composite or composite/metal joints because the uniform feed rate can prolong the drill life and control fiber breakout as the drill exits the composite. Again, speeds of 2000 to 3000 rpm with a 0.05 to 0.1 mm/rev (0.002–0.004 in./ rev) feed rate have been very successful. Slower or faster speeds and feed rates may prove better for some applications.

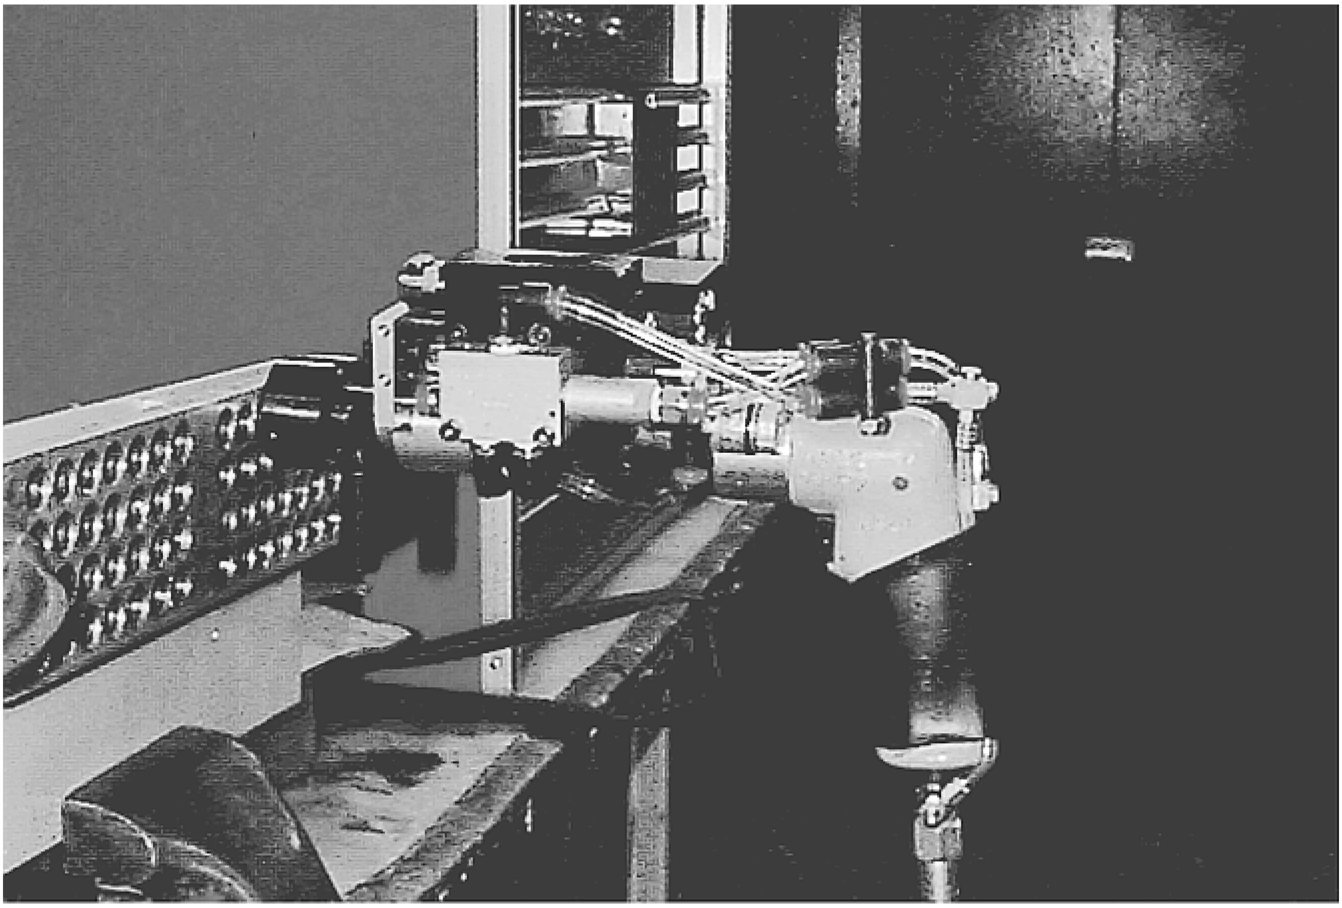

Fig. 6 Power feed tool with hard tooling plates

Peck drilling is a method that uses hard tooling and a power-feed drill motor with lock-in type nose bushings. Peck drilling is a repetitive process of the drill advancing to ever-increasing depths and then withdrawing from the hole to clear the debris and dissipate heat. This “woodpecking” action continues until the hole is complete (Fig. 7). For deep holes, the drill can be rapid advanced almost to the surface to be cut, then slows to the preset drilling feed rate to complete another peck cycle. The rapid advance reduces the drilling time, and stopping the rapid advance short prevents damage to the drill, which extends drill life. Peck drilling can be advantageous for drilling through material stack- ups as thick as 38 mm (1.5 in.).

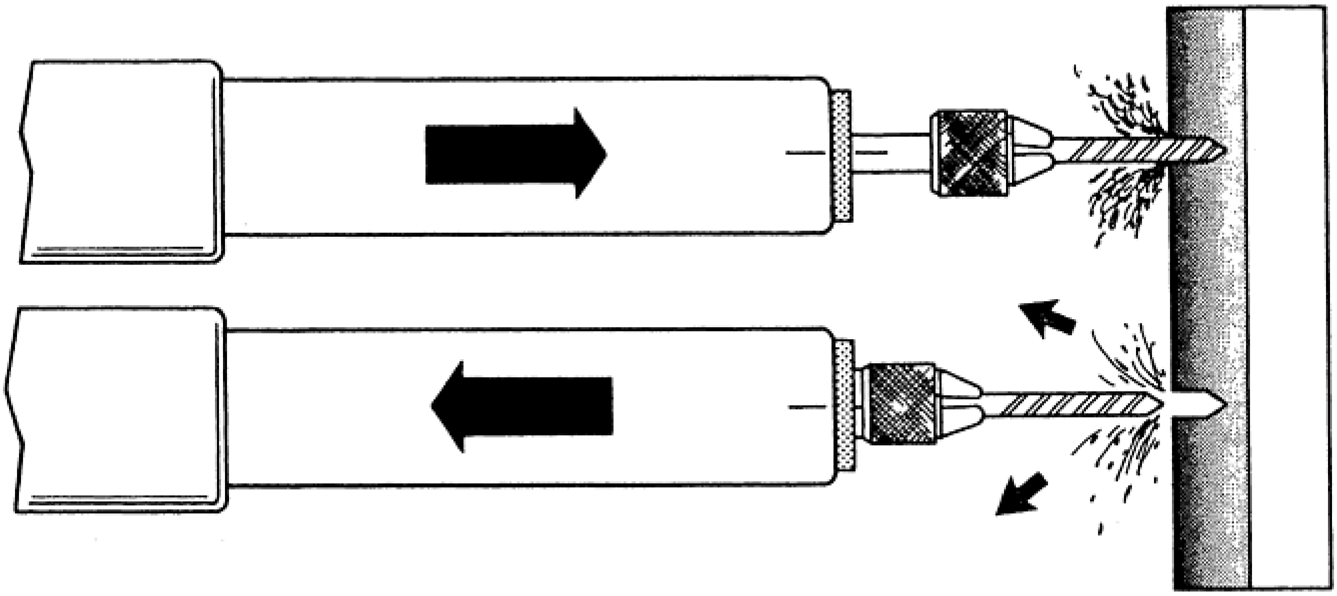

Fig. 7 Peck drilling in which drill advances into material, retracts, cools, and cleans chips before repeating the process

Automated drilling/fastener installation equipment has been successfully used with composite structures due to its controlled clamp- up, speeds, feed rates, drill/countersink combination cutters, repeatable fastener insertions, and collar swaging/tightening that are designed into the equipment. Automated equipment using numerical control (NC) programs can use hole- drilling techniques and benefits of hard tooling type operations without the hard tooling costs. The equipment can be combined with vision systems that can scan and “memorize” substructure locations prior to laying skins in position for drill-out. Another type of vision system can be used to locate key index or clamp holes tying a skin to substructure with the vision system “correcting” the programmed hole pattern to the actual key index/clamp hole positions. Many automated systems offer controlled clamp-up capabilities to minimize or eliminate gaps between parts. Most automated systems are extremely rigid, allowing drilling through thick stack-ups while using comparatively brittle cutters. Just as carbide cutters offer cutter life benefits over HSS cutters, polycrystalline diamond (PCD) cutters offer improved cutter life over carbide drills. Due to their brittle nature, PCD cutters require a rigid setup such as that offered by automated equipment to take advantage of their longer tool life.

Automated equipment can be programmed for fixed speeds and feed rates, for peck drilling, or for combinations of both. With correct selection of drills, feeds, and speeds, holes with a 0.076 mm (0.003 in.) tolerance can be produced in carbon/epoxy over aluminum structures using automated equipment. The drill/countersink combination cutters are especially beneficial as they ensure good alignment between the hole and countersink. These cutters have not been very successful in hand-drilling operations as hole size tolerance can be lost when the countersink portion of the cutter begins cutting. Automated equipment can be used just to prepare the holes, such as the Boeing F/A-18 C/D Wing Automated Drilling System (ADS) (Fig. 8), or the equipment can prepare the holes and install the fasteners, such as the Boeing F/A-18 E/F Wing Automated Drilling System (ADS) (Fig. 9).

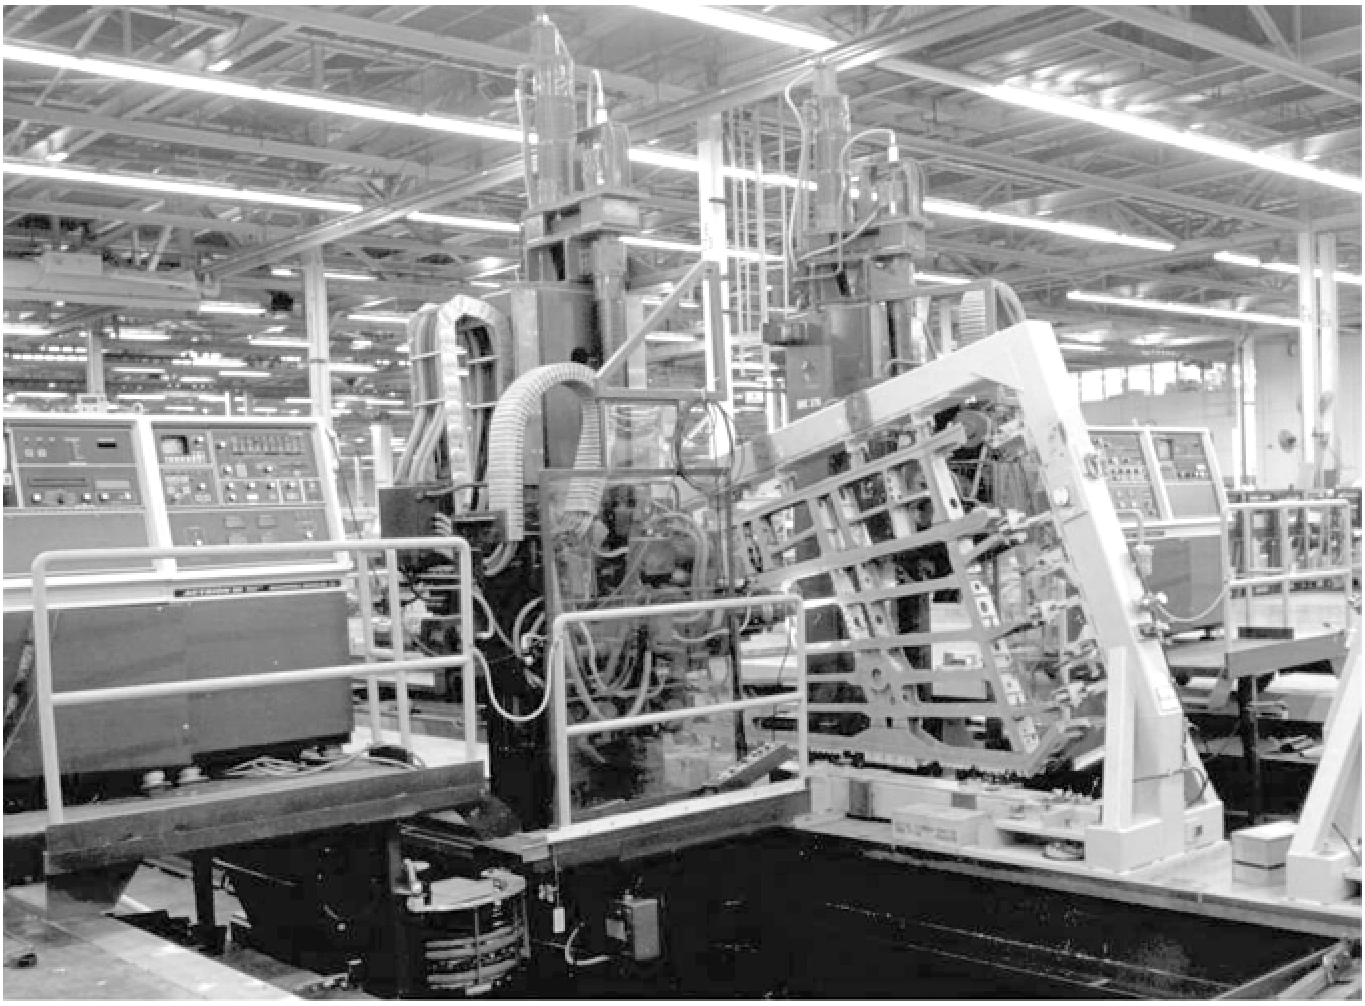

Fig. 8 Automated system for drilling fastener holes in wings

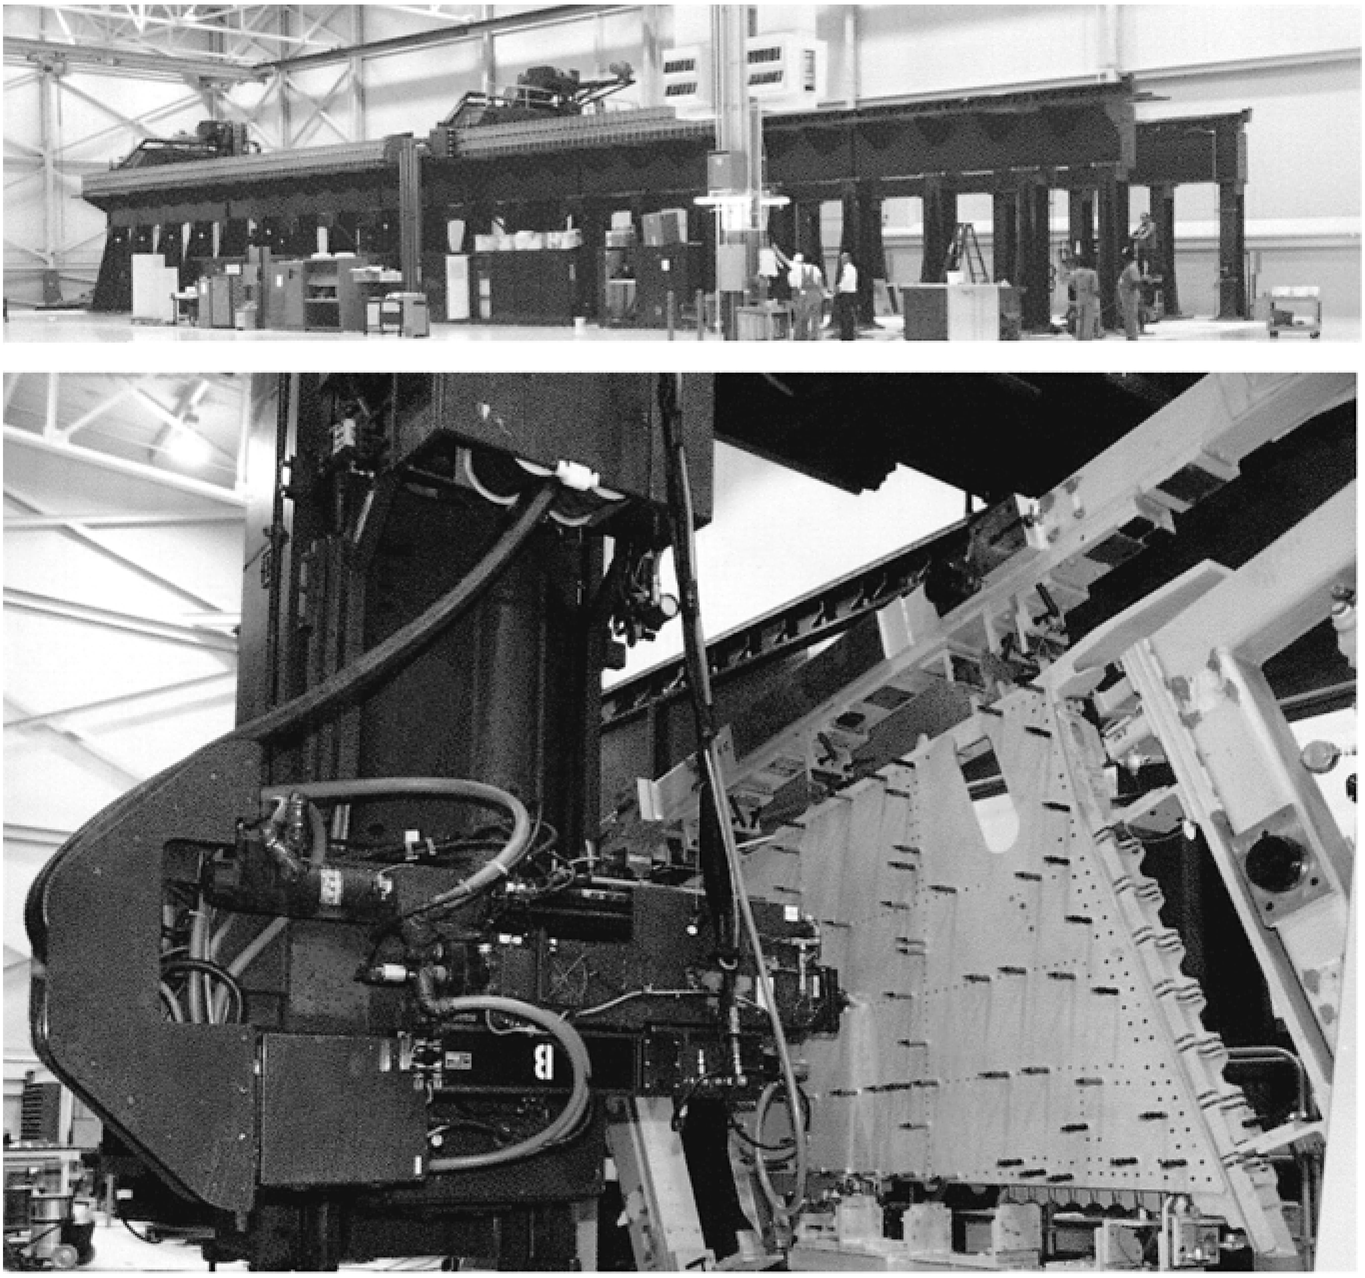

Fig. 9 Automated system for drilling holes and installing fasteners in wings

Cutting fluids are not normally used or recommended for drilling thin (less than 6.3 mm, or 0.25 in. thick) carbon/epoxy structure. The “dust” resulting from the drill process is broken fibers still encapsulated in resin so that they do not float freely in air. Industry practice has been to use a vacuum fixture or hose at the point of drilling and to use a vacuum to clean the structures after drilling. If cutting fluids are used, flood application is preferred to a light spray mist to avoid the dust from collecting or building up on the cutting tool, as this may result in an oversized hole.

Hole Drilling in Polymer-Matrix Composites

Michael J. Paleen and Jeffrey J. Kilwin, The Boeing Company, St. Louis

Reaming

When acceptable hole tolerances cannot be maintained from a hole-drilling process, a reaming operation is needed. As with drilling, carbide cutters are needed for holes through carbon/epoxy composite structure. In

addition, the exit end of the hole needs good support to prevent splintering and delaminations when the reamer removes more than about 0.13 mm (0.005 in.) on the diameter. The support can be the substructure or a board held firmly against the back surface. Typical reaming speeds are done at about one- half of the drilling speed. When the reamer removes about 0.13 mm (0.005 in.) or less on the diameter and surge control is used, the hole can be reamed without backup with little or no splintering or fiber breakout, especially if the composite parts have woven materials as outer layers or if there are bonded-on shims.

Hole Drilling in Polymer-Matrix Composites

Michael J. Paleen and Jeffrey J. Kilwin, The Boeing Company, St. Louis

Countersinking

Countersinking a composite structure is required when flush head fasteners are to be installed in the assembly. For metallic structures, a 100^{o} included angle shear or tension head fastener has been the typical approach. In composite structures, two types of fasteners are commonly used: a 100^{o} included angle tension head fastener or a 130^{o} included angle head fastener. The advantage of the 130^{o} head is that the fastener head can have about the same diameter as a tension head 100^{o} fastener with the head depth of a shear-type head 100^{o} fastener. For seating flush fasteners in composite parts, it is recommended that the countersink cutters be designed to produce a controlled radius between the hole and the countersink to accommodate the head- to-shank fillet radius on the fasteners. In addition, a chamfer operation or a washer may be required to provide proper clearance for protruding head fastener head-to-shank radii. Whichever head style is used, a matching countersink/ chamfer must be prepared in the composite structure.

There are three recommended choices of cutting tools for producing a countersink in carbon/ epoxy structure: standard carbide insert cutters, solid carbide cutters, or PCD insert cutters. For carbon/epoxy structure, the countersink cutters usually have straight flutes similar to those used on metals. For aramid fiber/epoxy composites, testing has shown that a countersink that incorporates S-shaped positive rake cutting flutes produces a fuzz-free countersink edge. If straight- fluted countersink cutters are used, a special thick tape can be applied to the surface to allow for a clean cutting of the Kevlar fibers, but this is not as effective as the S-shaped fluted cutters, as shown in Fig. 10. Use of piloted countersink cutters is recommended because it ensures better concentricity between the hole and the countersink with less chance of gaps under the fasteners due to misalignment or delaminations of the part. A combination drill/countersink cutter ensures a good fit; however, thus far these cutters have been successful only in automated equipment scenarios. Typical countersinking operations are done at about 500 to 1000 rpm (depending on countersink diameter—larger countersinks are done slower) with vacuum attachments to catch debris.

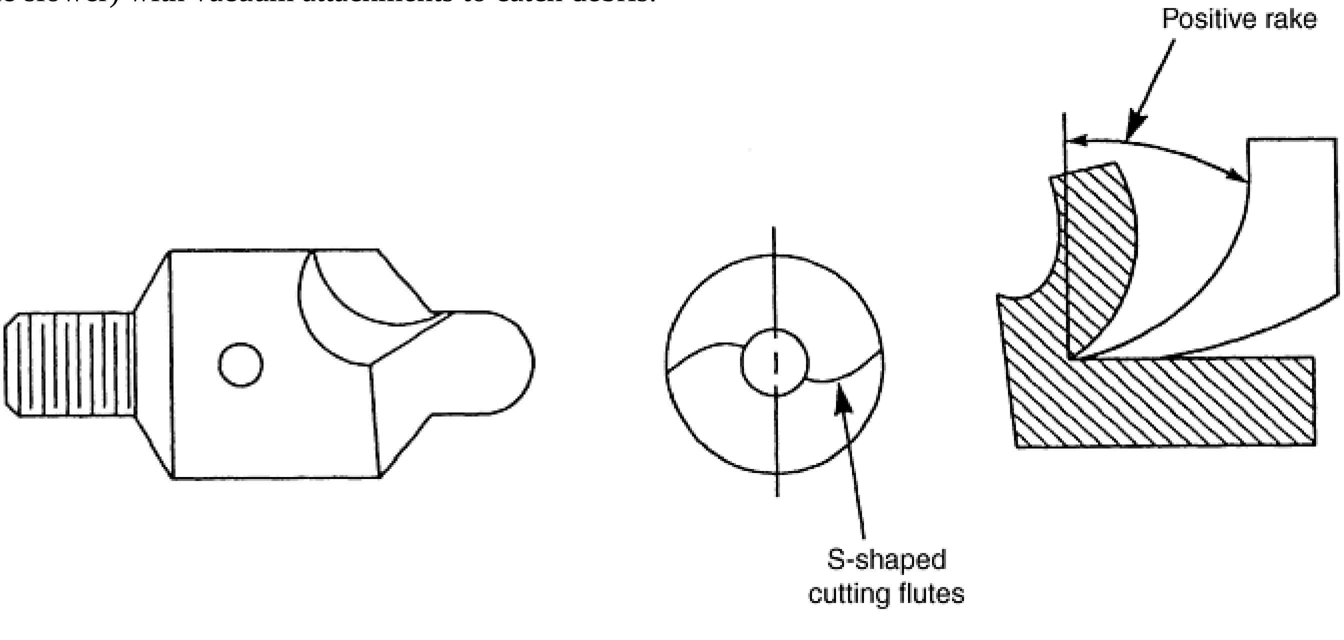

Fig. 10 Optimal countersink cutter for aramid fiber-reinforced composites

Depth control for countersinking can be obtained by inserting the countersink cutter in a microstop cage (Fig. 11) and adjusting accordingly. Proper countersink size can be measured using commercially available countersink diameter/depth gages, but only with a gage designed for the correct countersink included angle. A countersink gage designed for 100^{o} included angle countersinks cannot be used on 130^{o} included angle countersinks as incorrect readings will occur. Another inspection technique is to verify the countersink size with the same type of fastener specified for the hole fully clamped in the part and check the flushness. When a piloted countersink cutter is used, the pilot must be periodically checked for wear, as wear can cause reduction of concentricity between the hole and countersink. This is especially true for countersink cutters with only one cutting edge.

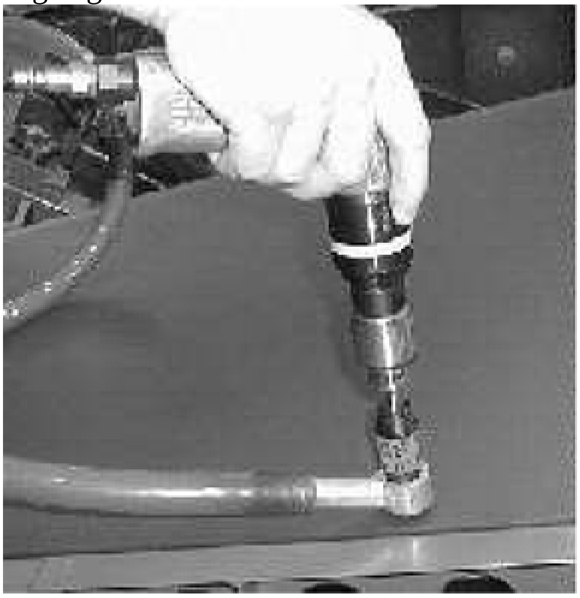

Fig. 11 Microstop cage for adjustable, controlled-depth countersinking

For piloted countersink cutters, position the pilot in the hole and bring the cutter to full rpm before beginning to feed the cutter into the hole and preparing the countersink. If the cutter is in contact with the composite before triggering the drill motor, splintering may result.

Hole Drilling in Polymer-Matrix Composites

---

Hole Quality

The quality of the drilled hole is critical; therefore, each hole should be visually inspected to ensure correct hole size and location and proper normality, as well as the absence of unacceptable splintering or fiber breakout, fiber pullout, delaminations, back counterboring, evidence of heat damage, and microcracking.

Delamination, separation of bonded composite plies, may occur at the drill entrance due to too fast of a feed rate for the speed, or at the drill exit due to too much feed force on unsupported materials. Splintering or fiber breakout conditions, fibers that break free from the surrounding resin matrix, may occur at the drill entrance or exit, especially in unidirectional material (Fig. 4). Fiber/resin pullout is a tear or breaking out of fibers and/or resin within a hole or machined edge. Microcracking is the creation of small cracks in the resin surrounding the fibers. Visual discoloration or partial melting of material surrounding a hole (usually worst on the drill exit side) is an indication of heat damage.

The required hole quality for the product must be defined to ensure the product will meet structural requirements and desired cosmetic requirements. Following is a general rule for acceptance of anomalies.

Defects smaller than a defined size (for example, 0.76 mm, or 0.03 in.) are acceptable "as- is." Defects a little larger but within a specified range (for example, 0.76–2.54 mm, or 0.03–0.10 in.) are rejectable but are automatically repaired, while those greater than the rejectable limit (for example, 2.54 mm, or 0.10 in.) are submitted to Engineering for determination if a repair (such as oversize fastener or filling of the defect) is an option or if part scrapage is required. The size limits may be dependent on location, structural loads, and cosmetics. If repairs are required for structural or cosmetic reasons, care must be taken to make good quality repairs. If repair materials are not carefully applied, the repaired part may be weaker than the damaged part. An example of such a condition is if the repair causes a buildup on one side of a fastener and thus a bad fit. The bad fit can produce bending loads in the fastener and highly concentrated bearing loads in the composite.

In addition to visual checks, the normal inspection methods and techniques for meeting dimensional requirements of the hole and countersink should be used.

Mechanical Fastener Selection

Robert T. Parker, Boeing Commercial Airplane Company

Introduction

FASTENER REQUIREMENTS for joining fiber reinforced composite structures differ from those for joining metallic structures. Fastener selection considerations for joining composites include corrosion compatibility, fastener materials, strength, stiffness, head configurations, importance of clamp-up, hole fit, and lightning protection.

When fiber reinforced composite materials began to be used in aerospace and aircraft structures, the inadequacy of conventional fasteners became apparent. Alloy steel was not compatible, cadmium plating quickly corroded away, reduced shear head fasteners pulled through during installation, and rivets crushed the composite or expanded in the hole and caused delamination of the laminated plies. A new set of requirements had to be established to determine which characteristics were optimal and which were detrimental. This article focuses mainly on carbon fiber composites; however, many of the principles discussed apply to aramid and glass fiber composites also. Corrosion compatibility would be less of a problem with noncarbon fibers, but then lightning-strike behavior may be more of a concern.

Additional information about general fastener selection criteria can be found in the article "Mechanical Testing of Threaded Fasteners and Bolted Joints" in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook.*

Corrosion Compatibility

Neither fiberglass nor aramid fiber reinforced composites cause corrosion problems when used with most fastener materials. Composites reinforced with carbon fibers, however, are quite cathodic when used with materials such as aluminum or cadmium, the latter of which is a common plating used on fasteners for corrosion protection.

Titanium and its alloys appear to be the fastener materials most compatible with carbon fibers. Fortunately, titanium alloys have the most desirable strength/weight ratio. Austenitic stainless steels, superalloys such as A286, multiphase alloys such as MP35N or MP159, and nickel alloys such as alloy 718 also appear to be very compatible with carbon fiber composites. Pitting corrosion has been seen in A286 under certain conditions. Copper-bearing alloys such as copper-nickel or Monel have a tendency to generate heavy corrosion products, although damage or loss of strength appears to be minimal.

Mechanical Fastener Selection

Robert T. Parker, Boeing Commercial Airplane Company

Fastener Materials and Strength Considerations

Titanium alloy Ti-6Al-4V is the most common alloy for fasteners used with carbon fiber reinforced composite structures. Ultimate tensile and shear strengths for Ti-6Al-4V are 1100 and 660 MPa (160 and 95 ksi), respectively. Ti-3Al- 2.5V and commercially pure titanium are used for some components of fastening systems. When higher strength is required, materials such as A286 or alloy 718 that have been strengthened by cold working can be used. Cold worked A286 fasteners can be obtained with an ultimate tensile strength of 1400 MPa (200 ksi) and an ultimate shear strength of 760 (110 ksi). The respective values for alloy 718 (cold worked) are 1515 and 860 MPa (220 and 125 ksi). Multiphase alloys can be obtained with a tensile strength up to 1800 MPa (260 ksi). In the past, multiphase alloys were only used as blind fastener stems or corebolts where ultra-high strength was required for the fastener to function. Today, multiphase bolts are being considered to replace alloy 718 where loads are increasing due to growth of some aircraft models. However, in composite structure, it takes a very thick structure to warrant the high shear strength (F_{su}= 910 to 1000 MPa, or 132 to 145 ksi) of multiphase alloys.

Mechanical Fastener Selection

Robert T. Parker, Boeing Commercial Airplane Company

Bolt Bending

Bolt bending is a much more serious issue in composite structure than in metal structure. Due to the increased interlaminar shear between the composite plies (similar to playing cards in a deck sliding past each other during bending), bending of the bolt occurs more easily. High- modulus and high-tensile-strength fastener material is desired where bending may occur. Stress-strain curve shape factor also plays a role. An example of a plastic

bending curve is shown in Fig. 1 for alloy 718 cold reduced to tensile strength of 1515 MPa (220 ksi). Susceptibility of bolt bending in composite structure introduces higher reaction loads on the fastener head; this requires more careful consideration of head configuration.

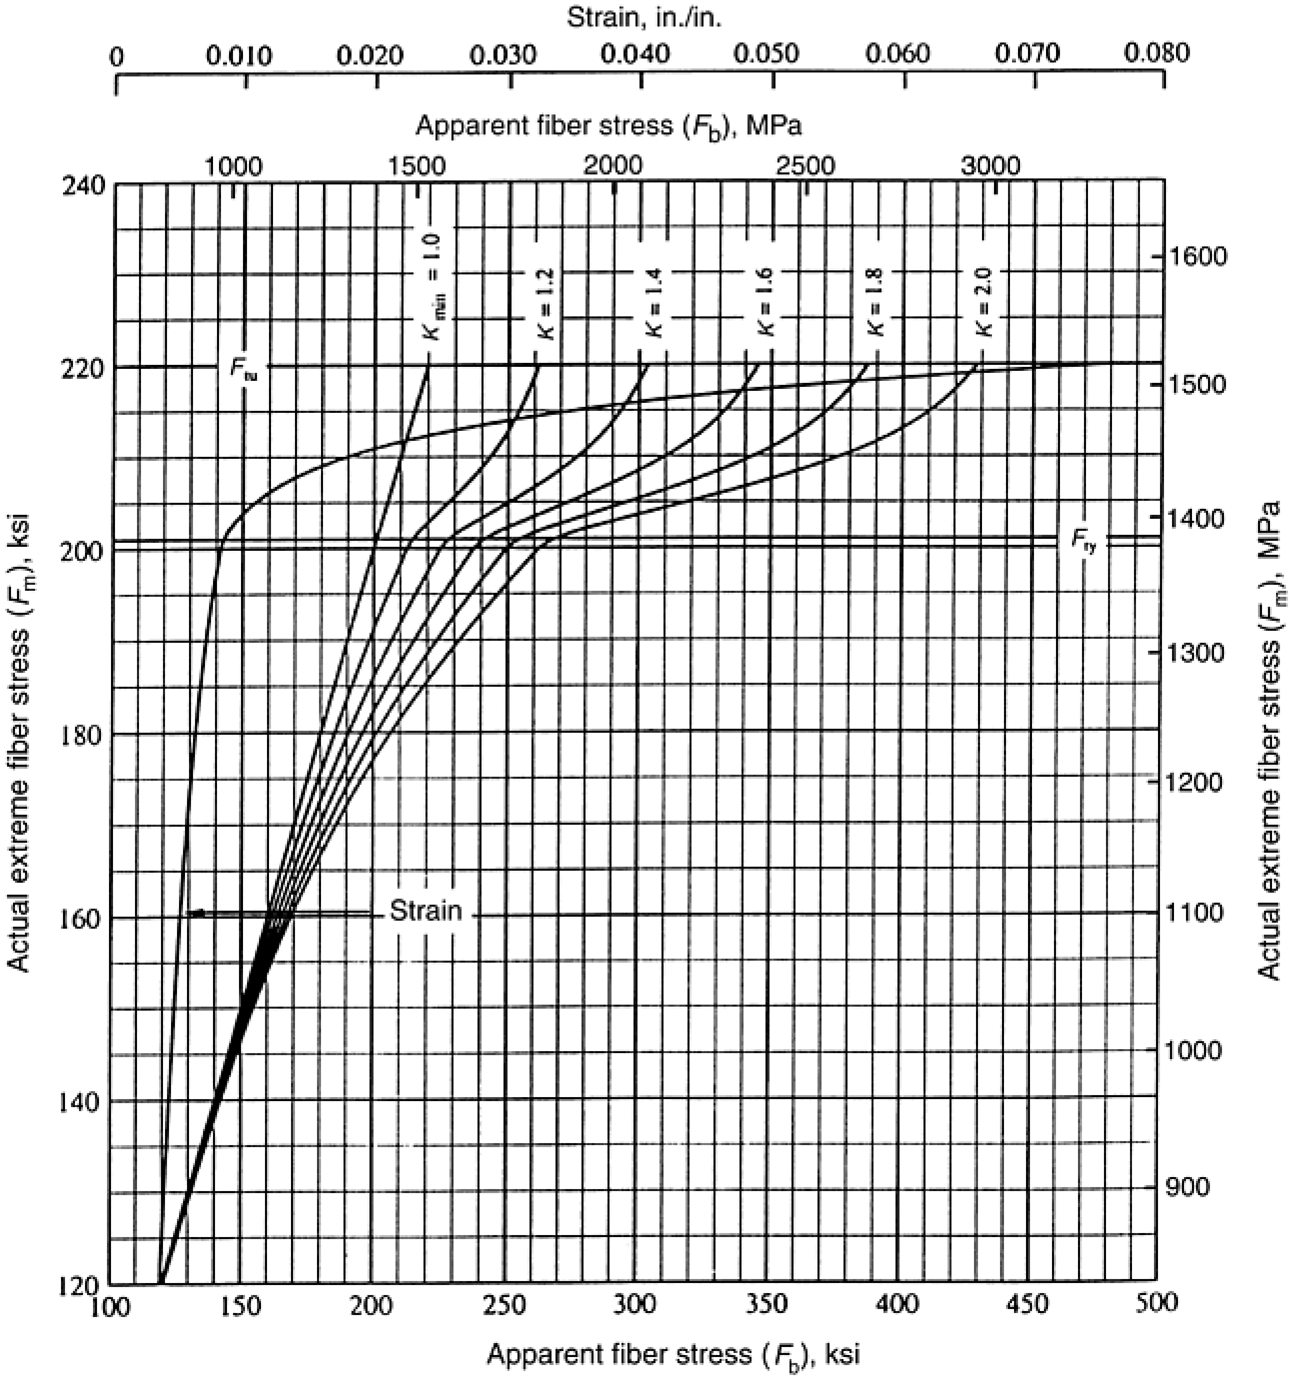

Fig. 1 Example of plastic bending curves for nickel alloy 718. F_{tu}, ultimate tensile strength; F_{ty}, yield strength.

Bending must also be considered in multiple- component fasteners such as blind fasteners. A threaded core bolt resists bending much better than a smooth bore pull-type blind fastener (Fig. 2); however, where fatigue loads may be present, the notches from the threads may influence the joint life. The threaded core bolt is usually capable of higher clamping forces (good for fatigue), but if eccentricity in the joint exists, the bending of the threads may still be undesirable. The designer must consider all of these variables, and then testing is required to evaluate the performance of the selected fasteners versus the design requirements.

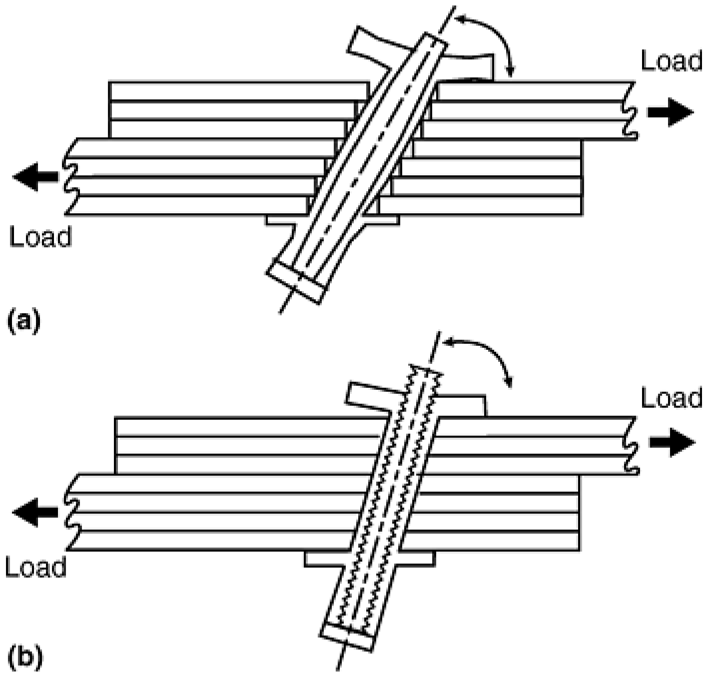

Fig. 2 Blind fastener bolt bending and deflection. (a) Smooth bore allows little resistance to bolt bending in multiple piece fasteners such as blind fasteners. The multiple pieces act as axial laminates and slide over each other. (b) The effect of the threads on the corebolt "lock" the corebolt to the other components and improve stiffness of the joint. However, the notches (threads) can be detrimental in fatigue if the loads are high enough to cause significant deflections.

Mechanical Fastener Selection

Robert T. Parker, Boeing Commercial Airplane Company

Head Configuration Selection

Many fastener head styles exist in industry today: 100° reduced shear, 100° tension, AN 509, low-profile protruding, 12-point fatigue rated, and so forth. Because of their viscoelastic matrix resin properties, carbon fiber reinforced composites are more sensitive to high bearing loads than are metals. This means fastener heads (as well as nuts and collars) should be designed with as much bearing surface area as practicable.

The 130° reduced-height shear head originated during development of a suitable blind fastener specifically designed for composite structures and introduced to the industry in 1980 (Ref 1). By examining a single-fastener lap shear joint specimen loaded in uniaxial tension (Fig. 3), it can be seen that as the load is transferred through the fastener, an eccentricity begins to develop, and fastener tipping, or "cocking," occurs. This specimen was used to optimize flush head configurations and measure the contribution of the fastener to the stability of the specimen by delaying cocking and eventual pull-through. Figure 4 shows the reaction loads on the head. Assuming that the specimen loads act through the centroids of the fastener, and taking moments about *A*, it can be shown that very little change is noted by changing the angle of the head; the big difference is in the area of bearing that supports the reaction load. From this analysis, the 130° flush head was developed. The maximum area for a reduced-height shear head was obtained by using the tension head outer diameter; this resulted in 130°, as shown in Fig. 5. As the distance between the centroids becomes greater, however, the reaction loads go up in value, as demonstrated in Fig. 6. Therefore, the 130° is limited to thin laminates as shown in Fig. 7 where a standard shear head would cause a knife-edge condition, and the 100° reduced-height shear head would pull through more easily. As the laminate gets thicker by design, the standard shear head can

be considered (up to 70% of the laminate thickness). It is best to use the tension head where possible (laminate thickness permitting) since that head will do best in bolt bending or pull-through. The smaller heads (lower head height) should only be used to accommodate thin laminates and prevent a knife-edge condition.

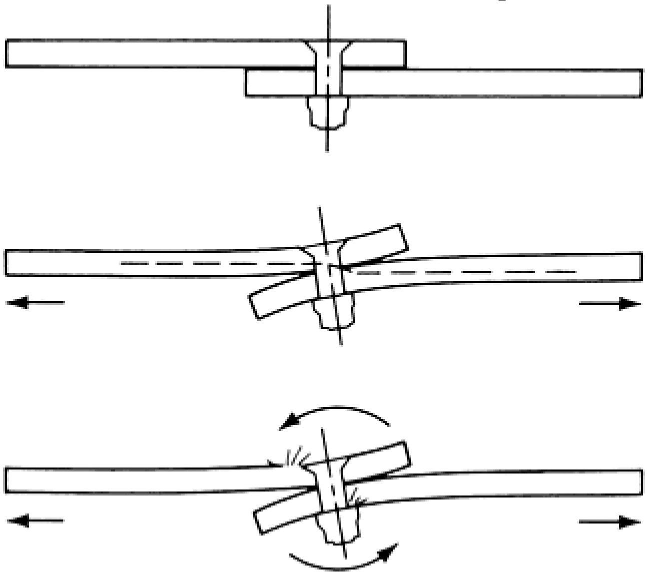

Fig. 3 Single fastener lap shear specimen in uniaxial tension

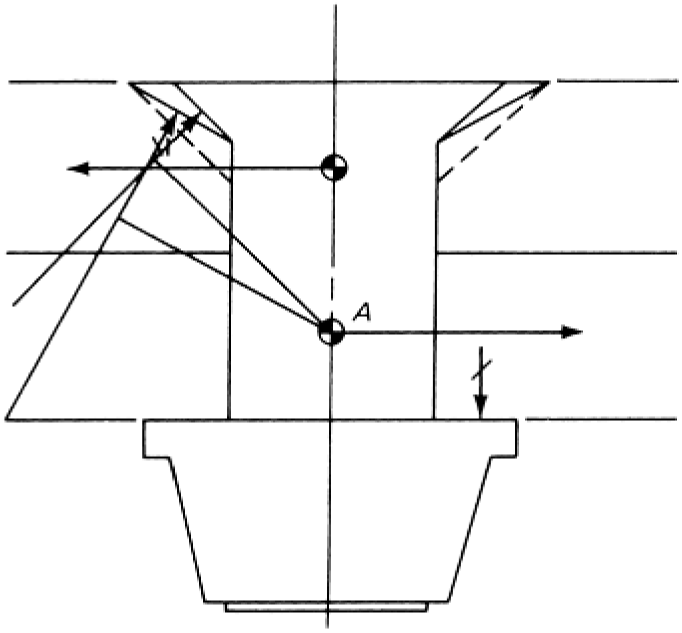

Fig. 4 Reaction loads of a flush head fastener in uniaxial tension

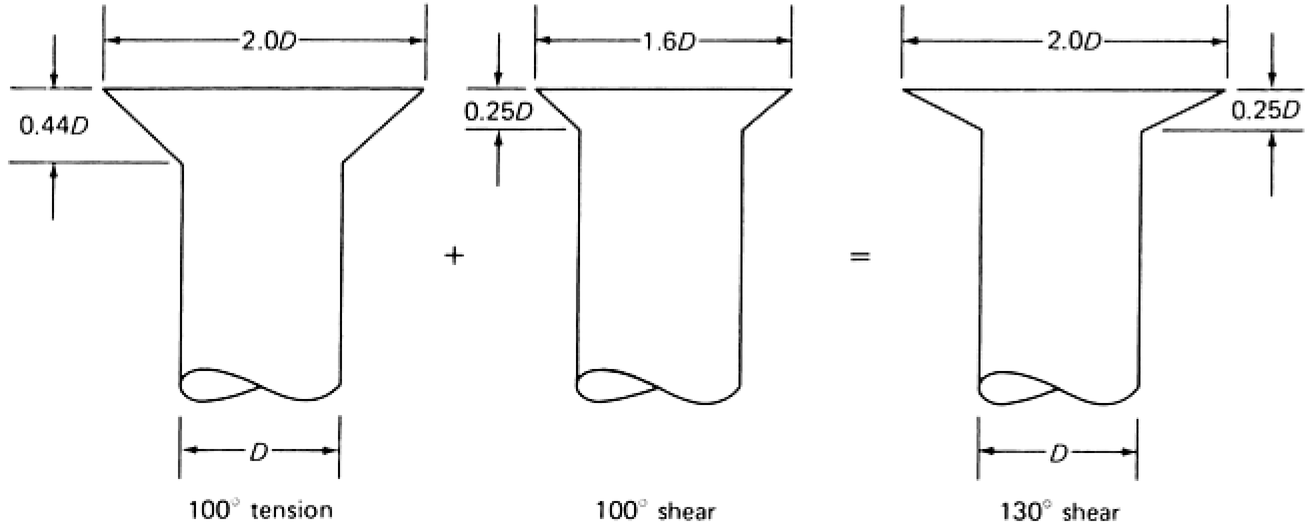

Fig. 5 Development of 130° head for shear

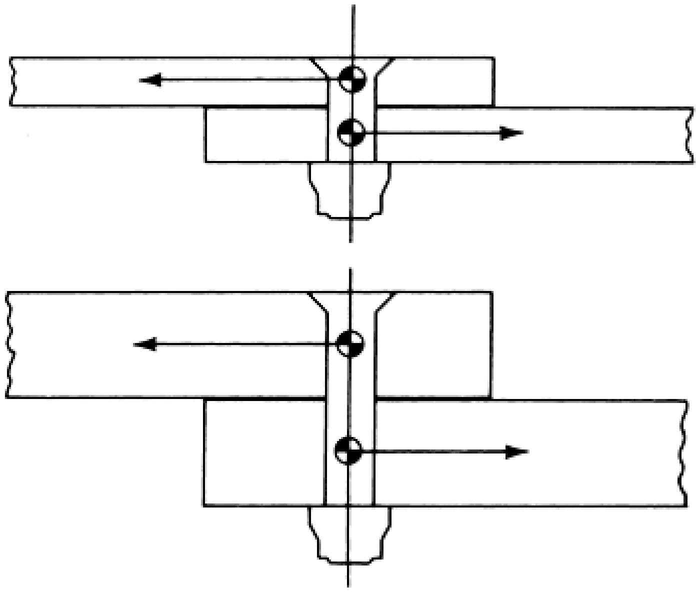

Fig. 6 Load distribution in fasteners joining thin and thick laminates

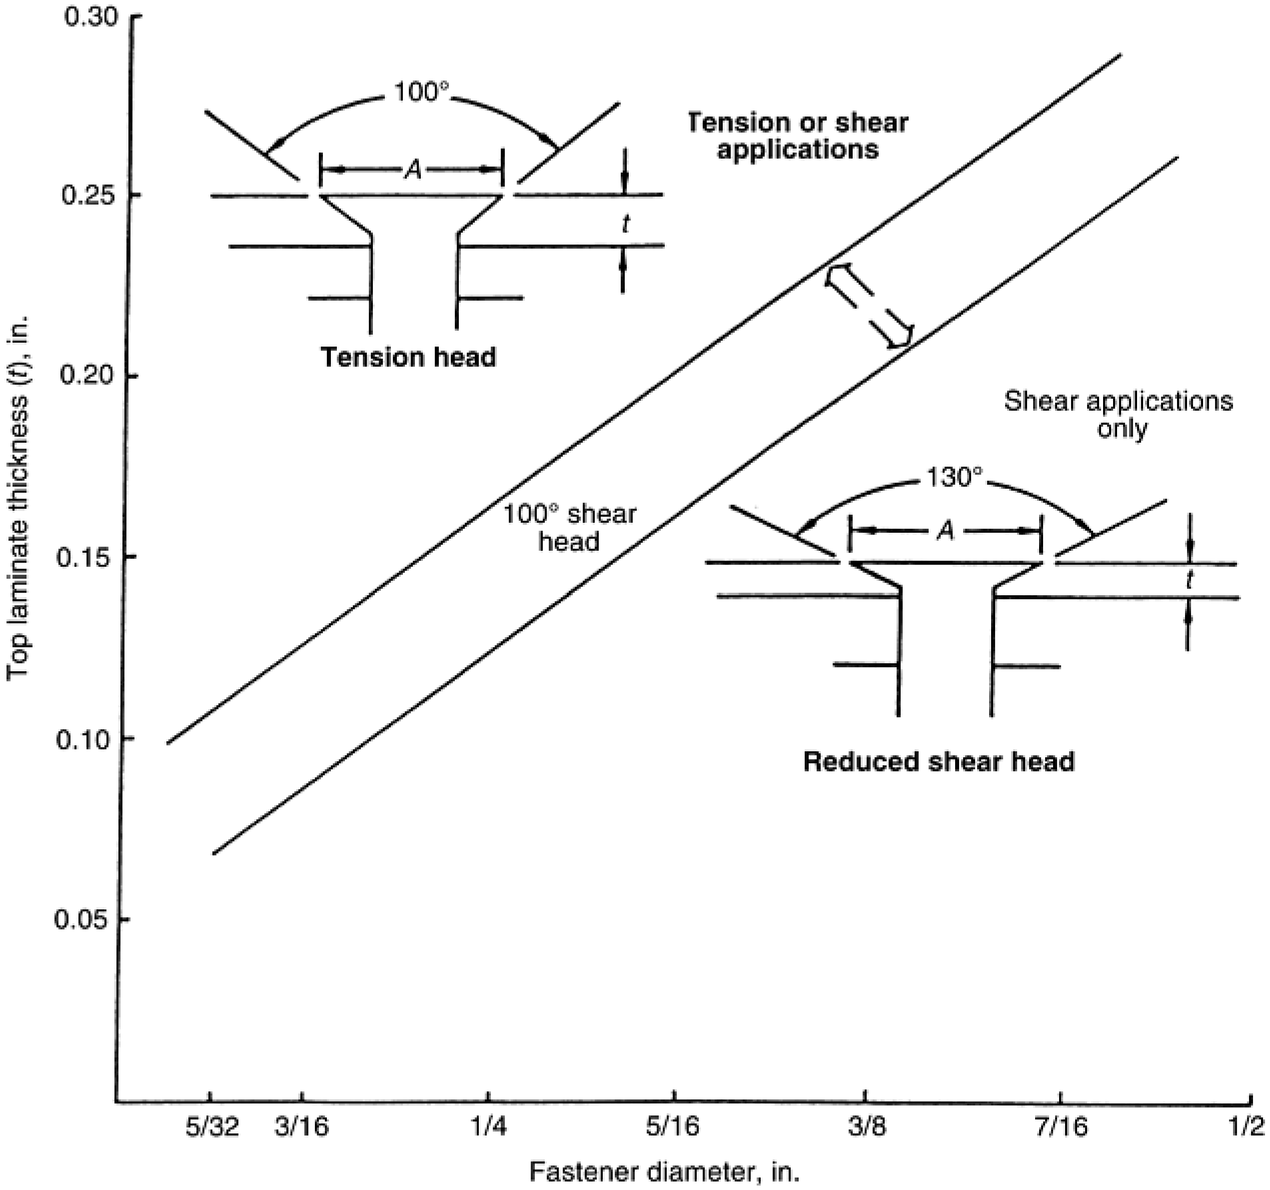

Fig. 7 Flush head applications for composite structures. The fastener head height should not exceed 70% of *t*, where *t* is the top sheet thickness. Head diameter, *A*, is the same for 100° tension and 130° reduced shear fasteners. Head diameter is 0.88 to 0.93*A* for 100° shear head fasteners.

Several protruding head configurations are available, but are not as sensitive as flush heads in joint performance. Cole (Ref 2) used different testing and analyses, including fatigue, and arrived at essentially the same conclusions.

Clamp-Up

When clearance fit holes are used, high clamp- up appears to be beneficial for joint strength and fatigue life. The clamping forces, however, must be spread out over a sufficient area so that the compressive strength of the resin system is not exceeded and the composite crushed. The role played by high clamp-up produces friction load transfer and delays cocking of the fastener in a loaded joint, which in turn may reduce ratcheting during cyclic loading. An improvement in fatigue performance has been shown from high clamp-up. Pratt (Ref 3) also found that high fastener preload, as well as large head bearing areas, were key factors influencing high lap shear joint strengths in composite structures. Phillips (Ref 4) found that load transfer fatigue testing with carbon fiber composites shows that gross load and stress concentration factors (K_t) at holes are not as critical. What is critical is bearing stress, because most failures are bearing-type failures caused by the fastener cocking under load and producing a high localized bearing stress. High clamp-up also delays slippage of the composite plies, which contributes to the high concentration of bearing stresses, as illustrated in Fig. 8. On the downside, continuous high clamp-up cannot be assumed or guaranteed over long periods of time. The time-dependent nature of composites can result in significant clamp-up relaxation during typical service lifetimes. Often, design data must be generated to account for this, by testing joints with fasteners installed at typically 50% of normal installation torque (Ref 5).

Chamfering of Holes

Whether or not chamfering should be required for composite structures to accommodate the head-to-shank fillet radius of protruding head fasteners has been debated. This author has seen data that show no obvious detrimental effects and an actual slight increase in lap joint strength with a measurable higher yield by not chamfering. In theory, the deformation of the material under the fillet radius of the fastener compresses the composite down into the hole-clearance, making a tighter fit and reducing fastener cocking. A comparison is shown in Fig. 9. Another theory is that the compression and bending of the fibers at the entrance of the hole “softens” the composite, reducing the theoretical stress concentration factor (K_t) and letting the composite behave in a less brittle manner. Part of the debate is “damage is damage,” and water or other contaminants can migrate in. On the other hand, chamfering causes a loss of bearing area. Nonchamfering should be limited to shear-type protruding head fasteners. Tension and fatigue rated protruding head type fasteners, with a large head-to-shank radius, still require a chamfered washer under the head.

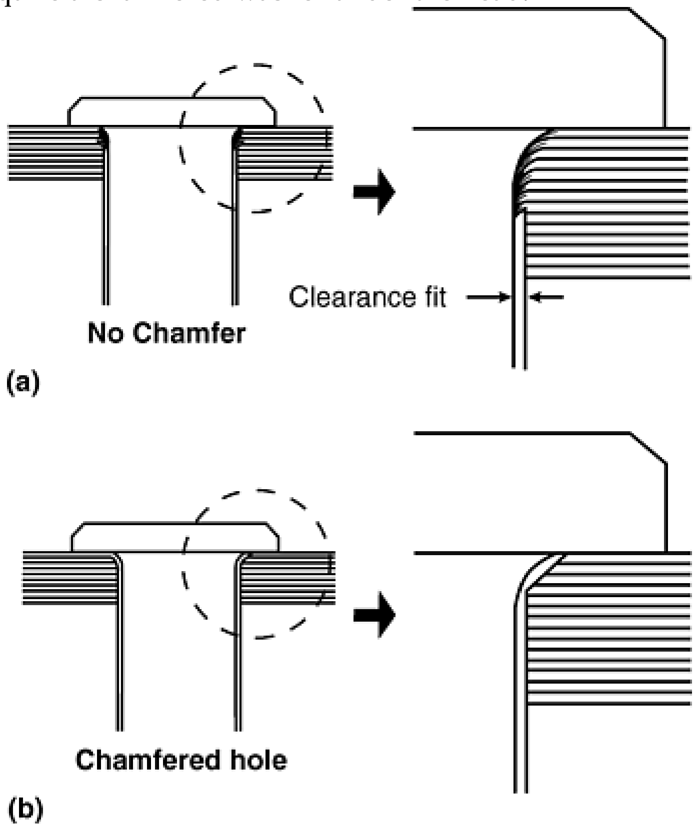

Fig. 9 Effect of chamfering holes. (a) Without chamfer, the composite material is compressed (displaced by fastener radius) and forced into hole clearance giving the effect of a net fit at the top of the hole. (b) Loss of composite material (chamfer) reduces bearing area and allows fastener to slip back and forth in clearance hole.

Interference Fit Fasteners

Another method of delaying cocking of the fastener under joint loading is to support the fastener for its full length. A net fit would be ideal, although impractical. Fastener manufacturers, working together with airframe companies, have developed methods of accomplishing an interference fit without detriment to joint performance. However, its advantages must be evaluated with regard to added cost and weight. In aluminum structures, bolts are frequently installed in "transition" fits, where, because of tolerance overlap, the bolt may be larger than the hole some percentage of the time. The bolts are pressed in or driven in with a rivet gun, with interference fits up to 0.0760 mm (0.003 in.). Not only does this interference fit in aluminum structures lock up the structure, but the hoop tensile stresses generated reduce the amplitude of the cyclic stresses next to the hole and improve the fatigue life of the joint.

With composite structures, however, driving the same bolt into interference causes high shearing forces on the reinforcing fibers and bends them down, breaking the matrix resin, as illustrated in Fig. 10(a) and (b). Work by Shoe (Ref 6) showed damage at as little as 0.01780 mm (0.0007 in.) of interference by this method. Because composite fibers will accommodate much more compression, a controlled expansion of a sleeve that remains statically in contact with the fibers (as shown in Fig. 10c and d) can produce interference up to 0.1525 mm (0.006 in.). This method was tested on major prototype hardware with excellent results. Unlike aluminum structures, however, composite structures gain no benefit from the greater interference. All that is desired is a "net" fit. The interference is used to absorb the tolerances on the hole and the fastener. Therefore, the interference limit need only be the total accumulation of tolerances to always ensure, at least a net fit, as a minimum.

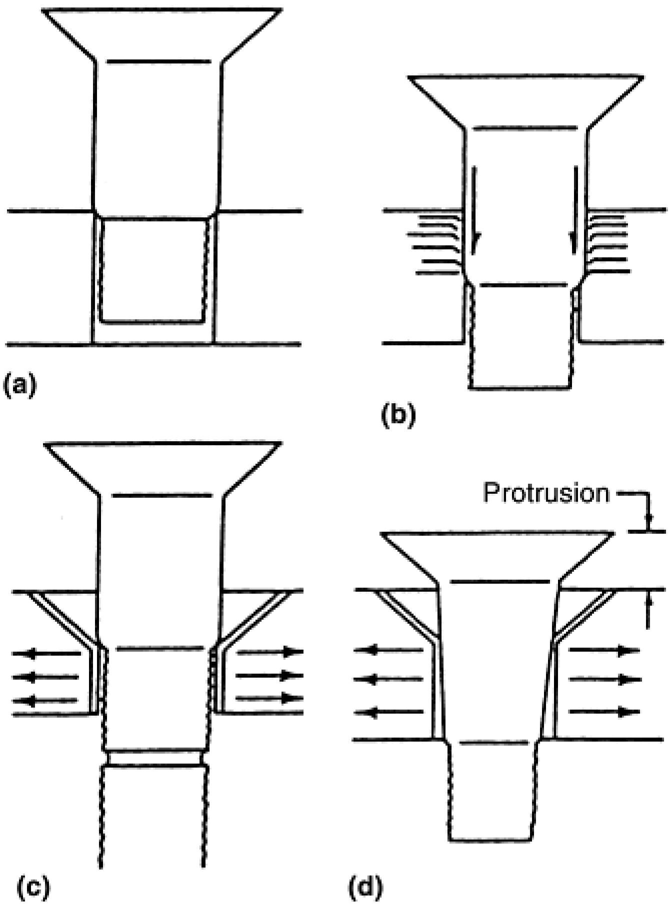

Fig. 10 Interference fit. See text for discussion.

The major advantages of the net/interference fit are lower joint deflection, equal fastener load sharing, reduction of relative fastener flexibility that causes localized high bearing stresses, and reduction or delay of hole growth/degradation (which can become excessive). An additional advantage is lightning-strike protection, which is a design consideration that is covered in the next section of this article. This author believes that major composite structures, such as a wing or large stabilizer, should have a certain percentage of sleeve-type interference fit fasteners to lock up the structure. Fasteners with all clearance holes can ratchet to one side when

the structure is loaded, causing severe permanent deformations. Sleeve-type fasteners (interference fit) could be strategically located to aid in electrical continuity or lightning-strike protection.

Several sleeve-type fasteners are available that are either intended for composite structure or adaptable with hole-size adjustment. Figure 11 shows a Lockbolt (Huck International, Inc.) fastener incorporating a sleeve. The pintail is much longer (function of grip length) since the whole grip protrudes out of the sleeve before installation. The assembly drops into the hole; as the Lockbolt is pulled into the sleeve, the sleeve expands radially a controlled amount to generate the interference. This same principle is incorporated into a threaded-corebolt blind fastener, the Radial-Lok (Monogram Aerospace Fasteners Inc.). With this fastener, the formation of the backside components pull the fastener body into the sleeve, expanding the sleeve and generating interference. Figure 12 shows the installation sequence. Another permanent fastener that has been used in interference in composite structure is the SLEEVbolt (Paul R. Briles Corp.). This fastener consists of a tapered shank bolt in an internally tapered sleeve that is cylindrical on the outside. The 48-to-1 internal taper keeps the bolt travel short during installation. Sufficient exposed threads are engaged with a nut, and the bolt is essentially “jacked” into place. Figure 13 shows two head styles available. Although this bolt was designed for metal structure, it can easily be adapted to composite structure by enlarging the hole and reducing the resultant interference by about 50%. Radial expansion in composites should not exceed about 0.15 mm (0.006 in.) on the diameter.

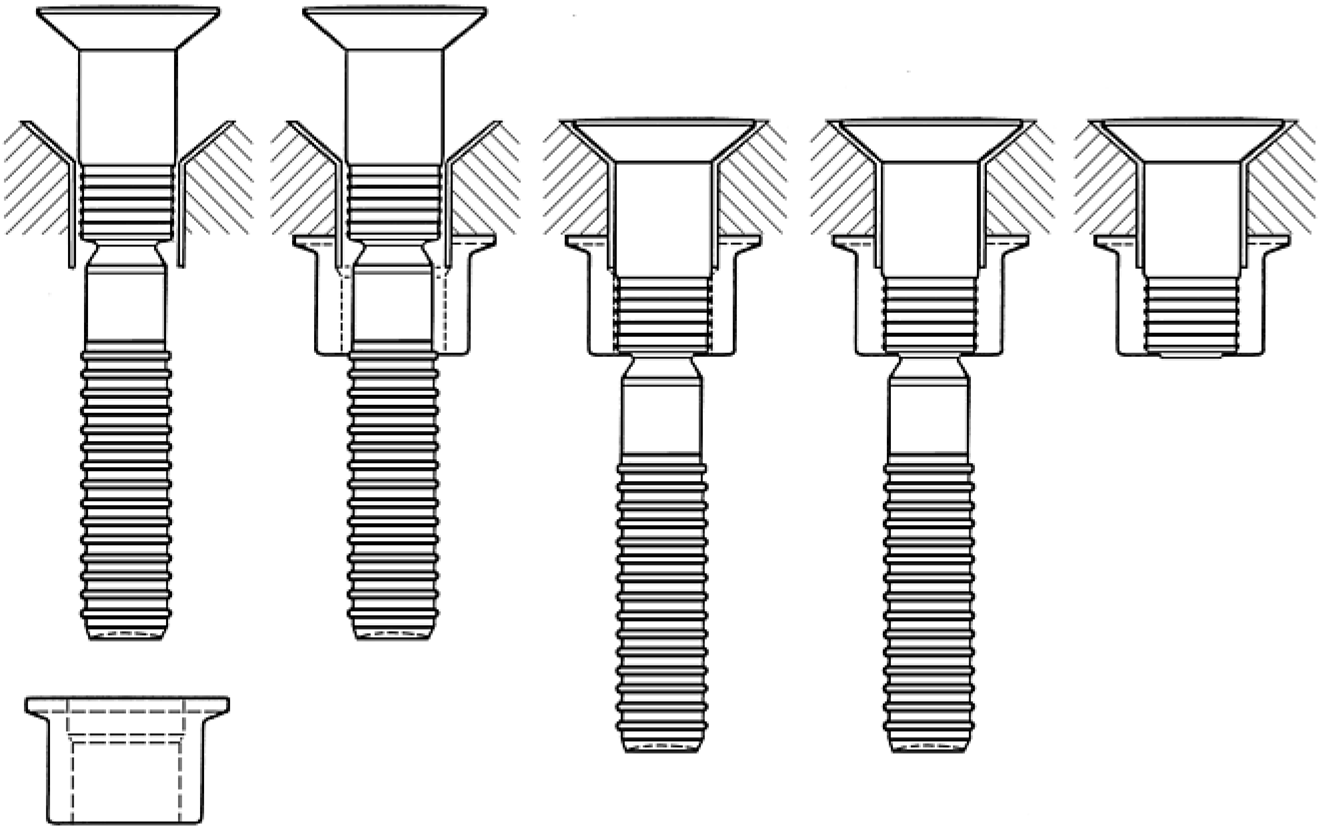

Fig. 11 Sleeve-type Lockbolt installation sequence

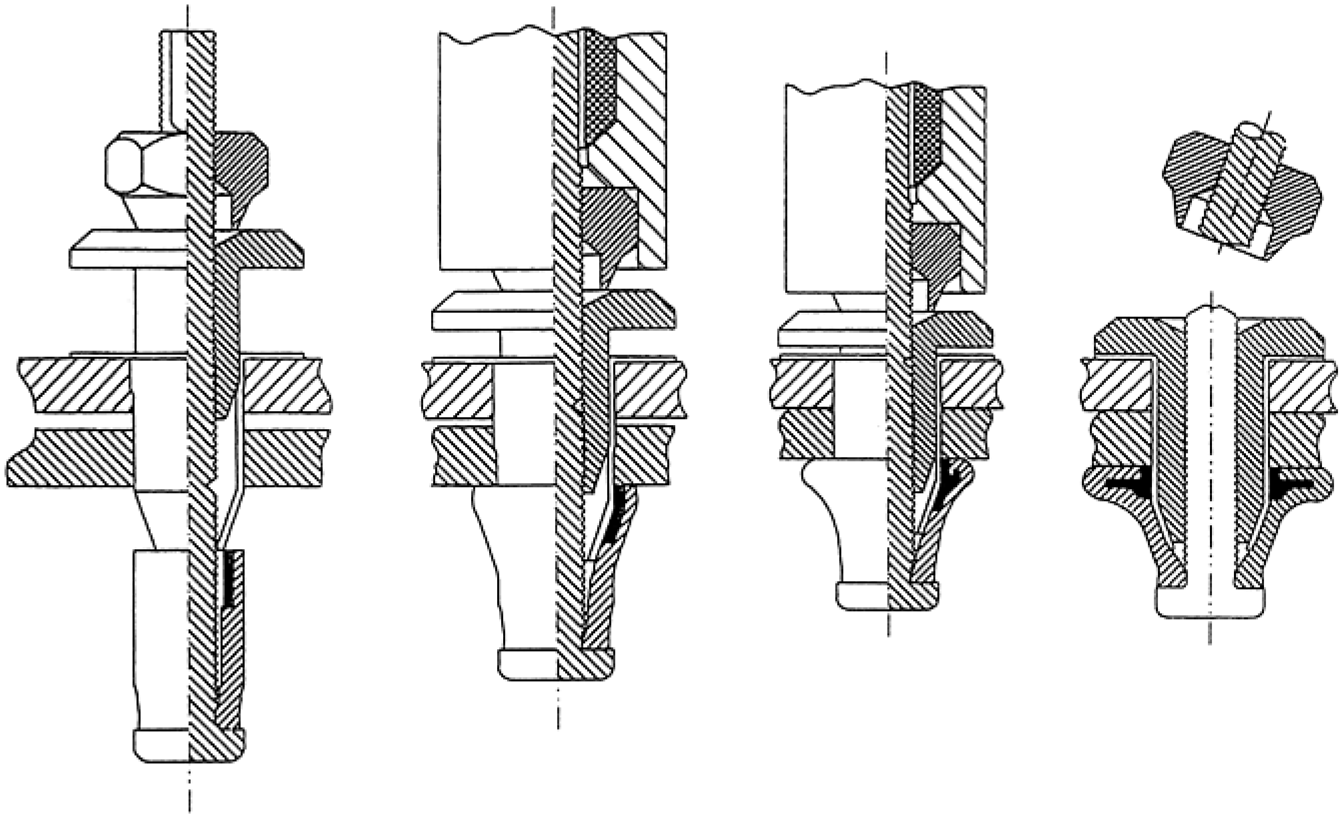

Fig. 12 Radial-Lok sleeve-type blind fastener installation sequence

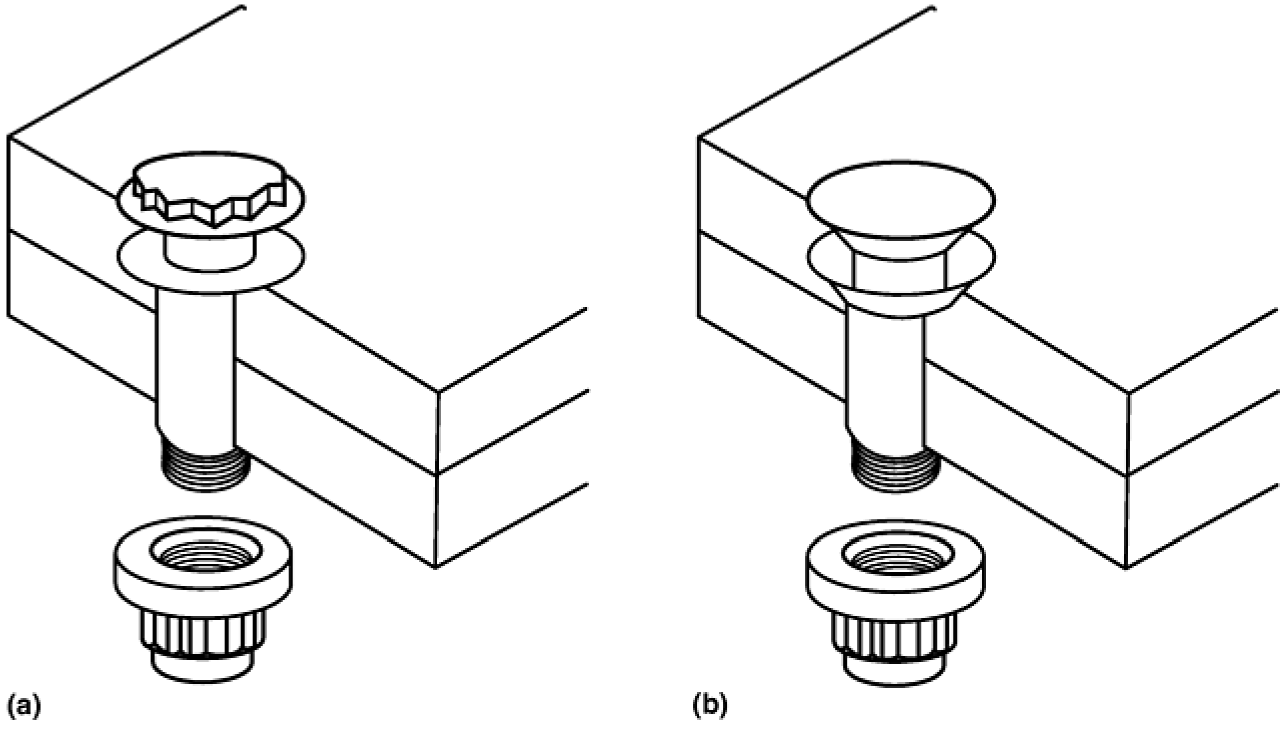

Fig. 13 Typical head styles of the SLEEVbolt fastener. (a) 12-point protruding head. (b) Flush head

When interference fit fasteners are required in mixed stack-up structure (composite laminate and metal sheet or plate), the structure is usually disassembled and the holes enlarged in the composite to prevent interference in that portion of the stack-up. Interference fit sleeves can solve this problem. The higher cost of the fastener can be offset by preventing disassembly, enlarging holes, and reassembly. However, caution needs to be exercised in eccentrically loaded joints of mixed stack-ups (thick composite skin with thick metal fitting) when using sleeved fasteners. Due to the low interlaminar shear modulus of laminate composite and the fixity of the metal fitting under cyclic eccentric loading, a concentration of bending occurs at the interface. Under cyclic loading,

localized strain hardening of the sleeve at the joint interface occurs, eventually leading to cracking of the sleeve at the interface (Fig. 14).

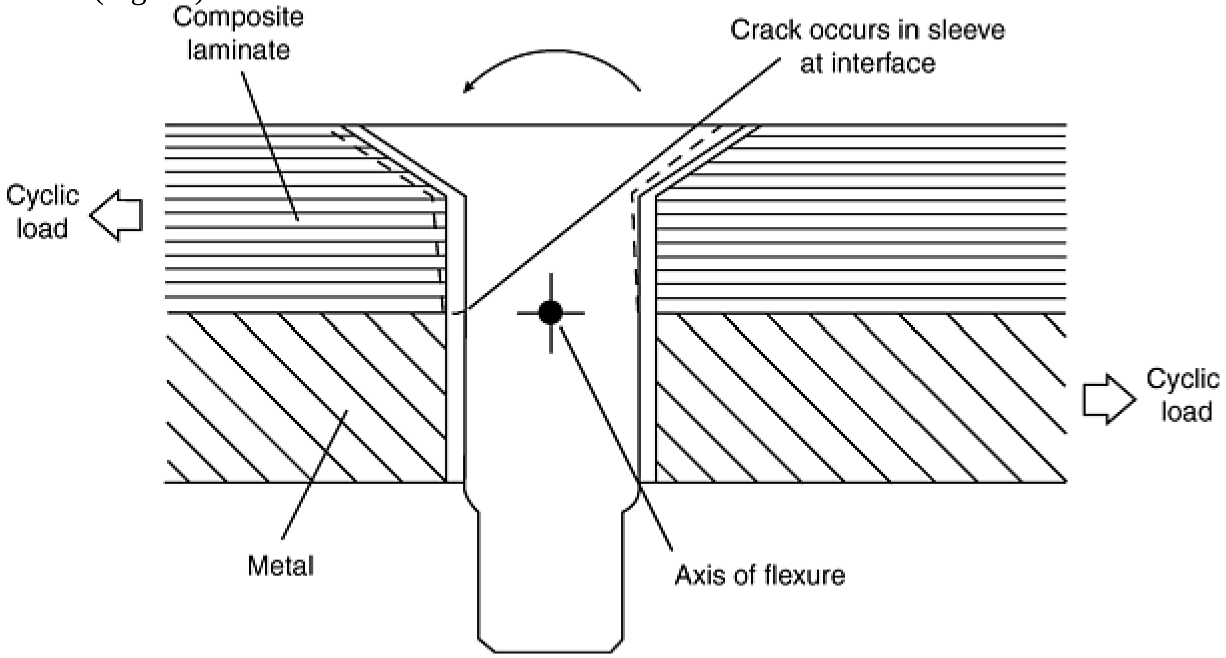

Fig. 14 Strain hardening of sleeved fastener in stack-up of mixed modulus materials, resulting in cracking under cyclic loading

Lightning-Strike Protection

An aluminum airplane is quite conductive and is able to dissipate the high currents resulting from a lightning strike. A carbon fiber reinforced composite airplane would act like an anisotropic conductor, that is, not as conductive in all directions. Also, carbon fibers are 1000 times more resistive than aluminum to current flow, and epoxy resin is 1 million times more resistive (i.e., perpendicular to the skin). If the lightning strike attaches to a fastener, the current must be dissipated through the fibers perpendicular to the hole. If the fastener is not in intimate contact with the sides of the hole (clearance fit), the instantaneous heat energy ionizes the air in the gap and creates an arc plasma that blows out, severely damaging the structure. Intimate contact of a bare fastener (and/or sleeve) is the best combination found to date for electrical current dissipation. “Hiding” the fastener from the lightning may also be a solution. A swept-stroke lightning strike (defined as a zone 2 strike) attaching to a fastener head can produce currents as high as 100,000 A. This current is conducted for a very short period of time (approximately 0.05 seconds maximum dwell time), but then it must be dissipated in that short time to minimize damage. Brick (Ref 7) has developed a fastener area-current relationship to predict whether a fastener has a large enough countersink and diameter to dissipate lightning-strike currents without arc plasma blowby. Although Ref 7 was directed more toward fuel environment, the method can also be used to minimize damage to the composite from lightning strike. Investigators Brick and Gosinsky (Ref 8) have determined that large

countersinks (tension heads) with high clamping forces or an interference fit are important factors in the choice of fasteners in a potential lightning-strike area.

Fasteners with corrosion-protection coatings, such as NAS 4006 aluminum-phenolic coating or equivalent, are not recommended in potential lightning-strike areas. Figure 15(a) shows a fastener with a corrosion-protection finish that has been artificially struck with approximately 100,000 A of current. Because the protective finish was an insulator, the current avoided the fastener and attempted to dissipate into the top fibers of the composite with a high-concentration gradient. The composite was heavily damaged several plies deep. In Fig. 15(b), a bare fastener that was struck with identical current intensity shows more damage to the fastener, but almost no damage to the composite plies. It is much easier to replace the fastener than to repair the composite. The grid pattern shown in Fig. 15(a) and (b) is a copper mesh overlay used to help dissipate the current on the surface. A bare finish is preferred on the fastener for maximum conductivity; however, depending on the fastener material, a phosphate fluoride or a passivated finish appears to be acceptable and is usually required for paint adhesion or electrical ground return.

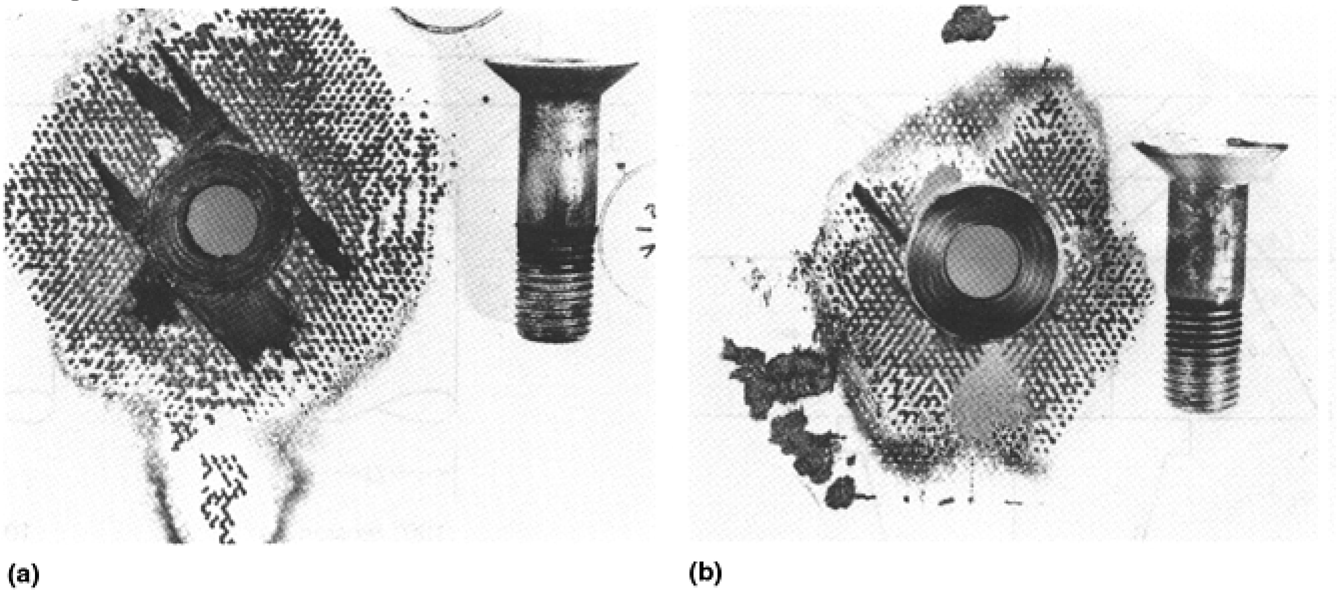

Fig. 15 Effect of corrosion-protection coatings on the lightning-strike resistance of fasteners for composites. (a) Fastener with corrosion protection finish, struck by 100,000 A. Heavy damage to composite. (b) Bare fastener struck by 100,000 A. No damage to composite

Mechanical Fastener Selection

Robert T. Parker, Boeing Commercial Airplane Company

Hi-Lok and Lockbolt Fasteners

Most composite structures for the aircraft industry are fastened with Hi-Loks (Hi-Shear Corp.) or Lockbolts (Huck International, Inc.), for permanent installations. The Hi-Lok is a threaded fastener that incorporates a hex key in the threaded end to react the torque applied to the collar during installation. The collar includes a frangible portion that separates at a predetermined torque value. Figure 16 shows a typical installation sequence. The Lockbolt incorporates a collar that is swaged into annular grooves. It comes in two types: pull-type and stump-type. The pull-type (Fig. 17) is the most common, where a frangible pintail is used to react the axial load during the swaging of the collar. When the swaging load reaches a predetermined limit, the pintail breaks away at the breakneck groove. The installation of the Hi-Lok and the pull-type Lockbolt can be performed by one mechanic from one side of the structure.

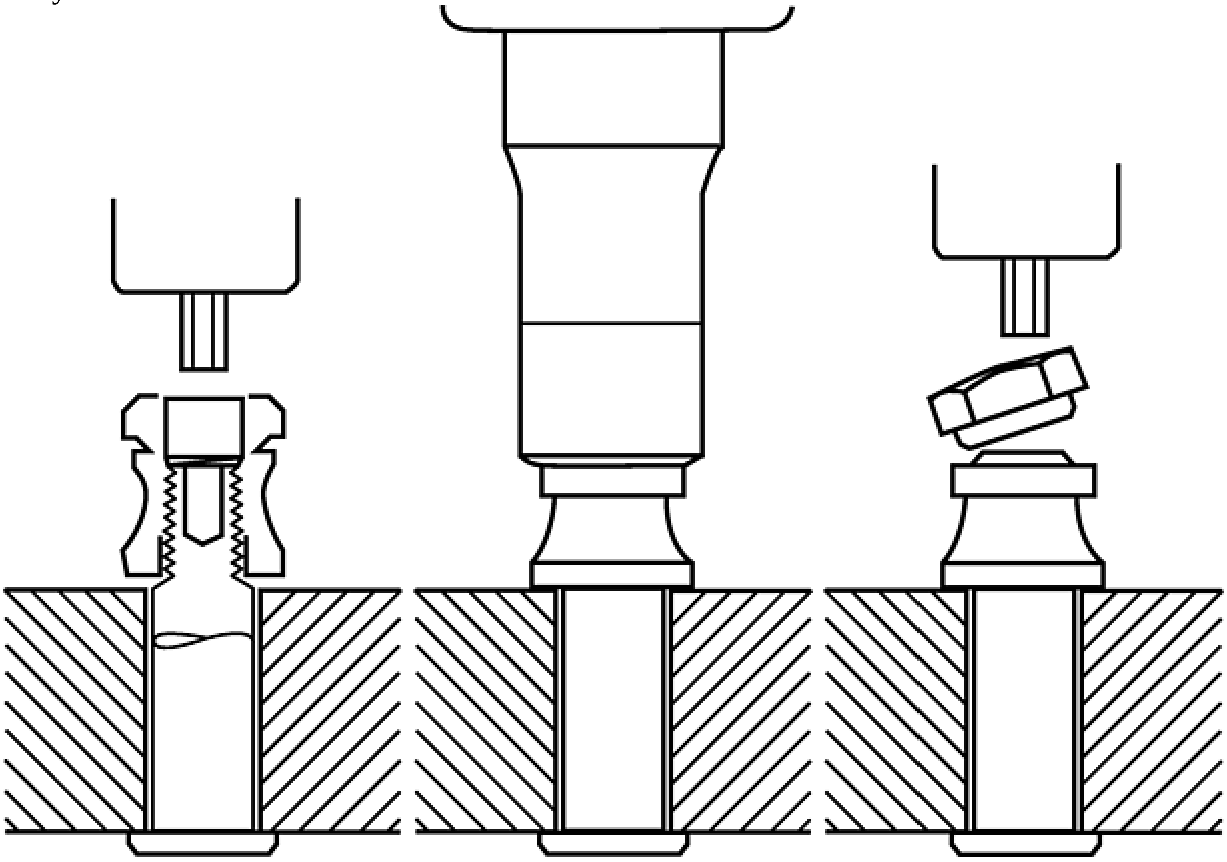

Fig. 16 Typical installation sequence for Hi-Lok fasteners

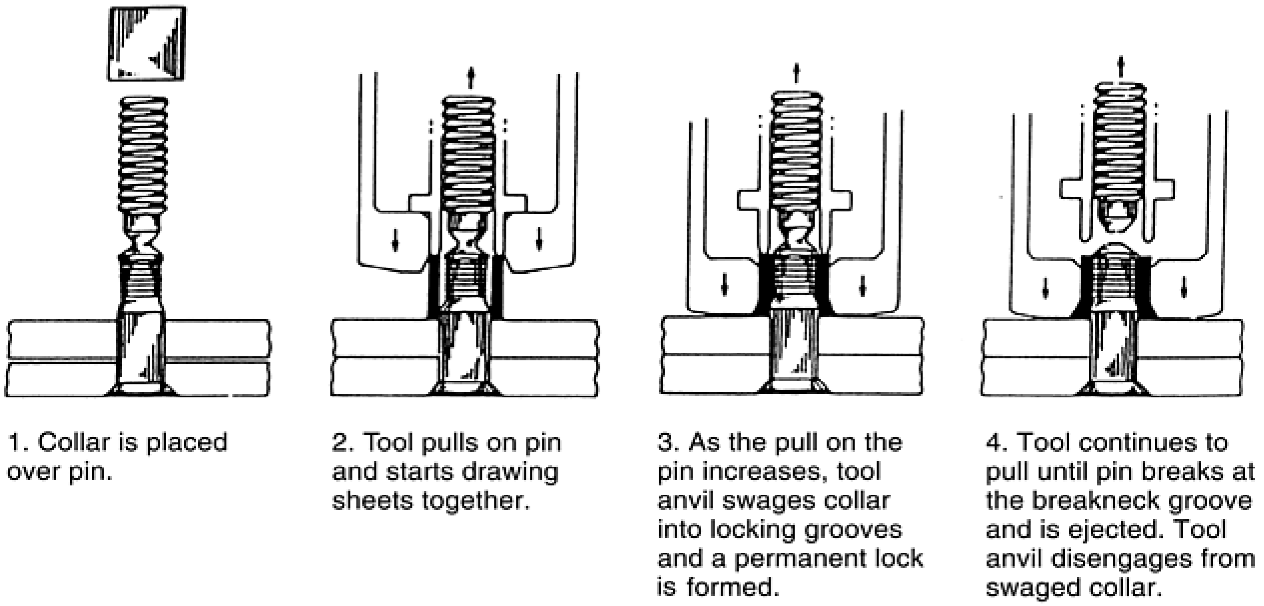

Fig. 17 Typical installation sequence for pull-type Lockbolt fasteners

The stump-type Lockbolt, on the other hand, requires support on the head side of the fastener to react the swage operation. This method is usually reserved for automated assembly of detail structure where access is not a problem.
The specific differences in these fasteners for composite structure in contrast to metal structure are small. For the Hi-Lok, material compatibility is the only issue; aluminum collars are not recommended. Standard collars of A286, 303 stainless steel, and, with special lubricants and or finishes, titanium alloy are normally used. The Lockbolt requires a hat-shaped collar that incorporates a flange to spread the high bearing loads during installation. The Lockbolt pin designed for use in composite structure has six annular grooves as opposed to five for metal structure.

Robert T. Parker, Boeing Commercial Airplane Company

Eddie-Bolt Fasteners

Although Eddie-Bolt fasteners (Fairchild Corp., Dulles, VA) are similar to Hi-Loks, they are a natural choice for carbon fiber composite structures. The Eddie-Bolt pin is designed with flutes in the threaded portion, which allows a positive lock to be made during installation using a specially designed mating nut or collar. The mating nut has three lobes that serve as driving ribs. During installation, at a predetermined preload, the lobes compress the nut material into the flutes of the pin and form the locking feature. Figure 18 shows the installation process. The natural advantage for composite structure is that titanium alloy nuts can be used for compatibility and weight saving without the fear of galling. The nuts spin on freely, and the locking feature is established at the end of the installation cycle. Other threaded-fastener systems usually have a crimp in the nut or collar that elastically deforms to create friction and act as a locking feature. The friction can be a problem with titanium rubbing against titanium, as this material is very sensitive to galling without special finishes or lubricants. Then again, the lubricant defeats the purpose of the friction lock.

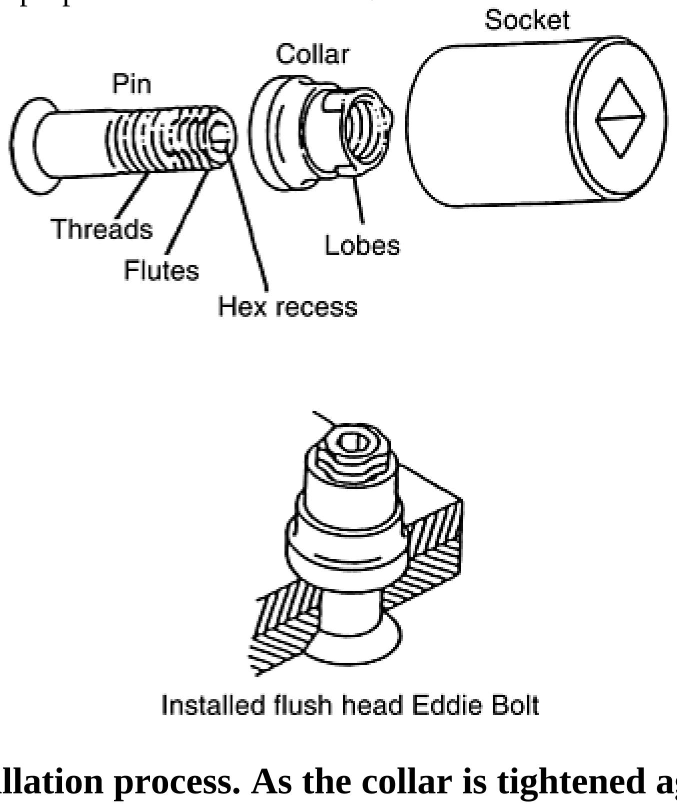

Fig. 18 Eddie Bolt installation process. As the collar is tightened against the structure and the correct preload is approached, the collar lobes begin to deform and roll into the flutes

on the pin. Mechanical lock is achieved by filling at least one flute. A washer is required between the collar and the composite surface to prevent damage.

Mechanical Fastener Selection

Blind Fasteners in Composite Structures

As composites were introduced into structural components, fewer fasteners were required. Stiffeners and doublers were co-cured with the skins, eliminating many fasteners. Panels became larger pieces; many times, this size increase caused accessibility problems. Blind fasteners or screws and nutplates must be used in areas with backside inaccessibility.

There are some advantages in using blind fasteners over nutplates:

- Faster installation
- Only one hole per fastener
- Tighter class of hole fit
- Usually lighter
- More easily replaced for defective installation

Several versions of blind fasteners have been developed for joining composite structures. The Composi-Lok (MAG Aerospace Industries, Inc., New York, NY) (Fig. 19a), is an example of a threaded corebolt type; the Ti-Matic (Huck International, Inc.) (Fig. 19b), is an example of a pull-type blind fastener.

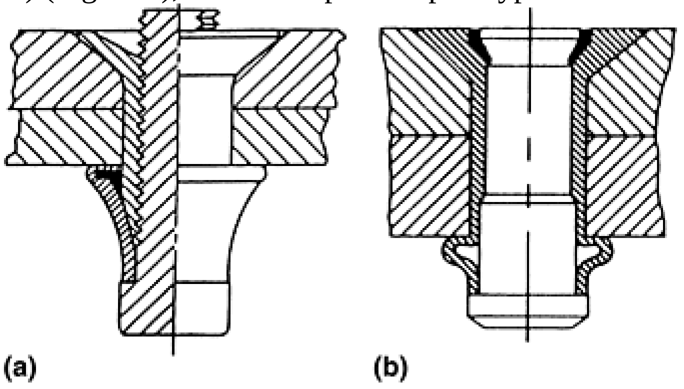

Fig. 19 Blind fasteners for joining composite structures. (a) Threaded-corebolt type. (b) Pull type

The threaded-corebolt-type blind fastener has the highest clamping forces (advantage for joint fatigue strength) due to the mechanical advantage of the threads and very little relaxation at the end of the installation cycle. The corebolt threads “lock” the corebolt axially, improving the bolt-bending characteristics. Bolt bending is a common problem in composite structure due to the low interlaminar shear modulus of laminated composites. The high clamping forces are distributed over the large footprint on the backside. This particular blind fastener was designed specifically for use in composite structure; however, it could be used in metal structure as well. Figure 20 shows the installation sequence. A sleeve is “jacked” (by the threaded corebolt) down over the tapered end of the fastener body and collapsed against the blind side of the structure. A small nonmetallic insert (not shown) keeps the sleeve deformation in the proper direction. Locking is provided by indents in the fastener body producing elastic deformation that increases friction and prevents the corebolt from loosening, much like a standard self-locking nut. The disposable drive-nut provides ease of installation and common tooling for both flush head and protruding-head configurations.

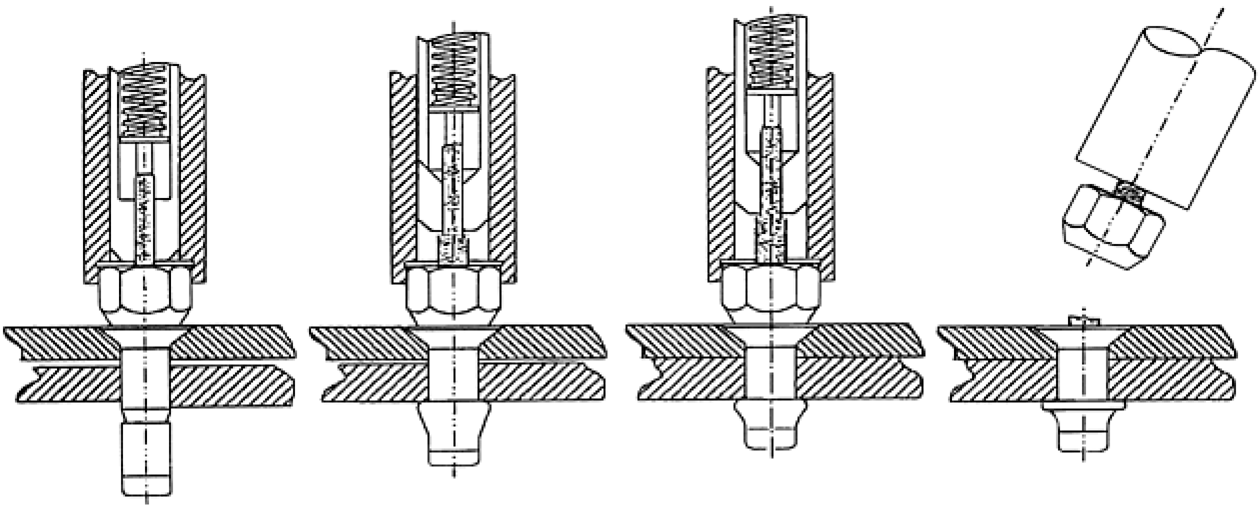

Fig. 20 Installation sequence for a threaded corebolt-type blind fastener

The pull-type blind fastener depends on a straight pull to provide the axial force necessary to collapse the sleeve or thin-walled portion of the fastener body. As the core pin is pulled upward, a groove, strategically placed, becomes positioned just in time for a locking ring to be forced into the groove. The locking ring provides retention of the core pin. Figure 21 shows the installation sequence. At completion of the installation, the excess core pin breaks away in tension and is discarded. The clamping forces are less than for the threaded-corebolt type, and the footprint is much smaller. However, the pull- type blind fastener installs more quickly, is usually lighter, and is less expensive. Joint fatigue testing has shown that the pull-type blind fastener does not perform nearly as well as the threaded-corebolt type, probably due to less clamp-up, smaller footprint, and greater susceptibility to bolt bending. Structural performance requirements should govern the choice of blind fastener type. It has been the philosophy of the design community that blind fasteners used in primary structure in aircraft be inspected on the backside (with a borescope) for proper formation.

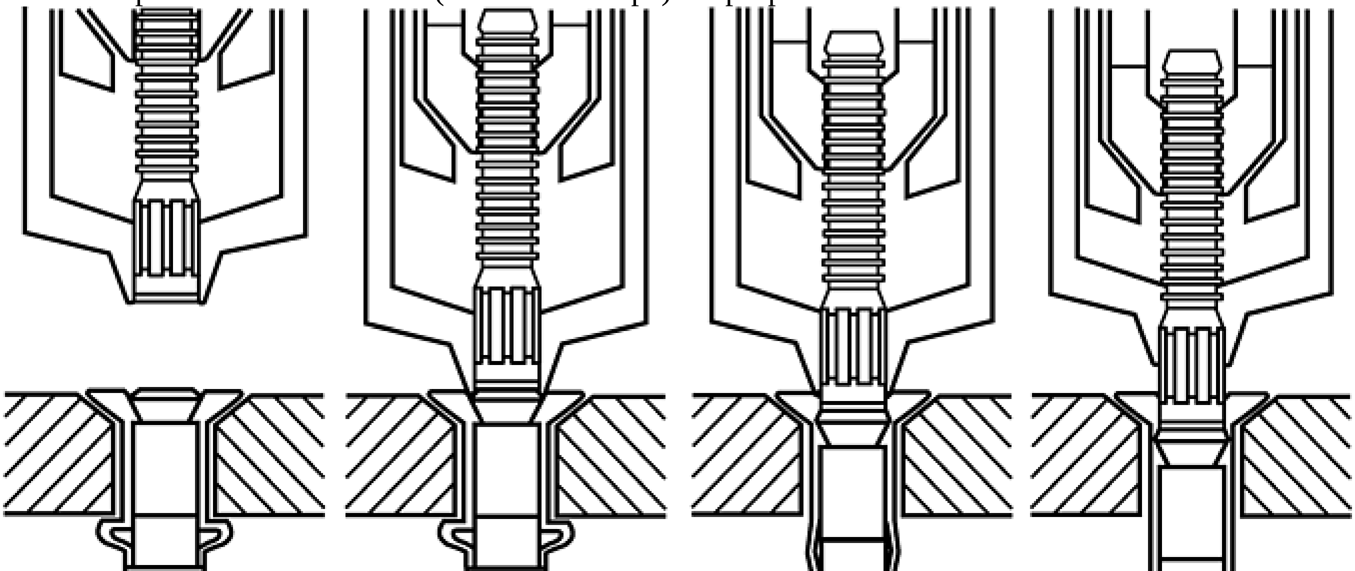

Fig. 21 Installation sequence for a pull-type blind fastener.

Screws and Nutplates in Composite Structures

If removal of a closeout panel is anticipated in the life of the structure, screws and nutplates are recommended in place of blind fasteners. Nutplates used in composite structures usually require three holes, two for attachment of the nutplate and one for the removable screw. Other methods of attachment used in metal structures (Davis Press Nut, Rivnut, etc.) have not been successful in composites. A major disadvantage with nutplate attachment is the alignment of holes. “Hole out,” net area stress, and “tear along the dotted line” are problems of concern for the designer. For close fastener spacing, rotating the nutplate attachment can reduce the “dotted line” effect, as shown in Fig. 22. Rotation of the nutplate, however, requires more edge margin, but then that in itself reduces the net area stress. Another method of minimizing the number of attachment holes is to use gang channel nuts, shown in Fig. 23. Gang channel made of composite material has been used in military airplanes where the nut element is replaceable. The channel is attached to the structure at much longer increments than if individual nutplates are used. The screw and nutplate assembly does not compare favorably with blind fasteners for structural performance in composite structure. Reference 9 was a study that compared static and joint fatigue performance for screws and nutplates with threaded-corebolt-type blind fasteners. Static joint tension ultimate strength for screws and nutplates was about 85% of the blind fastener capability; however, yield strength suffered the most with approximately 67%. The lower yield is due to the increased joint deflection and compliance of the fastening system. For the same reasons, joint fatigue strength is also much lower as shown in Fig. 24. For these reasons, screws and nutplates are not normally used or recommended for high-load transfer joints.

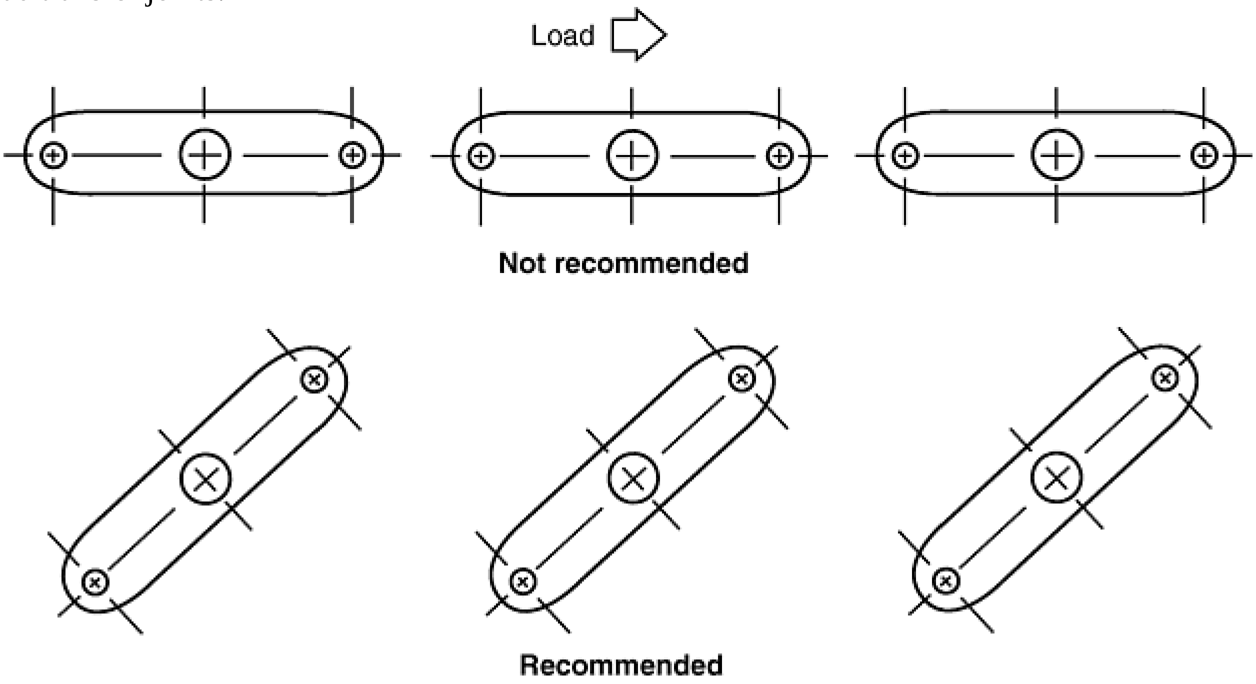

Fig. 22 Eliminating the effects of “tearing along the dotted line” with nutplates

Environmental Protection and Sealing

Leslie A. Hoeckelman, The Boeing Company, St. Louis

Introduction

ENVIRONMENTAL EFFECTS of ground and flight environments, including temperature extremes, damage by chemical fluids, moisture, and so forth, that affect the durability of polymer-matrix composites are an ongoing concern of aircraft manufacturers and operators. Carbon fiber reinforced polymer-matrix composites (or simply, graphite composites) present a special problem for assemblies that are bolted and bonded to metal structures because graphite, together with metals and alloys is in the electromotive series of alloys commonly used in aircraft structures (Table 1). A galvanic cell thus can form in the presence of moisture or other electrolytes between a carbon fiber reinforced composite and any of these metals that it contacts. Graphite, which is at the cathodic end of the series and which functions as a noble metal, is impervious to corrosion itself, but will accelerate corrosion in the adjacent less-noble metal.

Table 1 Electromotive series of aircraft alloys, in descending order of tendency to corrode

Electrolyte is seawater.

Anodic (most active)
Magnesium alloys
Zinc
Alclad 7000 series aluminum alloys
5000 series aluminum alloys
7000 series aluminum alloys
Pure aluminum and alclad 2000 series alloys
Cadmium
2000 series aluminum alloys
Steel and iron
Lead
Chromium

Brass and bronze alloys
Copper
Stainless and heat-resistant steels
Titanium
Silver
Nickel and nickel alloys
Gold
Carbon fiber reinforced polymer composites
Cathodic (least active)

Table 1 provides a guide for material selection based on the criterion of potential for galvanic corrosion. For example, there is considerably more difference in the galvanic potential between carbon fiber reinforced composite (CFRC) and aluminum than between CFRC and titanium or stainless steels. Likewise, there is considerably more difference in galvanic potential between CFRC and nonstainless steels than between CFRC and stainless steels. In addition, clad alloys and certain aluminum alloys have more galvanic potential than others.

Joining a CFRC to aluminum presents a potentially serious corrosion problem. The assembly of CFRC to aluminum is not prohibited, but it does require some special considerations and procedures.

Corrosion Control

Control of galvanic corrosion in aircraft structures usually involves either corrosion prevention or retardation of the corrosion rate. Prevention methods include barriers, material changes, and isolation (elimination of the moisture). Retardation methods include leaching of anticorrosion materials and consumable materials.

Barriers are the predominant method for corrosion prevention, applied either during fabrication or assembly. Fabrication-applied preventatives include materials such as fiberglass ply being co-cured onto the CFRC part surface. Another fabrication barrier would be a primer coat of paint or other organic coating applied to the part after machining and before assembly. This prevents the two materials from coming into contact. The primer or organic coating could also be in the retardation category, since anticorrosion compounds could be added to their chemistry. Assembly-applied preventatives include sealants and gaskets. A wet curing sealant, called a fay seal, is applied between the parts making up the assembly. A wet curing sealant, called a butt joint seal, is applied between the ends of two parts. A wet curing sealant can also be applied around the fastener shank and/or fastener head; this is called a wet installation. In some cases, an O-ring rubber seal can be placed on the fastener shank to form the seal. Seals around removable doors can use a form-in-place seal (FIP) or a formed gasket installed.

Materials Changes. Corrosion prevention via material selection includes using a more cathodic material in place of the aluminum with the carbon fiber reinforced composite. However, when using CFRC, aluminum, titanium, or stainless steel in aircraft structures, thermal expansion within the joint must also be considered along with the galvanic potential difference of the above materials. A comparison of thermal expansion coefficients is given in Table 2. The combination of CFRC and aluminum would result in the greatest thermal expansion mismatch, which would increase loads on the fasteners, adhesives, or sealants as the joint is subjected to in-service temperature variations. A thermal expansion mismatch also results in bonded joints when the bonding or co-

curing is accomplished at elevated temperatures. In fact, adhesive bonds between CFRC and aluminum have been known to fail when exposed to subzero temperatures (e.g.,–54 °C, or–65 °F), due to the large thermally induced stress gradient. The design of a CFRC-metal joint thus involves finding a balance between low cost, lightweight, availability, ease of fabrication, material mechanical property match, galvanic potential match, and thermal match. A good alternative consideration would be a CFRC-CFRC joint. However, the CFRC- CFRC joint still presents a galvanic corrosion problem with the metallic fastener, since they will be in contact with the carbon fiber ends.

Table 2 Thermal coefficient of expansion for composite and metallic materials

Material	Coefficent of thermal expansion, 10^{-6}/K	
	Longitudinal	Transverse
Carbon-fiber-epoxy (0°)	0.43	**29.2**
Carbon-fiber-epoxy (0°/ ±45°/90°)	3.4	**3.4**
Carbon-fiber-epoxy fabric (24 × 23–8HS)	2.7	**4.0**
E-glass epoxy (0°)	8.6	**…**
E-glass-epoxy (181-style weave)	9.9	**12.1**
Aramid-epoxy (0°)	–5.4	**…**
Aramid-epoxy (181-style weave)	–1.8	**–1.8**
Aluminum alloys	23.4	
Steel	10.8	
Titanium	10.1	
Stainless steel	**18**	

Values for composite laminates may be taken as typical; however, actual values for specific materials, especially in the graphite-epoxy system, can vary widely from these values.
Source: Ref 1

Isolation (elimination) of the moisture or electrolyte is the final method of corrosion prevention. This essentially is the “keep it out and keep it in” philosophy. Fay surface, fillet, and butt joint seals satisfy this requirement. These sealing methods are discussed in the section “Sealing” in this article.

Retardation of the corrosion rate includes leaching of anticorrosion materials or a coating of a consumable/sacrificial material. The leaching compound may be found in the primer on fabricated parts or in the sealant that is applied during the assembly of the parts. Generally, the leachant has been a compound of cadmium or chromium. Due to environmental concerns, the current requirement is for an anticorrosion compound without cadmium or chromium. The material manufacturers are working to make this formulation. A sacrificial material is generally a very thin layer of a material (e.g., pure aluminum) applied to a part via ion vapor deposition during the fabrication process.

Environmental Protection and Sealing

Leslie A. Hoeckelman, The Boeing Company, St. Louis

Design Considerations

Sealant joint design and installation workmanship usually are not the first consideration when structures requiring joints are designed. Therefore, sealants in joints often fail, resulting in a significant cost to replace or,

in some cases, a complete joint redesign. Since most joint designs are unique to the rest of the structure design, some general guidelines are useful.

Shear, tension, and compression stresses are typically encountered in the sealant joint. Thermal expansion or contraction, structure movement, and environmental forces are the source of these stresses, which can deform the sealant and cause strain. Sealants must be able to accommodate a certain amount of movement; this property of a sealant is called percent elongation. Figure 1 shows a simple butt joint and the extension/compression experienced by the sealant. Figure 2 shows a simple fay surface joint and the lateral movement experienced by the sealant in the joint.

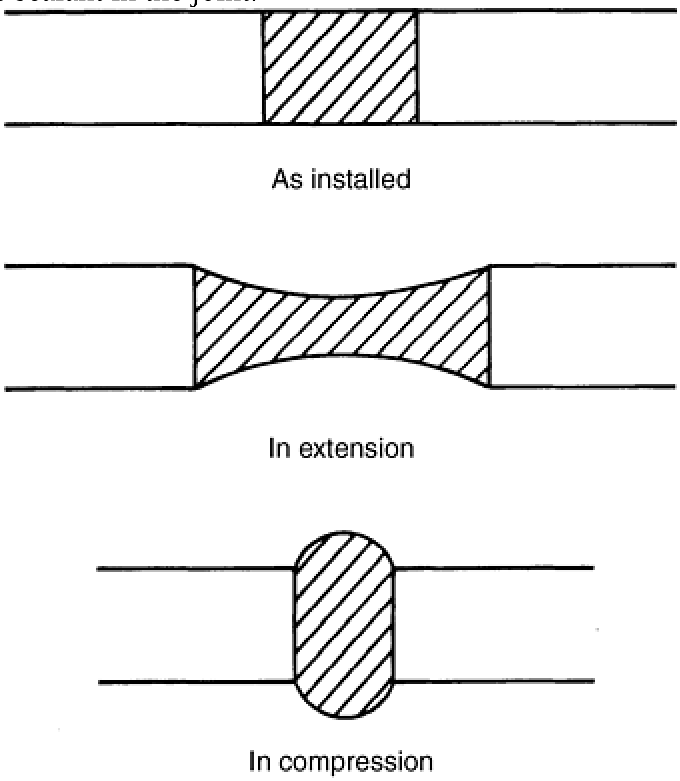

Fig. 1 Simple butt joint. Source: Ref 2

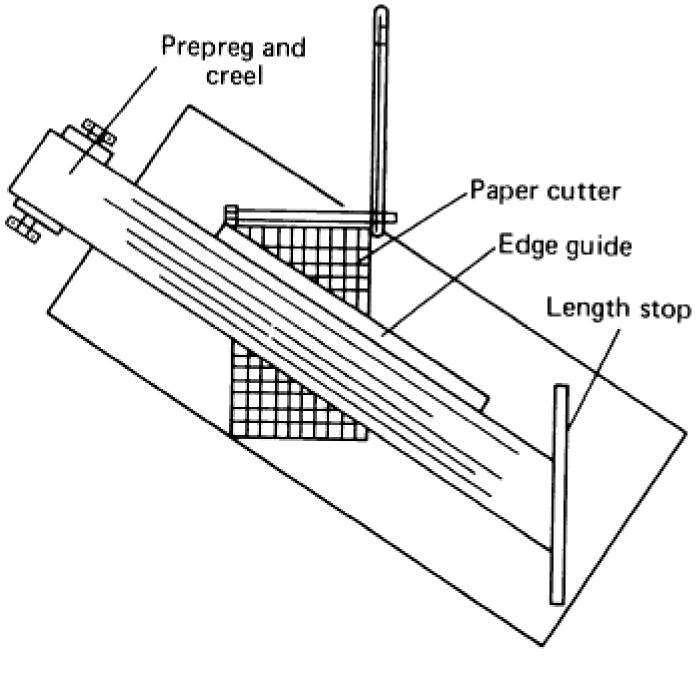

Fig. 2 Simple lap joint. Source: Ref 2

Good joint design is dependent on the mechanical and chemical resistance properties of the sealant material, the characteristics of the materials forming the joint (substrates), and on the joint configuration. Assuming that the general sealant properties such as chemical resistance and temperature capability are suitable for the joint

application, there are certain other sealant and substrate material characteristics that must be considered by the designer, including sealant adhesion capability to the substrate, cohesive strength of the sealant material, percent elongation, and cohesive capability of the substrate.

Adhesion of the sealant to the substrate is an inherent property of the sealant/substrate interface and may be enhanced by the use of a primer (generally called an adhesion promoter). The cohesion (resistance to tearing) is an internal physical property of the sealant material. This will determine the minimum cross-sectional area of the joint. Percent elongation and elastic recovery is the ability of the cured sealant material to stretch. Cohesive strength of the substrate is usually associated with composite materials. A substrate that does not have sufficient strength to support the stresses that develop at the sealant/substrate interface will fail internally.

There are several important design considerations for the joint itself (Ref 2):

- Sufficient sealant/substrate interface to provide adequate adhesion
- Sufficient cross-sectional area to avoid cohesive failures
- Maximum surface area to volume ratio to reduce strain
- Accessibility for seal installation
- Accommodations for sealant cure requirements

Because sealant may fail either cohesively or adhesively, both properties are important and must be balanced to the joint requirements.

Environmental Protection and Sealing

Leslie A. Hoeckelman, The Boeing Company, St. Louis

Sealing

Common methods used to seal aircraft structures are: fay surface, fillet, butt joint, and form- in-place (FIP) seals (Fig. 3). While there are various tools and equipment available, various dimensions to be held, various materials to use, and an adhesion promoter and a detackifier to use before and after application, there is one requirement that cannot be stressed enough: the sealing surfaces must be clean. The water break free test is the most common method to verify that a surface is clean. However, it should be noted that a water break free test cannot be used in many production operations. Many procedures have been developed to obtain a water break free surface. The area to be sealed, primed, or coated must be free from all grease, oil, dirt, and other foreign materials that can hinder the adhesion of the applied material.

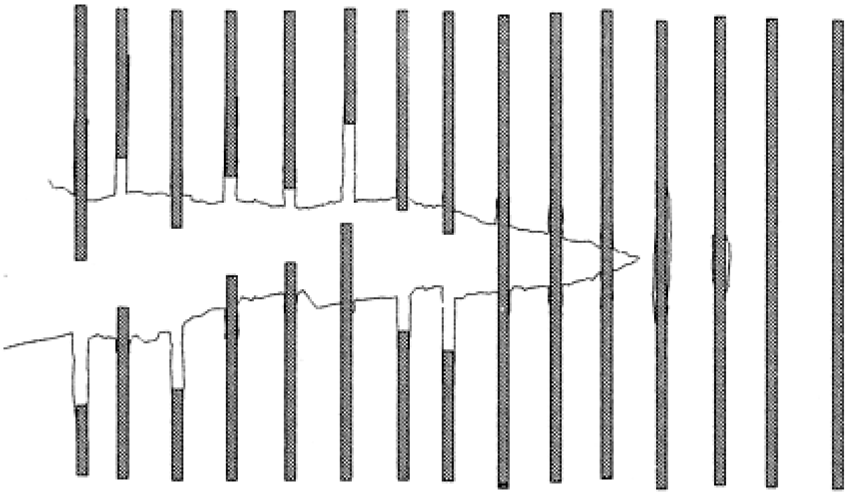

Fig. 3 Seal types

Cleaning of the structure can take the form of a water and detergent scrub, followed by a solvent material wipe and then the “two-wiper cleaning” process. This last step removes the foreign materials (contaminant) that might be left behind if the cleaner was left to evaporate. In this cleaning process, one wiper is dampened with the solvent and the other is dry. The dampened one is applied to the part first, and, before the solvent can evaporate, the second dry wiper is used to dry the part. Repeated turning of the wiper presents a new surface to the part. In some instances, the surface is lightly abraded and recleaned prior to sealing. In some cases, the water and detergent scrub are skipped as part of the cleaning process.

Sealant materials are categorized into several groups: base material types, temperature ranges, fuel wetted surfaces, and noncorrosion ability. The most common base material is polysulfide. The polysulfides typically use an accelerator material to cure the base rubber. This material is available within a normal temperature range of–55 to 120 °C (–65 to 250 °F) with short time exposure to 180 °C (360 °F). These sealants are available in a wide variety of types, including those specifically formulated for fay surface sealing and wet fastener installation. Other types are specifically formulated for fillet seals, butt joint seals, fuel tank sealing, and low density, low adhesion for removable panels. Formulations are also available for other special conditions. Within each of these categories, there are short and long application times (pot life) fast cure, minimum/low viscosity applications (spray or brush), and extrusion gun or spatula grades. It should be noted that the polysulfide sealants vary somewhat in their maximum service temperature and their continuous versus peak temperatures. Material suppliers and company/ military/commercial specifications should be consulted for specific selections. The second- most-used material is the silicone category. These materials typically are used for the next higher temperature regime, in the range of–60 to 260 °C (–80 to 500 °F). The silicones use two different cure mechanisms, either catalytic or moisture (from humidity).

Fay surface sealing is a process that seals two surfaces that come into contact with each other in a fastened joint (Fig. 4). The fay seal is mandatory for adequate corrosion protection. Wet sealant fastener installation is also mandatory. The two surfaces are cleaned, and an application of an adhesion promoter may be applied to the two surfaces. Sealant material is next applied in a manner to coat one of the entire mating surfaces, monitored by material squeeze-out on the edges of the party boundary. Lower-viscosity materials are used for fay sealing thin sheets. When thick parts are assembled, a higher- viscosity material is used. Longer assembly time materials are required for large assemblies, such as large skins over spars, ribs, stringers, and longerons. Figure 5 shows examples of application tools for fay sealing. The roller often is used to obtain a uniform preassembly sealant thickness. The comb nozzle is used for small and/or narrow parts that need to be fay sealed. The notched comb also is used to apply a uniform preassembly sealant thickness.

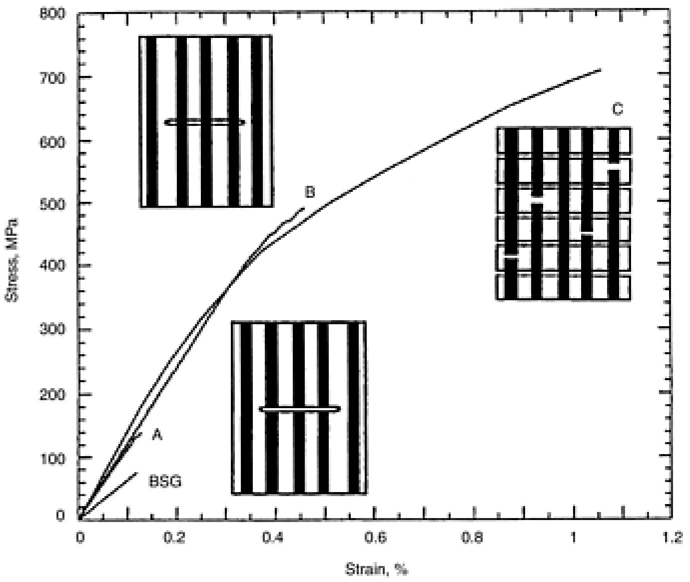

Fig. 4 Fay-surface seal

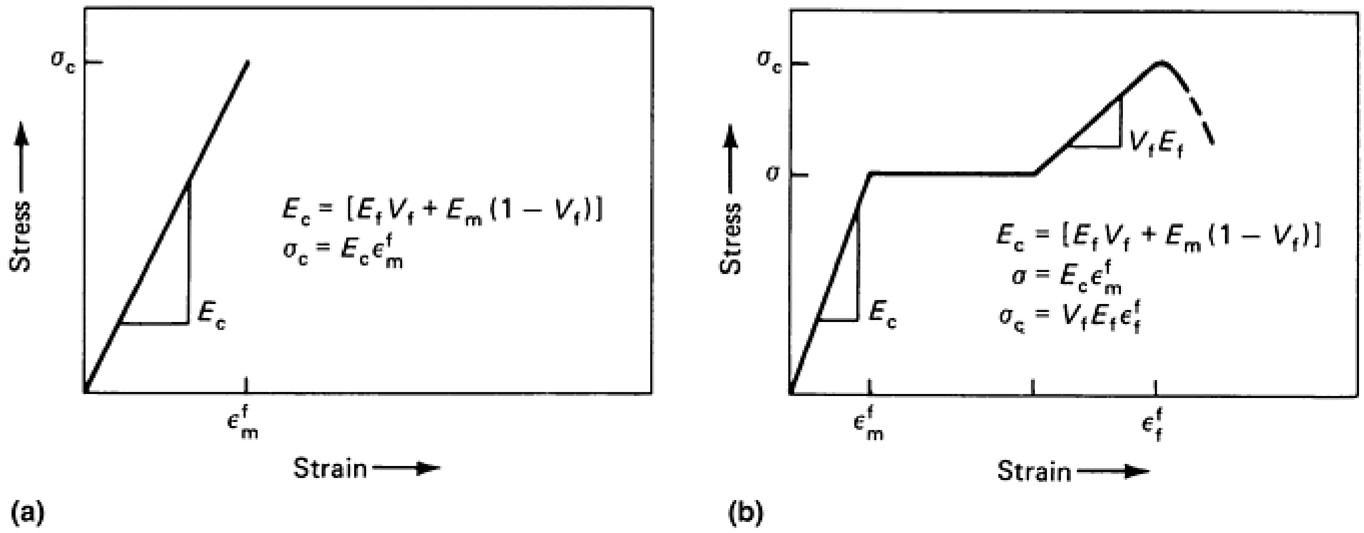

Fig. 5 Fay-seal nozzles

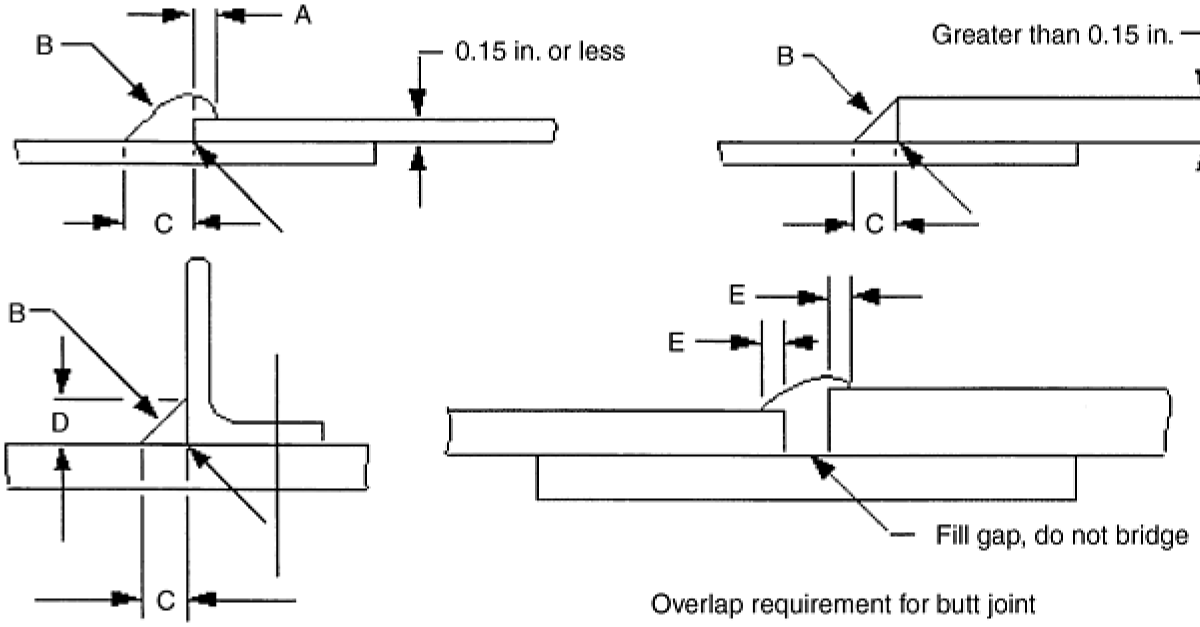
Fillet sealing is a process that seals the edge of two surfaces that come into contact with each other in a fastened joint (Fig. 6). The fillet seal is used to prevent fuel, water, or air from getting out of where it should be or getting in where it should not be. The fillet seal constitutes the primary seal (backed up by the fay seal) in many joint designs. Fillet seals are usually located inside of the aircraft mold line. Wet sealant fastener installation is also mandatory. The two surfaces are cleaned, and an application of an adhesion promoter may be applied to the two surfaces. Sealant material is next applied in a manner to cover the interface of the one part to the other (Fig. 6). This is monitored by checking the dimensions “a,”“b,”“c,”“d,” or “e” as appropriate and shown in Fig. 6. A high-viscosity material is used for fillet seals, so that the fillet shape will be retained with the thixotropic properties of the material. Short assembly times are desired for the fillet application. A detackifier may be used over the sealant material to allow work to resume over the fillet, before the fillet seal is cured enough to be tack free. The detackifier minimizes the potential for drilling chips to stick to the sealant material. Special filleting tools are used to obtain the correct size and shape of the fillet bead.



Material type	A and B, in.	C, D, and E, in.
Metals	0.10–0.15	0.15–0.25
Carbon fiber reinforced epoxy composite joined to dissimilar metals (such as aluminum)	0.15–0.25	0.2–0.3

Note: When upper material is greater than 0.15 in., then A = 0.

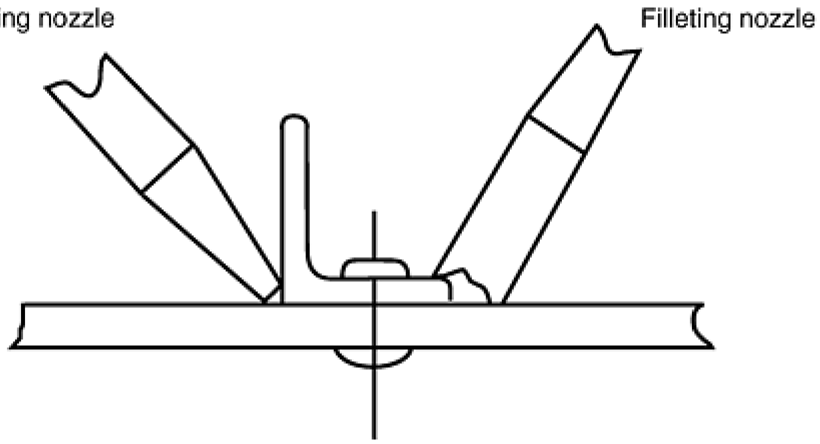


Fig. 6 Filleting criteria

Brush sealing is used to overcoat the collar, buck rivet tail, or other nut element of the installed fastener (Fig. 7). This process uses a lower-viscosity material and short assembly times. Detackifier may be used over the brushable sealant. This process is used in pressure areas, such as the cockpit, crew station, or cabin areas. Spray sealing is beginning to replace brush sealing for large areas. The spray is produced using a 14 MPa (2000 psig) pump and an airless spray head. The orifice and the spray cap determine the fan size and shape. The spray uses a low-viscosity, brushable grade, polysulfide material and further thins it with a solvent to obtain a specific Zahn cup time. Two to four applications are required with a solvent flash off time between applications. The same cleaning process is used for spray sealing. A nonwater-based adhesion promoter is spray applied prior to the actual spray seal process. The spray is applied approximately halfway up a spar web and 50 to 100 mm (2–4 in.) out onto the inner mold line of the skin.

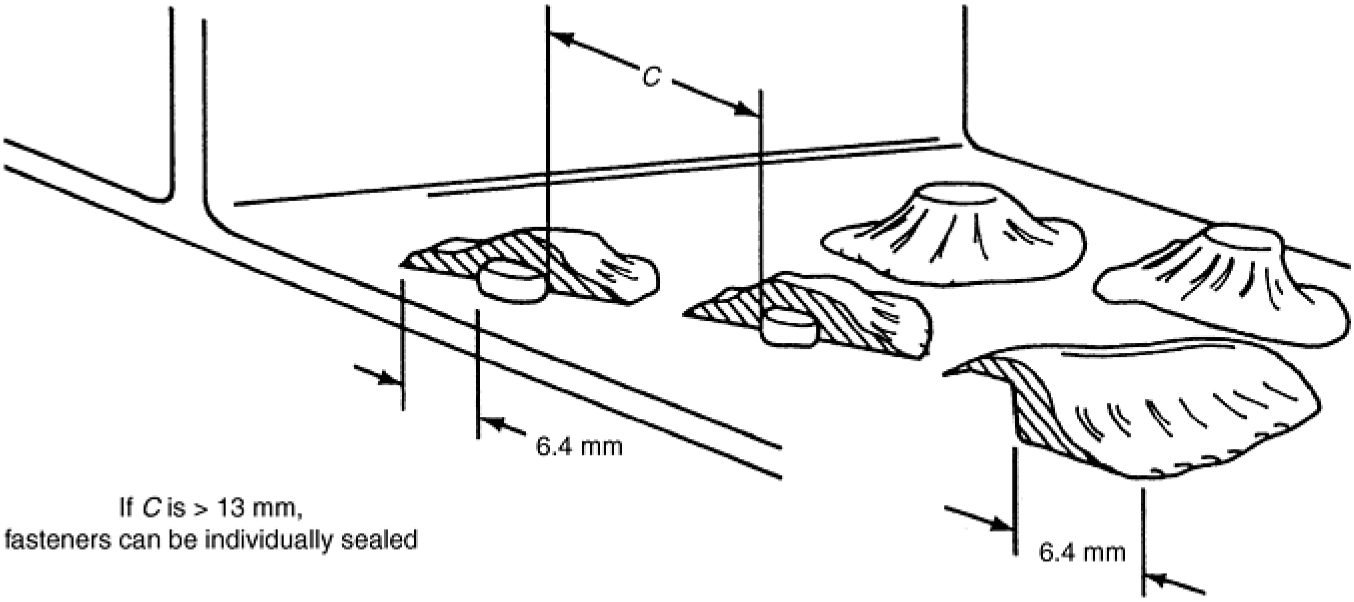

Fig. 7 Sealant overcoat of fasteners. Source: Ref 3

Butt joint sealing and FIP seals are the last sealing processes during assembly. The butt joint seal is applied between the edges of two parts (Fig. 8). This fills in the gaps between them. Nozzles are used to apply the sealant in the gap between the two skins. The FIP seal is used to seal access bay doors and removable doors and panels (Fig. 9). The door sill is cleaned like the other sealing processes. Spacers are attached to the sill to provide a specific seal thickness when completed. The location can be around the fastener using a donut-shaped spacer, or it can be located away from the fastener using the hole of the donut or some other shape (Fig. 9). When the second location is used, the volume where the spacer was removed is then filled in with the sealant used for the seal. The width of the FIP seal is dictated by the general design requirements for the assembly, but is usually approximately 13 mm (0.5 in.). After all of the spacers are located, the sill then has an adhesion promoter applied, and it is allowed to dry. Any puddling of the adhesion promoter must be soaked up with a wiper. During this time, the door has mold release applied to the edge and the sealant contact surface and then allowed to dry. Two or three coats of mold release may be required, depending on the specific mold release used. The door and the skin area around the door has masking tape applied to facilitate cleanup. Sealant is applied to the doorsill and the door installed with a specific sequence of fasteners. When the sealant is cured, the door is removed with the aid of a plastic wedge. Care is required to prevent damage to the seal. After the door is removed, the excess cured sealant and the mold release is cleaned up, and a powder parting agent is applied to prevent the door from resticking to the sealant.

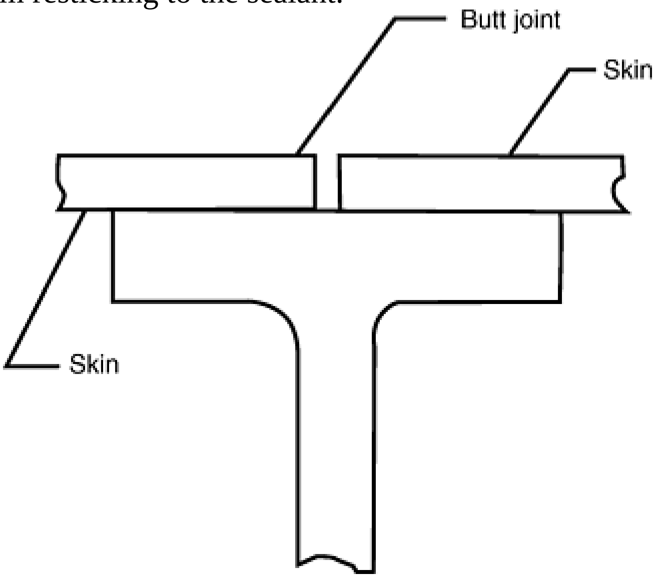

Fig. 8 Butt-joint seal

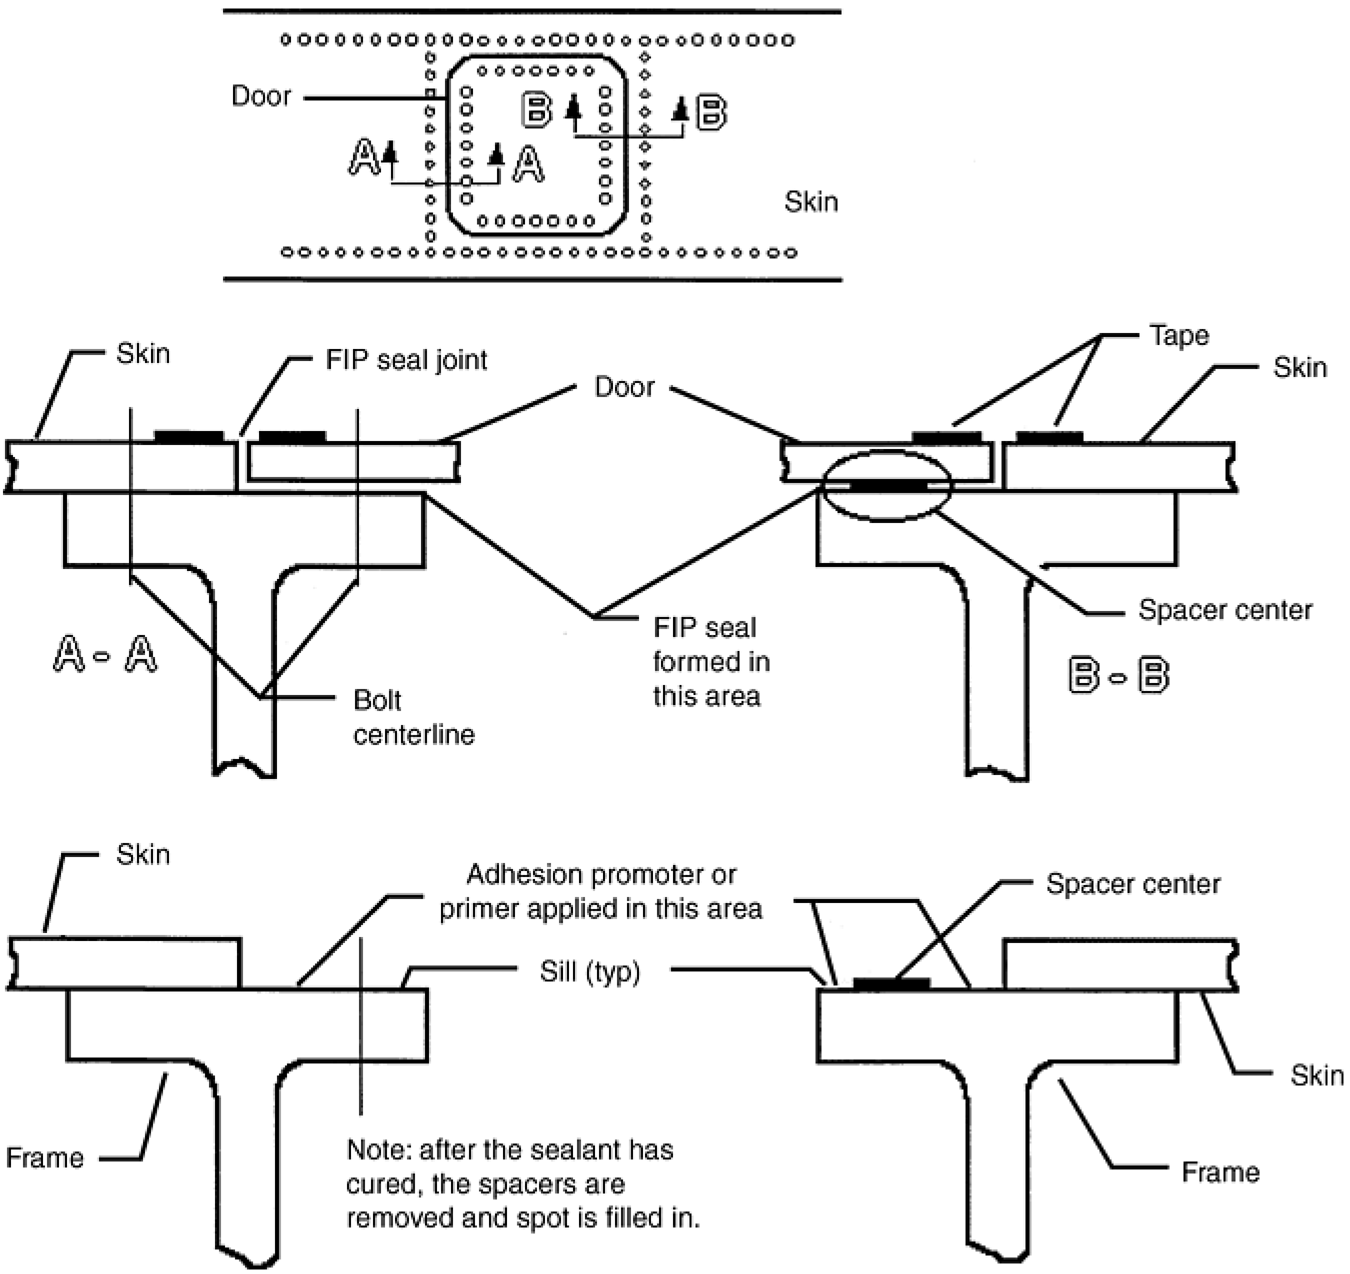

Fig. 9 Form-in-place (FIP) seals

Many fuel tanks use a noncuring sealant injected into a seal groove. This is considered to be a repairable fuel-boundary seal. It can be a polysulfide or a fluorosilicone material, called the groove or channel sealant. The channel sealant can have beads or chopped rubber, as a filler, mixed into the paste sealant. The filler material will migrate in the sealant when a flow of fuel begins to swell the paste. The filler material then moves to where the flow is exiting. The filler material forms a “log jam” at this point, and the sealant flows around them, resealing the groove. This material is injected into a channel that goes around the periphery of the tank. The material is injected in such a manner as to apply pressure to the sealant in the channel groove. Injection of this material is done at elevated pressures of 14 to 28 MPa (2000–4000 psig) at the nozzle tip. The tip pressure is dependent on the material thickness of the skin and frame, thicker parts have higher allowed tip pressure. This sealing method is generally used in conjunction with fay and fillet seal described above. A typical wing tank without a bladder would use fay seal between the skin and the spar caps, then a fillet seal at the edge of the spar cap of the wet side of the wing skin. This would be followed by either a brush overcoat of the fasteners with sealant or spray sealing over the fasteners, up the spar web, and out over some of the inner mold line of the skin. After the polysulfide has all cured, then the channel seal material would be pumped into the channel

Channel seals require a channel groove machined or formed into the spar cap (Fig. 10). The width, depth, and location are determined based on the structural loading, volume contained in the channel groove, and the general design requirements. If the groove follows the fastener pattern, then the width will be greater than if the groove is on one side or the other of the fastener pattern. Groove depth must be minimized because the groove

is counted as a gap in the fastener design. However, the groove needs to be deep enough to contain a sufficient volume of sealant material to maintain a good seal. Injection of sealant into the groove also must be considered because sealant materials are very viscous and require a significant amount of pressure to move them through the groove, typically 14 to 28 MPa (2000–4000 psig) nozzle tip pressure. Injection points need to be designed at approximately every 100 to 150 mm (4–6 in.). The injection can take place through the fastener, through a fastener hole with an injection tool (Fig. 11), or through a hole in the skin that gets plugged.

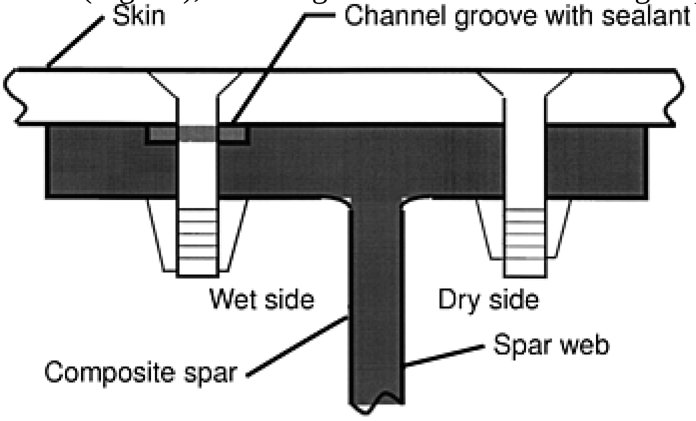

Fig. 10 Channel seals

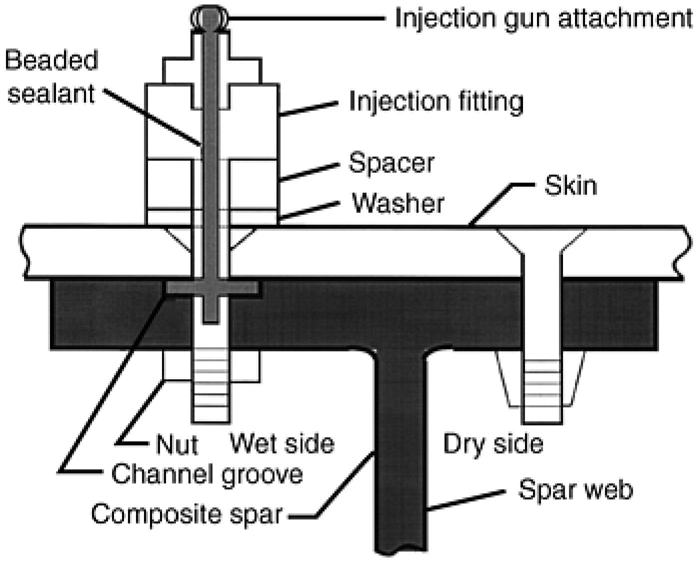

Fig. 11 Channel seal injection

Sealant application equipment includes pneumatic application guns with different sealant extrusion nozzles and with various size sealant cartridges ranging from 0.03 to 0.6 L (1–20 fl oz), pneumatic channel sealant injection equipment with a pressure regulator and gage for reduced tip pressures (used for sealing short lengths of channel groove and for field repairs), and airless spray sealing equipment. Sealant filleting and scraping is done using various hand tools.

Primer and Topcoat Systems

The primer and topcoat function as a system; therefore, the topcoat must be chemically and physically compatible with the primer system. The ability of the system to meet the user performance requirements is determined by how well the surface is prepared prior to coating.

Surface Preparation. Carbon fiber reinforced composite surfaces are prepared by scuff sanding or grit blasting to obtain visual dense scratches and loss of gloss. Priming or painting is conducted as soon as possible after surface preparation, and painting must take place within 36 h. If the part will not be painted within 12 h, it should be wrapped in clean roll paper prior to painting. Abrasive cleaning (grit blasting) is the preferred method of preparing unpainted CFRC surfaces (it is required for the mold-line surface) followed by dry wiping. Parts containing close tolerance holes are grit blasted and primered prior to drilling holes in the detail skin. Carbon fiber reinforced composite parts that are not grit blasted such as parts with complex geometry and/or locations inaccessible to grit blasting, reworked areas, and parts with thin, unsupported cross sections, are processed by removing any peel ply if present on the surface, dry wiping the composite surface, scuff sanding with 150 or 180 grit sandpaper by hand or with a pneumatic sander, and removing all sanding dust from the surface by dry wiping. Care must be taken not to sand into a free edge because it may cause edge delamination.

The entire primed or painted exterior composite surface is sanded using 180 grit or finer sandpaper to remove all surface gloss and contamination using an air-driven sander attached to an air-driven high-efficiency particulate air (HEPA) vacuum. Hand sanding is permissible for areas of less than 0.4 m^2 (4 ft^2) where mechanical sanding is not feasible.

Aircraft exterior mold-line surfaces are cleaned with detergent using the following process:

1. Wet down the aircraft, spray detergent on the surfaces, and scrub previously sanded areas with nylon abrasive pads. The detergent is allowed to set approximately 2 to 3 min on the aircraft, but not allowed to dry.
2. Rinse the aircraft with hot water 50 to 60 °C (120–140 °F) until the runoff water is free of detergent residue and evidence of the detergent (bubbling) on the aircraft is gone.
3. Wipe the exterior mold line using clean wipers (it is not necessary to wipe dry). The wiper is visually examined for contamination, if the aircraft surface still appears dirty. After the second cleaning, areas still dirty are allowed to dry and are locally hand cleaned.

Following detergent cleaning, the aircraft exterior mold-line surfaces are steam cleaned using a minimum steam pressure of 1379 kPa (200 psig), and the surfaces are raised using ambient- temperature clean tap water. Proper steam cleaning of intersecting surfaces and door fastener areas is particularly important. Surfaces should not be touched or contacted in any way after steam cleaning without personnel wearing proper protective clothing/coverings, such as gloves, overalls, boots, and protective caps. The aircraft is allowed to dry for a minimum of 4 h before painting, and surfaces to be painted are inspected for water and aircraft fluid drips and surface contamination immediately before painting.

Application of Primer. For all CFRC Parts requiring primer, one smooth, wet, continuous coat of the applicable catalyzed primer is applied to achieve 0.02 to 0.035 mm (0.8–1.4 mils) dry film thickness, a wet film thickness of approximately 0.09 to 0.13 mm (3.5–5 mils) will achieve the desired dry film thickness. The primer is allowed to dry a minimum of 5 min before applying additional primer to meet thickness requirements. Parts are cured 6 h prior to further processing. If more than 24 h elapse between primer applications, the surface must be hand solvent cleaned and scuff sanded prior to applying any additional primer coat(s).

Primer drying time depends on the atmospheric temperature and humidity conditions. Curing of a waterborne primer requires that the water evaporate first, which is achieved in the quickest way by air movement over the part. Elevated-temperature drying cycles may be used instead of air drying. Baking a part before the water evaporates will cause small blisters. Follow the material manufacturer's recommendation for elevated-

temperature cure (Cure temperatures must not exceed 121 °C, or 250 °F, for composite parts). To ensure that drying is satisfactory:

- Primer film may not show any sign of solvent pop or blistering due to insufficient flash-off time.
- Primer film must resist marring by no. 250 tape and to pass a dry tape test upon cooling to room temperature.

Application of Topcoat. Parts should be at room temperature before topcoat applications. Surface roughness or overspray is removed by sanding with nylon abrasive pads or 320 grit or finer sandpaper after the primer has dried sufficiently to allow sanding. Areas containing excessively heavy roughness, runs, or sags are sanded using 240 grit sandpaper, and sanding dust is removed from seams by blowing with air and from skin surfaces by wiping with wipers dampened with TT-N-95 aliphatic naphtha. If the time interval between primer and topcoat application exceeds 24 h, areas must be sanded using 320 grit or finer sand paper, cleaned, and have a primer applied and allowed to dry a minimum of 1 h before applying the topcoat.

The topcoat should be allowed to dry for a minimum of 8 h at 24 °C (75 °F) minimum and less than 90% relative humidity before the aircraft is removed from the paint booth. Allow 16 h minimum dry time if the aircraft will be exposed to moisture after moving from the paint booth. If outdoor temperatures average less than 18 °C (65 °F), the aircraft is dried for a minimum of 48 h in a heated indoor area before storing outdoors. Time limits apply from the last paint application on the aircraft, excluding touch-up.

Primer and Topcoat Testing. Primed aircraft mold-line surfaces are wet-tape tested per ASTM D 3359, “Standard Test Methods for Measuring Adhesion by Tape Test,” prior to final painting. Test locations are specified by engineering. The primer on the part should be air cured for a minimum of 12 days prior to testing.

ASTM D 3359 dry tape tests also are performed to determine the adhesion of the aircraft exterior finish. A minimum of 48 h air cure is required prior to testing.

Gloss measurements, taken only on the aircraft mold line, are made on flat surfaces only; measurements are not required on composite surfaces. The gloss readings at any location measured with a 60° gloss meter should be (a) gloss colors, 90 minimum; (b) semigloss colors, 15 minimum 50 maximum; (c) lusterless colors, 7 maximum; (d) lusterless black, 3 maximum.

The dry film thickness of the coating must fall within the minimum/maximum dimensions shown in Table 3. The coatings may be applied in any number of coats, provided the thickness and other requirements are met.

Table 3 Recommended primer and topcoat thicknesses

Application	Thickness			
	min		max	
	mm	**mil**	**mm**	mil
Interior (primer only), 2 coats	0.02	0.8	0.03	**1.4**
Exterior (primer), 1 coat	0.01	0.4	0.025	**1.0**
Exterior (topcoat), 2 coats	0.03	1.4	0.05	**2.0**
Exterior nonmold-line—primer and topcoat	0.04	1.8	0.08	**3.0**
Exterior mold line—primer topcoat, primed skins	0.04	1.8	0.10	**4.0**
Mold line leading edges—primer and topcoat	**0.12**[a]	**4.6**[a]	**0.18**[a]	**7.0**[a]

(a) Greater thickness is achieved by spraying on additional topcoat for abrasion resistance.

The maximum exterior mold-line dry film thickness should be determined by averaging individual measurements evenly distributed over the entire aircraft mold line as required by engineering. Individual maximum thickness values greater than those listed in Table 3 provided the average is within the range shown. Measurement locations should be representative of the general overall mold line. Thickness measurements are not taken on surfaces sprayed from multiple directions, demarcation line areas (color overlap areas), surfaces topcoated prior to final paint, and leading edges.

Defects in cured primer that are cause for rejection include non-continuous film and blistering, and lifting. The substrate can be visible through the primer, provided the minimum film thickness requirements are met.

Defects in cured topcoat that are cause for rejection include noncontinuous film; blistering, lifting, and fisheyes; runs and sags; streaks; blushing; film contamination; and gross orange peel.

Primer and Paint Application Equipment. Spray application of primers and topcoats is performed using only high-volume, low-pressure (HVLP) spray gun pressure or siphon feed, or electrostatic spray guns. Interior, hard-to-reach, and limited access spaces are excluded from the HVLP mandatory requirement.
Spraying at a distance of less than 150 mm (6 in.) between spray nozzle and part will cause poor atomization, a distance of more than 250 mm (10 in.) can cause dry spray, or orange peel with gloss topcoats. Figures 12 and 13 show spray painting patterns and common surface finish defects.

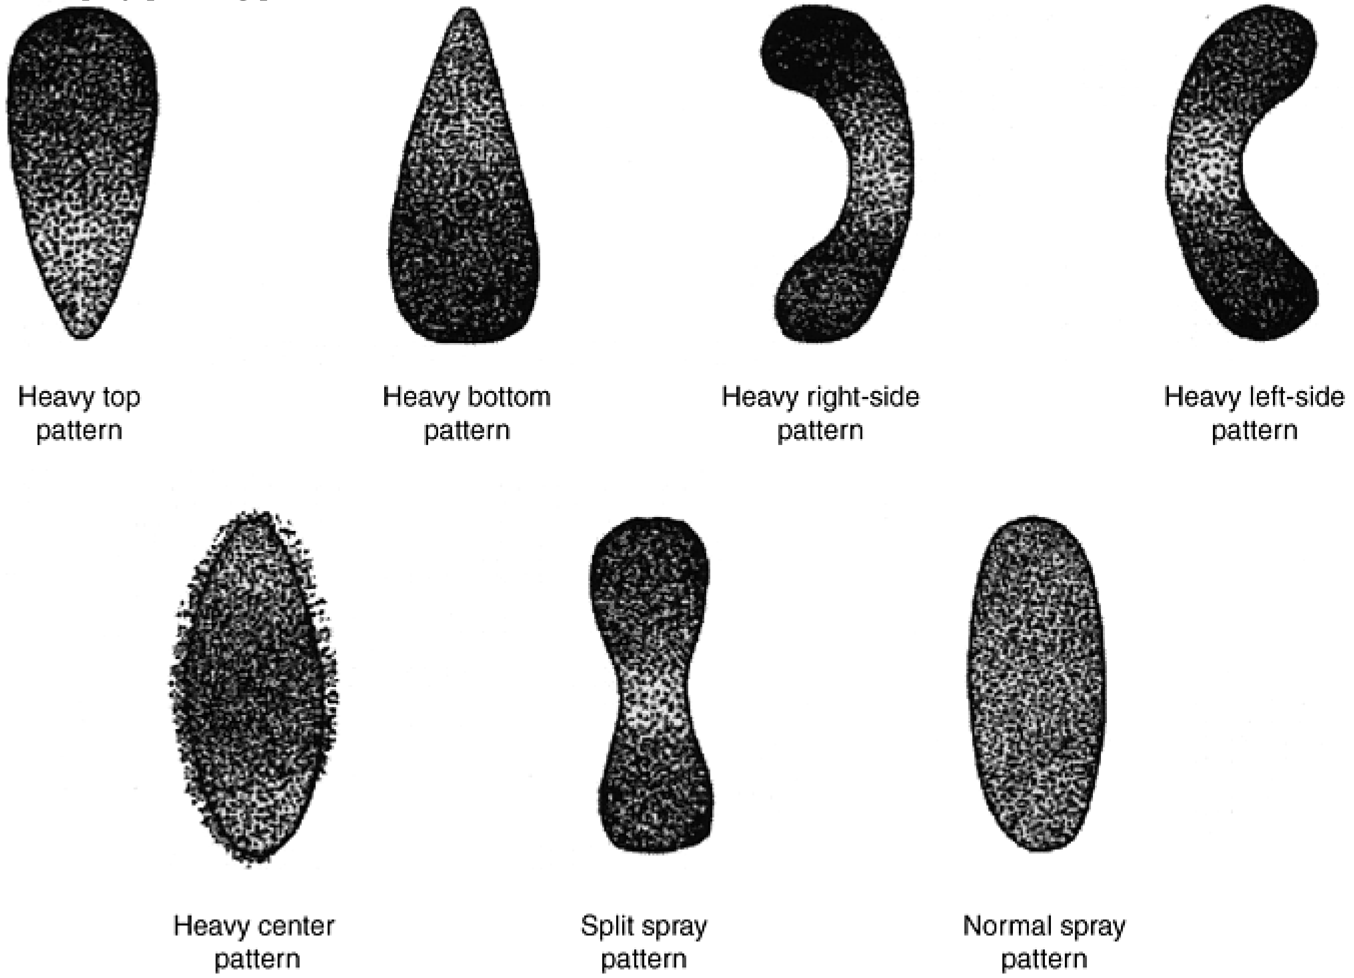

Fig. 12 Spray-painting patterns

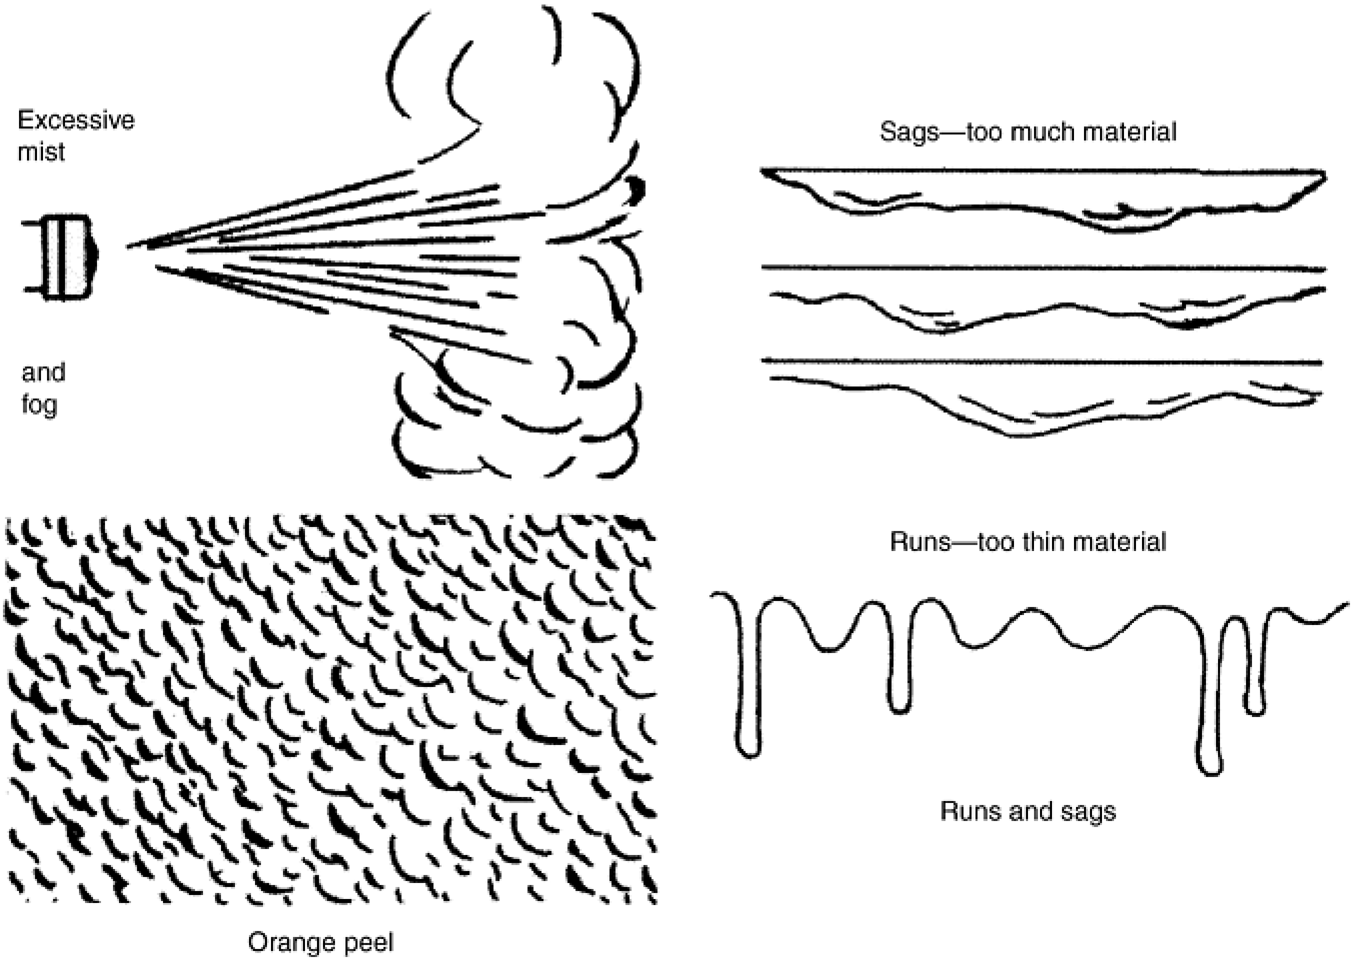

Fig. 13 Typical paint application defects

Maintaining records of the paint and solvents used on the mold line of each aircraft for final painting and paint detail parts by paint booth is recommended. This excludes paints used for markings, insignias, and touch-up. The record should include:

- Aircraft model and unit number
- Date of painting
- Date and time of mixing (for each paint)
- Paint specification
- Vendor name
- Vendor product number, batch number, date of manufacture for each component (i.e., base, curing, solution, thinner)
- Quantity of each component mixed
- Date and time of application of each paint
- Temperature and humidity conditions
- Date and time of aircraft removal from paint shop

Viscosity measurements should be taken only on materials mixed in quantities larger than 3.78 L (1 gal) for use in final painting of mold-line surfaces. Viscosity checks in paint shops are approximate measurements; standard ASTM procedures are not required. All records should be kept on file in accordance with environmental, contractual, and quality assurance requirements or as appropriate.

Chemical safety information on sealants, primers, and topcoats can be found in Material Safety Data Sheets (MSDS), which are required by OSHA Regulation 29 CFR 1910.1200 HAZARD COMMUNICATION to be furnished by the material supplier.

Classes of materials and chemicals that may be toxic, flammable, or otherwise harmful and therefore require appropriate personal protective equipment and safe work procedures include adhesion promoters, paint

removers and strippers, polyurethane paint and coating systems, cleaners, solvents, acids, oxidizers, and alkalines.

Extrusion of Particle-Reinforced Aluminum Composites

William C. Harrigan, Jr., MMC Engineering, Inc.

Introduction

THE EXTRUSION of particle- and whisker- reinforced aluminum composites is similar to the extrusion of the matrix alloy. The presence of the reinforcements increases the shear strength at the extrusion temperature and increases the pressure requirements for the extrusion. The high pressures required for the extrusions and the high shear strength of the composites lead to higher heat generation during the extrusion. Alloys such as 7075 that are susceptible to “hot short” tearing have the same tendencies when used as matrix alloys for composites. Precise billet preheat temperature control and low speed control of the extrusion are necessary to avoid overheating of the composite during the extrusion. Presses designed for “hard-alloy” extrusions are needed for the composites.

William C. Harrigan, Jr., MMC Engineering, Inc.

Dies and Shapes

Extrusions have been made with shear-face dies, conical-feed dies, and with bridge dies. Cross sections of billets with embedded mesh extruded through dies with feed angles between 0 and 75° are shown in Fig. 1.

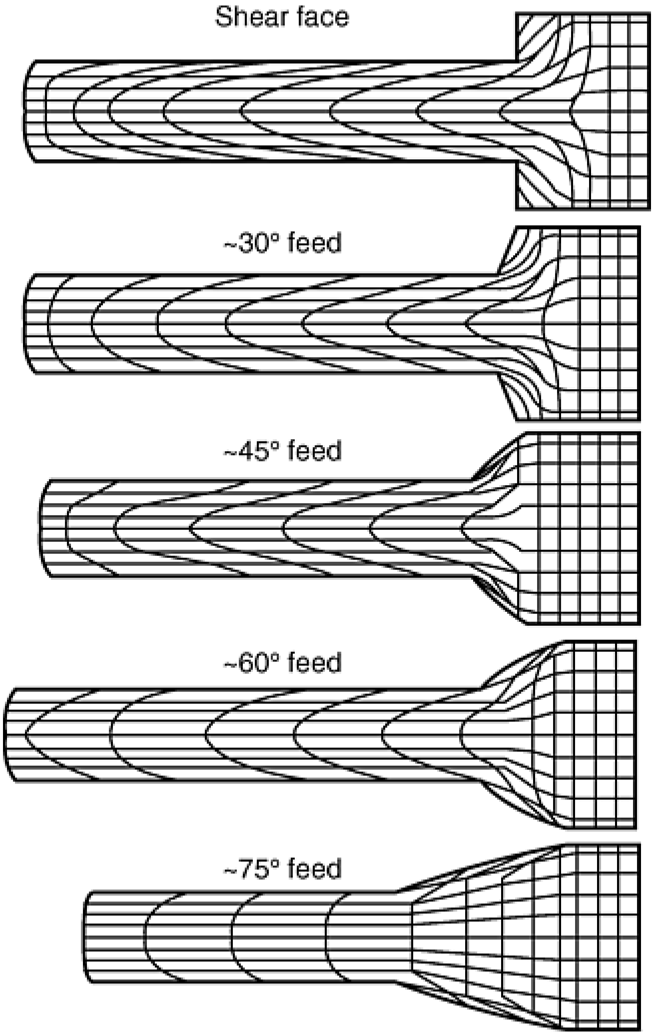

Fig. 1 Cross section of billets with embedded mesh extruded through dies with feed angles between 0° and 75° showing flow characteristics of the various die shapes

The material flow pattern for each of these dies demonstrates the complex flow for the 0°, shear-face die to the uniform flow through the 75° die. The 75°-type die is often referred to as a streamline die. The uniform flow through the streamline dies minimizes damage to reinforcements in whisker-reinforced composites and aligns the whiskers in the extrusion direction. These dies have been used to maximize the mechanical properties of whisker-reinforced aluminum composites in the extrusion direction; however, the mechanical properties in the transverse directions are reduced by the alignment. A further consequence of the streamline die is the greater amount of "butt" loss in the long entrance to the final shape. This material-loss cost must be weighed against the property improvement in any application.

Hollow shapes have been made with forward extrusion with a die and mandrel and with "bridge" dies as well as backward extrusion. An example of a die and mandrel setup is shown in Fig. 2. The hole for the mandrel to pass through may be created by drilling billets or by piercing the billet in the extrusion press. This type of die produces seamless tube. The concentricity of the outer and inner diameters is a problem with this type of extrusion, and precise wall tolerances require drawing the tube after extrusion. An example of a "bridge" or "port hole" die setup is shown in Fig. 3. This type of die produces "seamed" tube that has good wall-thickness tolerance and thin-wall products. Examples of products made with bridge dies are thin-wall tubes for bicycle frame manufacture and a triple- hollow airfoil extrusion used for the exit guide vanes for the 4*xxx* engines produced by Pratt & Whitney Corporation for the Boeing 777 aircraft.

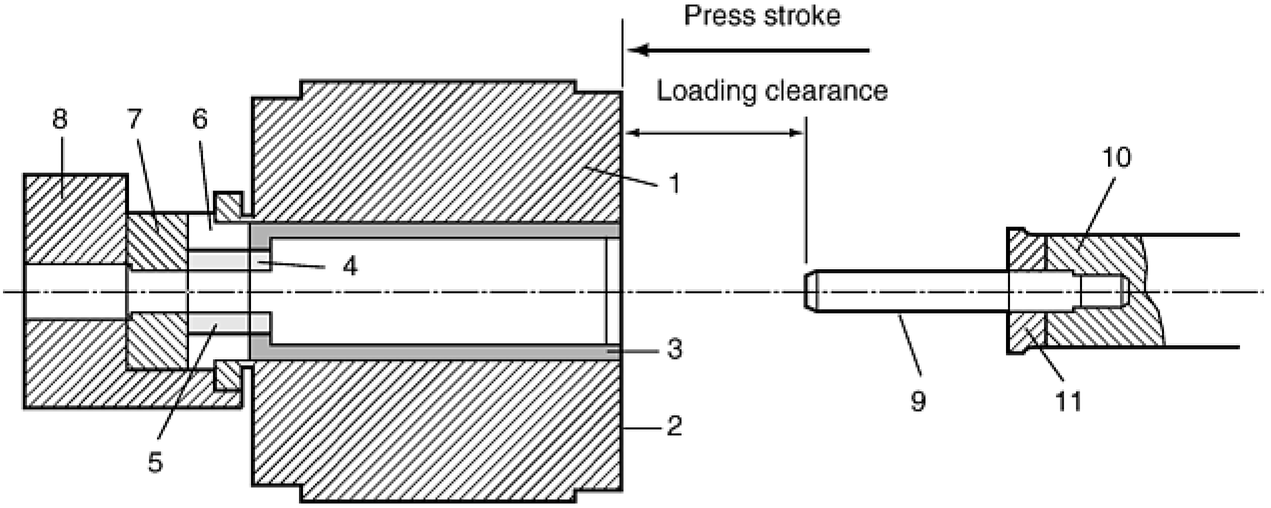

Fig. 2 Schematic of a die and mandrel extrusion setup for producing a single tubular product. Press and die components shown are 1 and 2, container; 3, liner; 4, extrusion die; 5, die backer; 6, die holder; 7, bolster; 8, press body; 9, mandrel; 10, extrusion stem; 11, seal block.

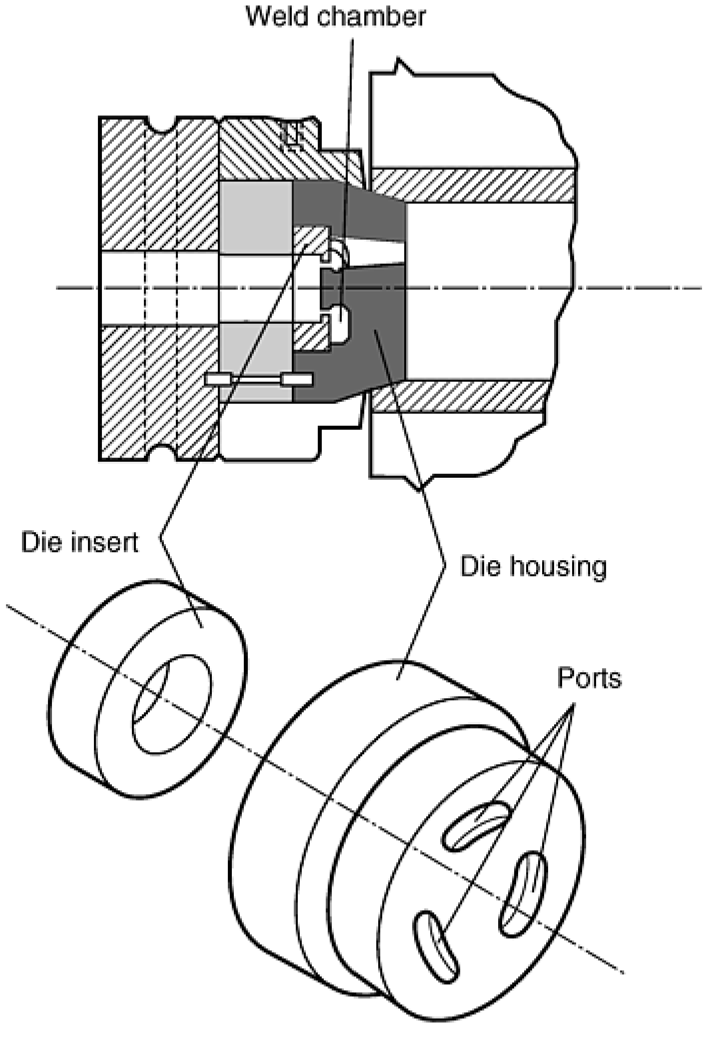

Fig. 3 Schematic diagram of a bridge or port die for extrusion of a shape containing a hollow

Parts have been made with multiple holes per die. A small angle extruded for electronics racks is shown in Fig. 4. A six-hole die was used to produce this part from a 150 mm (6 in.) diameter billet. The multihole extrusion was used in order to keep the area ratio between the product and the container to between 30 to 1 and 45 to 1. This range of extrusion ratios has been found to result in good control of the extrusion process and produces a

product that has well-defined mechanical properties. Extrusions have been made with extrusion ratios between 5 to 1 and 150 to 1 with satisfactory results. This product was solution treated in 12 m (40 ft) lengths, stretch straightened, and aged before being delivered. The amount of stretch is dependent upon the reinforcement level. The angles contained 25 vol% silicon carbide particles and remained in straightness tolerance after 1.5% stretch. Lower reinforcement levels require larger stretch amounts to bring the extrusions into tolerance.

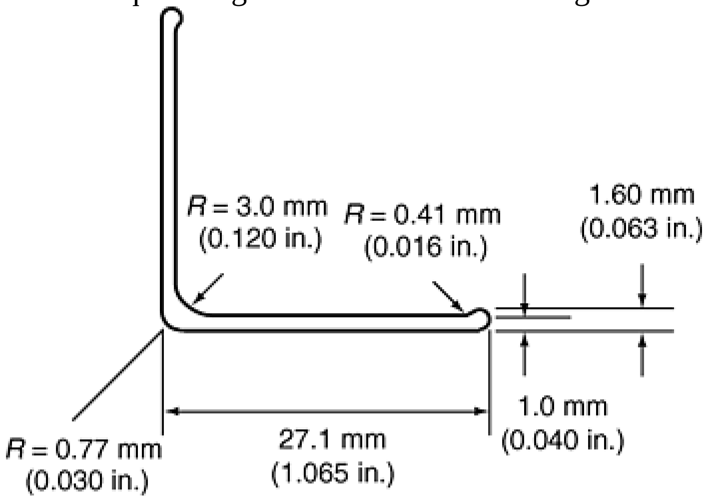

Fig. 4 Drawing of extruded angle for electronic rack. *R*, radius

Extrusion of Particle-Reinforced Aluminum Composites

William C. Harrigan, Jr., MMC Engineering, Inc.

Effects of Reinforcements

The ceramic particles in the composite interact with the dies in two ways. The most immediate interaction is the wearing of the dies by the hard ceramics. The second interaction is the removal of the oxides from the die surface, which allows the clean iron to react with the aluminum matrix. The resulting brittle iron aluminide is very brittle and causes tears in the surface of the extrusions; such tearing includes hot shortness at high temperatures as well as ductility-related tearing at lower temperatures and speeds (Ref 1). The use of surface lubricants and conical dies minimizes the surface reaction, but results in nonsmooth surfaces caused by trapped excess lube. A second way of protecting the dies from the composite is the application of a ceramic coating on the die surface. The first successful coating system was a combination titanium carbide/titanium nitride deposited on the dies by a chemical vapor deposition (CVD) process. The dies need to be heat treated after the coating is applied to them. This coating produces parts with good surface quality while the coating remains intact. The ceramic particles in the composite wear the coating off quite rapidly. Approximately 76 m (250 ft) of 25 vol% composite can be extruded through a coated die before the coating is worn off. Another way to deal with the wear of the composite is the use of insert dies. A steel die body is made to hold a wear-resistant insert that has the desired shape cut in it. Such an insert is shown in Fig. 3. The insert is sacrificial and is replaced when the composite wears the opening beyond the part tolerance. Several materials were evaluated for wear during the extrusion of Duralcan 6061/ Al_2O_3/20p composites. This study (Ref 2) demonstrated that cermet and ceramic inserts resist wear by the composite better than CVD or nitrided steel inserts.

Post-Processing and Assembly of Ceramic-Matrix Composites

David Lewis III, Naval Research Laboratory; M. Singh, QSS Group, Inc., NASA Glenn Research Center

Introduction

POST-PROCESSING of ceramic-matrix composites (CMCs) can be as critical to the successful and cost-effective use of these materials as the processing involved in producing the materials themselves. In only rare cases can these materials be produced in the finished form in which they are used. In nearly all cases, some form of post-processing is required. Post-processing, as defined here, includes those various processes that might be required to produce finished components from the CMC materials, such as:

- Machining or finishing operations
- Coating of the CMCs for thermal, chemical, or other reasons
- Joining of CMCs into CMC assemblies, or joining of CMC components to other components
- Assembly operations involving CMC components and other materials
- Nondestructive evaluation of CMCs, CMC components, or assemblies incorporating CMCs

This is illustrated schematically in Fig. 1. The path followed depends on whether the initial CMC processing is used to produce stock for fabricating components or to produce the components or assembly directly. Note that in the case of direct fabrication of assemblies, there can be significant inclusion of joining technology in the initial processing stage. Joining could include a variety of techniques, such as adhesive bonding, brazing or welding, and assembly with mechanical fasteners.

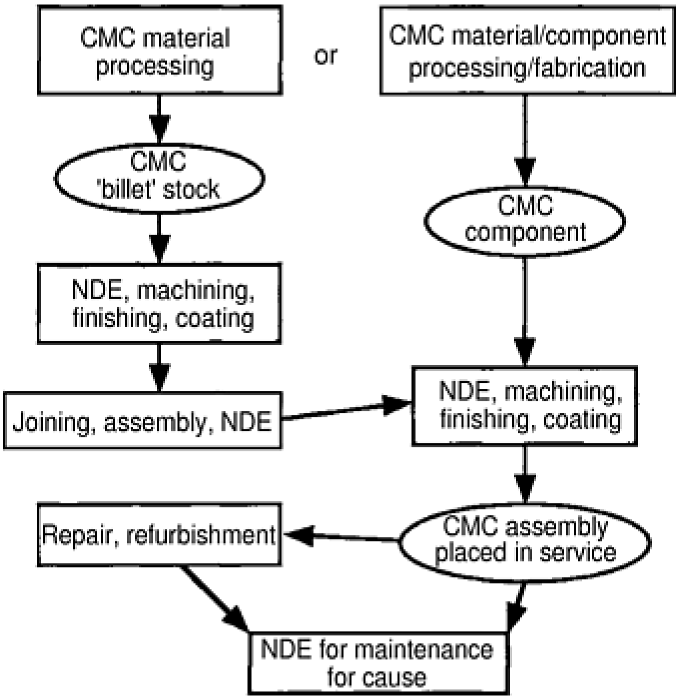

Fig. 1 Flow chart for postprocessing of CMCs, with two possible variants related to use of either "billet" stock followed by conventional processing—machining, joining, etc.—or near-net shape processing with joining during processing. Note occurrence of nondestructive evaluation (NDE) in several different areas of postprocessing.

This article discusses the specific needs for science and technology in these areas, and the current state-of-the-art relative to the goal of employing CMCs in a variety of applications. One comment is appropriate: there is a large body of work relative to post-processing of CMCs and related materials (carbon-carbon [C-C] composites) that is very difficult to access because of classification, export control laws, and research and development that is deemed to be proprietary. There is, for example, extensive work on machining, joining, and coating of C-C composites for various military applications, which could be accessed by those with the appropriate clearances and need to know. The National Aeronautic and Space Administration (NASA) programs on the high-speed civil transport program and its successor on hypersonic vehicles have provided extensive development in the areas noted previously, but much of it is proprietary to the companies involved in the programs. Similarly, there are U.S. Air Force programs for high- temperature CMCs for engines and hypersonic structures and U.S. Navy programs on use of CMCs in various naval applications, such as engine components, that contain much relevant, but rather inaccessible information. The primary obstacle with much of this information is its restricted dissemination under U.S. export control laws.

Post-Processing and Assembly of Ceramic-Matrix Composites

Machining and Finishing of CMCs

Science and Technology Needs. While there are some processes capable of producing CMC components to near-net shape, such as the Lanxide direct metal oxidation process (High Performance Materials Group, MSE Inc., Newark, DE) (Ref 1), various solid freeform techniques (Ref 2, 3), and other techniques, such as injection molding (Ref 4), gel casting (Ref 5), and matrix infiltration into fiber preforms (Ref 6, 7), none of these has the capability of producing components to the tolerances and surface finishes typically required, for example, dimensional tolerances of 2 to 200 μm and surface finishes better than 25 μm root mean square (rms). The Lanxide process is the closest to net shape, producing a product very close in dimensions and shape to a starting

aluminum-ceramic fiber preform, but is restricted in the choice of constituents for the composite. The techniques involving matrix or matrix-precursor infiltration into a fiber preform are limited in precision by two factors: the precision in forming of the fiber preform and the stability and dimensional tolerance retention of the preform during the matrix incorporation and consolidation step. The other techniques cited all involve substantial shrinkage on removal of organic binders and liquids and during sintering to final density. The linear shrinkage involved is typically on the order of 20 to 30% and depends on local density and geometry, thus limiting the precision achieved in the final component. As a result of the problems with various types of CMC processing, post-processing machining will generally be required to achieve the necessary dimensional tolerances, which, of course, depend on the particular application and requirements. Machining may also be necessary to achieve the surface finish required by a particular application; again, this is very sensitive to the particulars of the application. Finally, post-processing machining may be required to achieve contours or geometries not amenable to the particular CMC processing used or more readily done via post-processing.

Available Machining Technology. Unfortunately, in recent years there has been very little in the published literature on this subject, despite a large number of publications of processing and measurements of various properties of CMCs. There is one recent and comprehensive review article (Ref 8) on this topic, and one can find some information in the proceedings of the National Institute of Standards and Technology- sponsored meetings on ceramic machining (Ref 9). The conclusion that presumably can be drawn from this is that conventional ceramic machining procedures, or modifications of such procedures, can readily be used for machining and finishing of CMCs. This has been the authors' experience in approximately 20 years of work on these materials. With the use of appropriate tools, primarily diamond, these materials can be machined nearly as easily as conventional ceramic materials. In some ways, these materials (CMCs) are easier to machine, because they are typically designed for damage tolerance and thus are less susceptible to machining damage, permitting faster machining in many cases. On the other hand, with some types of CMCs, such as unidirectional fiber materials with the fibers weakly bonded to the matrix to achieve high toughness, there is a tendency for fiber pullout when the direction of the cutting media is parallel to the length of the fibers. Very rough machining can produce extensive fiber-matrix debonding and thus damage the CMC.

Some work published on laser machining (Ref 10, 11, 12, 13, 14, 15, and 16) has been successfully applied to other materials in the past. This certainly shows promise for cutting and drilling CMCs with little damage to the materials, but requires modification to existing laser machining systems to achieve the high fluence necessary to ablate or vaporize refractory ceramic materials. Other techniques that have been explored for machining CMCs include ultrasonic cutting and waterjet cutting (Ref 17), both of which have advantages and disadvantages for particular uses. In addition, electrical discharge machining (Ref 18) can be used effectively for composites with sufficiently high electrical conductivity. All of these techniques can be competitive with conventional diamond machining for CMCs, and in many cases, they may be substantially cheaper, because of the high cost of consumables in diamond tooling for CMCs.

It is very likely that with those commercial operations actually using CMC components in systems, standard machining techniques have been developed. However, it may be necessary to wait for a larger and more mature CMC industry before such techniques are not deemed to be valuable proprietary information, and these techniques are set down in handbooks of standard machining practice or disclosed by manufacturers of CMC “billet stock” goods. One additional complication, which is also present in the polymer-matrix composite industry, is the wide variation in the nature of CMCs. These can be made from a wide range of fiber types, fiber architectures, and a wide range of matrices, the effect being that the machining parameters for various CMCs could also vary widely. A commercial entity using CMCs would likely have focused on a single material or related class of materials, where both the processing parameters and those for post-processing could be developed. This information may or may not be applicable to other types of CMCs.

The possibility exists of finishing some of these materials in the green state, where lower- cost tooling (carbide, high-speed steel) can be used, and any damage from the machining or finishing operation can be healed during the sintering or subsequent heat treatment. This may preclude the need for more extensive machining or finishing operations on the final product (Ref 19).

Coating and Surface Treatments for CMCs

Science and Technology Needs. While CMCs have been extensively promoted as the solution to high-temperature materials problems, existing CMCs may, in fact, also need protection themselves to survive particularly aggressive environments, or for other reasons. Most current CMCs are not stable for long periods in environments that attack the fiber-matrix interphase material. For example, the boron nitride (BN) and BN/SiC coatings developed by the authors and coworkers are subject to oxidative degradation, converting the boron nitride interphase from a debond coating into one that bonds the fiber strongly to the matrix, eliminating one of the primary toughening mechanisms in CMCs. In other cases, use of thermal barrier coatings may be necessary, either to protect the CMC itself from extremely high-temperature environments, or, in the case of a high-conductivity CMC, to protect an underlying metal or polymeric structure. There could be other reasons for the use of coatings on CMC components as well, with very different motivations, such as the use of conversion coatings to change the emissivity of the material and control the wavelength of the radiation emitted by the material when hot. This could be of importance for CMCs used as radiators in cooling systems or in heating systems, for example, in radiant burner tubes. There are a number of critical considerations that must be addressed to achieve a successful coating system for a CMC. These include chemical and thermal compatibility of the coating with the CMC, in addition to the coating meeting the requirements for its intended use, for example, effectively blocking oxygen transport in an antioxidation coating. One of the critical needs with coatings that has been addressed is that of the thermal mismatch stresses between a CMC substrate and coating, which can be modeled effectively using finite element methods and closed form techniques (Ref 20). These permit coating selection and design to minimize the stresses, which can greatly limit the service life of a coated CMC component.

Available Coating and Surface Treatments. There are a multiplicity of ways to produce coatings for CMCs, ranging from very low-cost techniques such as fired-on painted, dipped, or sprayed coatings (Ref 21); through techniques such as flame or plasma spraying (Ref 22); to the more exotic techniques such as physical vapor deposition, chemical vapor deposition, and so on. The particular appropriate technique is controlled by two factors—the cost tolerance of the application, and the ability to put down the required coating materials in the desired form. There are also several limitations with regard to some coating techniques, such as difficulty in coating complex shapes, and with the effects of the coating environment (e.g., high temperature and aggressive environment in a chemical vapor deposition reactor, and high temperatures associated with plasma spray). As a last resort, where coatings are impractical or impossible, the CMC itself may be modified to meet the particular requirements, although at some sacrifice in other properties, for example, incorporating oxidation barriers into the CMC itself, rather than relying on coatings (Ref 23).

Post-Processing and Assembly of Ceramic-Matrix Composites

David Lewis III, Naval Research Laboratory; M. Singh, QSS Group, Inc., NASA Glenn Research Center

Joining of CMCs

Science and Technology Needs. Joining is a critical need when either the requisite shapes cannot be produced directly from CMCs, or when the components or assemblies are larger than can be fabricated with the CMC process technology. Effective use of joining typically requires that:

- The joint and joining process does not degrade the properties of the CMC component.
- The joint must be as strong and as durable as the CMC components.
- The joint does not introduce any deleterious residual, thermal, or mechanical stresses.
- Some quality assurance method is available to ensure the quality of the joint after fabrication, and possibly during service.

Joining may also be required to transmit various types of loads, necessitating different kinds of joint designs and joint technologies, for example, shear stresses in large-area lap joints or tensile stresses in butt joints or tee joints. See Fig. 2 for schematic representations of various joint configurations. In the large-area lap joint, shear loads can be accomplished with a relatively low- strength joint, considering the relatively low shear strengths of most CMCs. It is much more difficult with a simple butt joint or tee joint, where the joint material must be as strong in tension as the CMC, which can have very respectable tensile strengths.

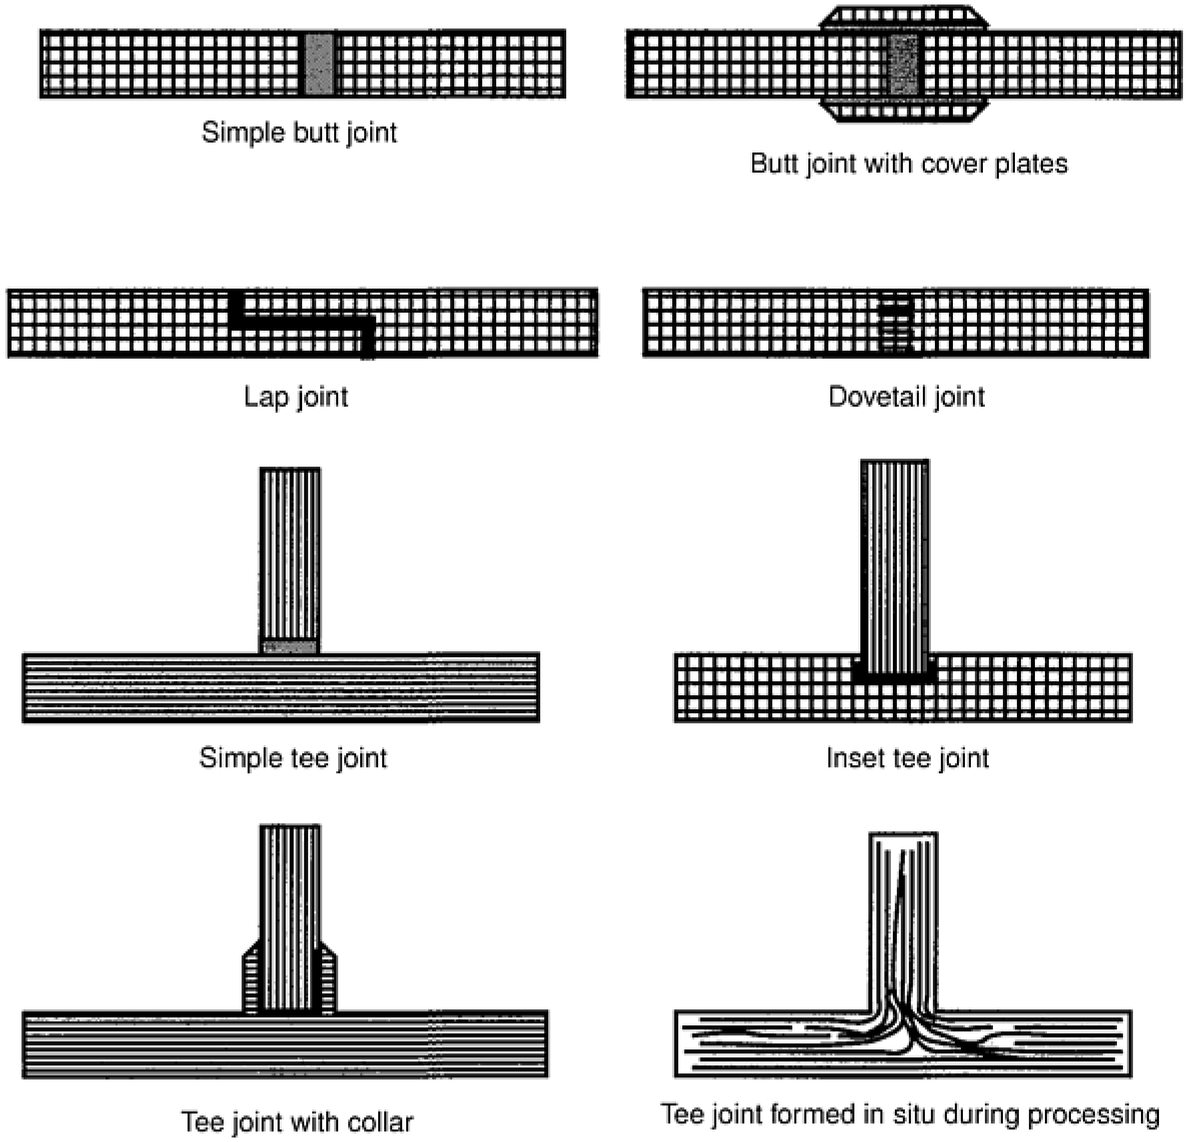

Fig. 2 Schematics of various types of joint designs for CMCs used to carry either tensile or shear loads. Different joint designs involve greatly varying amounts of cost and effort in joint fabrication and have greatly varying joint properties; some joints can be formed during processes such as reaction forming, rather than in postprocessing.

Available Joining Technologies. Joining, as noted previously, can encompass a variety of techniques, as required by application needs or by material and processing constraints. This can include adhesive bonding, which might be appropriate for locations seeing only moderate temperatures, but is unlikely to be used for CMCs, which are typically selected for use at high temperatures. For higher-temperature applications, bonding via glass ceramics and preceramic polymers (Ref 24, 25, 26, 27, 28, and 29) or reaction bonding (Ref 30, 31, 32, 33, 34, 35 , and 36) is feasible and has been widely studied for both CMCs and C-C composites. Some forms of such bonding can be accomplished during the initial fabrication step, as in the use of melt infiltration to join fiber preforms into a complex assembly during the matrix infiltration step. Several examples of this are shown in Fig. 3 for the joining process developed at NASA Lewis Research Center (now NASA Glenn Research Center) (Ref 36) and Fig. 4 for CMC heat exchanger components (Ref 35). Joining of CMC components can also be achieved through mechanical fasteners, where a variety of high-temperature fastening systems has been developed for this purpose. There are extensive research and many publications and reports in this area, both in the open literature and in the restricted literature (Ref 29, 37, 38, 39, 40, 41, 42, 43, and 44). One interesting development has been the use of microwave energy for CMC joining, which has some great advantages over conventional heating in being able to locally heat joints without subjecting the entire assembly to high temperatures (Ref 45). At this point in time, for some classes of CMCs, joining appears to be a relatively mature area, with much technology available from which to choose. Readers should also consult the

article on joining in the previous edition of this Volume (Ref 46), which covers much of the earlier work in this area, and the review articles listed in the references (Ref 47, 48, and 49).

---

Assembly of CMCs

Science and Technology Needs. As noted previously, when CMC components required for applications are either too large to be fabricated in one piece with existing process technology, or the shapes are too complex to be fabricated, or it is required to assemble CMC components and other parts into a large and complex assembly, techniques for doing so will be required, including tooling, fixtures, alignment methods, and joining and fastening techniques. Some of these are probably transferable from metal and polymer-matrix composite technology, but the CMCs may introduce some special problems. These relate to the higher hardness of these materials, which may cause abrasive wear on fixturing and tooling; their higher stiffness and lower strain capability, which reduces the ability to force-fit parts; and their thermal expansion behavior, which differs from that of metallic and polymeric materials, requiring consideration of thermal expansion differences if substantial temperature differences are encountered in the assembly process, as in a brazed assembly.

Available Assembly Technologies. As noted previously, there is very little information published, either in the open or restricted literature, on this topic, though the nature of some programs would suggest that the problems

associated with assembly of CMC components into large structures have been solved, to a large degree. For example, Fig. 5 shows two large disk brake assemblies, one using CMC bolts to join CMC disks, the other using bolts and ribs for the same purpose—to provide internal cooling passages in a CMC brake disk. These two components were produced by assembly and joining of a fairly large number of CMC subcomponents—disks, bolts, and ribs (Ref 35). The U.S. Navy currently uses CMCs in various forms in several aircraft and aircraft engines; these materials are presumably used in hot sections on the various stealth aircraft. Ceramic-matrix composite assemblies are being tested in helicopter engine applications, and CMCs are being actively considered for a number of uses in fusion power systems. In all of these cases, it is likely that the final component must be assembled from a number of smaller subunits, with provision for attachment to adjacent metallic or polymeric structures. Three examples found include two aerospace applications (Ref 50, 51) in the restricted literature, and one related to fusion power (Ref 52). Hopefully, in the future we will see more information published regarding this area of the technology required to use CMCs.

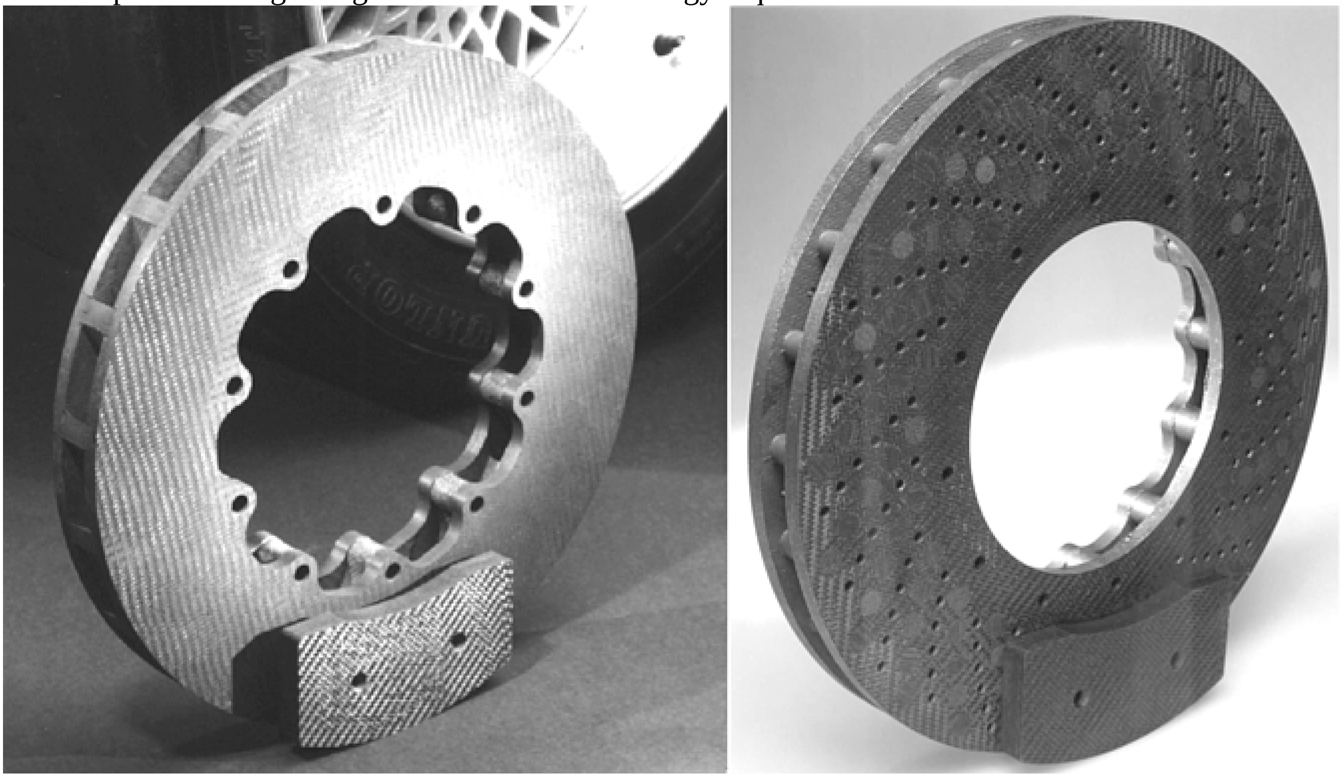

Fig. 5 Prototype C/SiC CMC disk brake assembly fabricated from CMC disks, bolts (right), and ribs (left). CMC brakes are now in use on two German production automobiles and provide greatly improved braking performance over metal disks. Courtesy of W. Krenkel, German Aerospace Research Center

Nondestructive Evaluation

Science and Technology Needs. Nondestructive evaluation (NDE), in its general sense, appears several times in Fig. 1 and is a key need for use of CMCs, especially in critical applications where material or component failure would pose unacceptable risks. Nondestructive evaluation may be desirable in judging the quality of CMC material or components initially produced, and would normally be used as a process control device, if feasible and affordable. In addition, effective NDE techniques are desirable after machining, joining, coating, and assembly operations, again to ensure the quality of the postprocessing steps. Finally, when the CMC component or assembly is placed in service, it may be necessary or preferable to have an NDE technique capable of determining whether, during service, property degradation or some form of damage has occurred that would require replacing or repairing the CMC material. In many applications, where repair or replacement costs are high and the costs of failure in service are similarly high, it is advantageous to have a technique that indicates when a component is about to fail. The component can then be replaced just in time (that is, not too late and not prematurely). In the same vein, if a CMC component is repaired in service, it would be desirable to have an NDE technique capable of judging the success of the repair.

Available NDE Technologies. In this area, there is a very large body of work performed and published, but no definitive results regarding the most appropriate NDE techniques for various types of CMCs. There is extensive work published on ultrasonic NDE (Ref 53, 54, 55, 56, 57, 58, 59, 60, 61, and 62) but no satisfactory way of doing this on large CMC articles. Ceramic-matrix composites are typically very lossy at the acoustic frequencies required to detect critical flaws, for example, 100 kHz to 100 MHz, and it is difficult to couple enough energy into materials to get effective NDE, especially for large components. With the additional complication of complex shapes and rough surfaces, the real need is for a noncontact method for ultrasonic NDE, with sufficient energy input and sensitivity to be effective. However, this does not yet exist (Ref 60). A variation on the ultrasonic method is the use of mechanical resonance measurements, that is, measurement of the complex mechanical impedance of a component (resonant frequencies and width of resonance peaks) (Ref 55, 56, 57, 61, 62, 63, 64 65, 66and 67). This measurement can be sensitive to certain types of defects and in-service damage, and in some cases can be used as an effective process control system and for characterization of in-service damage and degradation. The typical changes seen are shifts in the resonance peaks, broadening of the peaks with defects and damages, and appearance of new peaks with significant defects or damage.

Another NDE technique, which has advantages in being noncontact and capable of large- area coverage but suffers in resolution, is thermal imaging—effectively, a measure of local thermal diffusivity in a material. This has been demonstrated to be useful for detection of certain types of defects in CMCs, where the defects are of sufficiently large size and differ substantially in thermal diffusivity from the base material (Ref 58, 61, 62, 67, 68, and 69). Yet another technique, which has been explored by a number of investigators, is that of microradiography and computed x-ray tomography. These can certainly be effective for detection of relatively small defects, where there is sufficient atomic number contrast, but they suffer from problems with the scale of components that can be characterized (Ref 58, 59, 61, 62, 70, 71, and 72). With conventional x-ray energies, the penetration depth is limited to a few centimeters for most CMC materials, greatly limiting the scale of products that can be characterized in this manner. The solution to this problem, increasing the x-ray energy via synchrotron sources, and so on, is hardly practical for industrial situations. Some other techniques have been explored as well for NDE of CMCs, including neutron diffraction for measurement of residual stresses and in

neutron radiography (Ref 59, 73), the classic method of dye penetrants (Ref 71), and optical techniques employing laser scattering (Ref 59, 62), but with little promise of wide applicability at this point. There are several review articles and comparisons of different techniques available on this subject (Ref 58, 59, 61, 62, and 74). Another good source of information on NDE, at present, is the NDE Working Group at NASA Glenn Research Center (Ref 75), which has had a great deal of experience applying NDE techniques to the CMCs involved in the NASA and Air Force programs on the high-speed civil transport and hypersonic vehicle programs.

Introduction to Quality Assurance

Grover Aaron Henson III, Design Alternatives Inc.

Introduction

THE COMPOSITES INDUSTRY is vast and far-reaching. Technology integration around the globe has enabled materials and manufacturing companies to intermingle ideas in design and development, manufacturing, and, of course, quality. The leading question is always, what is quality? Quality is *flawlessness.*
To achieve flawlessness, a quality system must be in place. This system is initially developed with four critical steps: integration of quality processes and procedures at the design phase, imposed traceability, documented continuous improvement, and *customer satisfaction.*
Quality assurance for composites is progressively changing. Many analysis tools and manufacturing methods continue to be developed to improve the quality of composite products. This Section of the Handbook discusses various quality processes and techniques that readers can implement with some assurance that they are not alone. It also examines various aspects of the quality life cycle, starting with characterization of the fiber and resins through understanding what was manufactured via nondestructive evaluation.

Introduction to Quality Assurance

Grover Aaron Henson III, Design Alternatives Inc.

In-Process Monitoring

The quality of composite laminates has traditionally been determined in the cured state, which does not allow for process correction of a nonconforming condition. The quality of the composite material was based on validating the physical and mechanical properties of that structure after cure. A greater focus now is being placed on understanding the critical resin impregnation process during the fabrication stage. This effort supports the concept of "predicting" quality at the earliest point in the process. Much of the quality analysis performed in year 2000 begins its evaluation at the dry fiber level and continues through to a cured state. The reader is presented the importance of progressing from post-manufacturing inspection/verification (noncorrectable) to in-process inspection/verification (correctable-predictor) methods. This philosophy is critical to process improvement, cost reduction, and schedule enhancement goals.
Validation of composite products to a level of flawlessness begins with the design identification and selection of the correct resin and fiber. The entire manufacturing process must be considered during this selection process, to minimize quality cost and schedule impacts.
Resin studies define the constitution and chemical makeup, which categorizes resins into various families. These families dictate the processing environment requirements, manufacturing properties, and structural application of each resin. This information provides the designer with reliable choices in processing, cost, and life cycle performance.
The fiber selection process takes into consideration design strength and modulus requirements. Typical fiber configurations include continuous and discontinuous, woven, unidirectional tape, and three-dimensional braided preforms. Fiber materials include graphite, glass, aramid, and others. The fiber configuration and material are major components when analyzing the mechanics of fiber-reinforced composites.
Structural integrity requires the correct resin, fiber, orientation, and cure. Material orientation is a critical factor when using composite material for load-bearing structure. The ability to "tailor" material orientation allows the designer to create structure that is lighter weight than traditional aluminum structure. Therefore, verification of lay-up orientation process is key to the structural integrity. Ply orientation is verified and controlled with laser

alignment equipment that guarantees accuracy and repeatability. Use of laser noninvasive verification processes greatly improves process efficiency and quality at the lay- up touch labor level.

The next generation of composite products will embrace more noninvasive methods of in- process validation and verification of material properties. The ideal of reducing and eliminating post-process end-item inspection and verification should be the goal of all existing and potential composite manufacturers. Quality assurance is the facilitator of product conformity to all other support organizations. Quality must be an integral member of the design effort to ensure quality is designed in with minimal impact and maximum benefit to the product.

Grover Aaron Henson III, Design Alternatives Inc.

Quality Assurance Factors

All engineering support groups must understand what constitutes a quality product for all other support groups. Therefore, a typical composite laminate lay-up process would include review and confirmation of the following items:

- Incoming raw material(s) conformity
- Released engineering requirements (includes process specifications and acceptance criteria)
- Approved tooling
- Approved planning documents
- Trained process operators and inspectors to enable self-inspection of ply orientation and configuration location
- In-process controls of critical processes and parameters, such as material out time and cure parameters (time, temperature, and pressure)
- Statistical process control (SPC) data collection of key process variables to ensure process capability and performance
- Nondestructive evaluation
- Verification of dimensional and configuration conformity

Each of these aspects is critical to the quality of a laminate.

Introduction to Quality Assurance

Grover Aaron Henson III, Design Alternatives Inc.

Tooling and Assembly Considerations

Until recently, fabrication procedures for composite laminates were almost exclusively focused on autoclave processing. With the increased focus on next-generation composite processing affordability, out-of-autoclave curing has become a common goal. Processes such as vacuum-assisted resin transfer molding, resin transfer molding, electron beam curing, room- temperature curing, oven curing, and resin-fiber infusion are being adopted to meet the new affordability objectives.

The tooling concepts for out-of-autoclave processing are much more affordable and faster to fabricate. New materials include foam, lightweight wood, pressure-formed thin steel and aluminum, and thin composite materials. This type of tooling approach allows for rapid change capability in development programs and lower cost at the production levels. Longevity and accuracy are among the benefits of these new tooling concepts.

Traditional composite cure tooling is fabricated from steel, aluminum, or high-temperature composite materials. These types of materials are required to withstand the temperature and pressure of typical thermoplastic cure process. Their cost is high, and they require significant lead time to manufacture. Change is not a viable option with conventional autoclave-type tooling.

Year 2000 three-dimensional engineering offers reduced tooling cost by using computer-generated models to dictate radii, control surface geometry, and streamline complex surface contouring. This technology is integrated with numerical-controlled equipment to make tools much faster than conventional methods, as well as real-time inspection capability.

Process operators are becoming the "process owners," because they provide source-controlled quality based on real-time SPC data. Data are collected real time as the process runs, and the operator is notified to make authorized adjustments to the process to maintain conforming product. All of these features are effective in reducing the time required to manufacture new tooling and in eliminating end-item inspection.

As various industries explore the fabrication techniques of larger unitized structures for aircraft, ships, and other transportation vehicles, monitoring and controlling the composite laminate is essential. Less and less is the quality (flawlessness) of a laminate totally in the hands of the materials manufacturers, because resin infusion is becoming real time during the final fabrication stage. Several methods have been developed for real-time monitoring and controlling of liquid molding processes. The objective is to have real-time knowledge of resin location during processing. Combining resin monitoring with flow modeling greatly reduces or eliminates end-item inspection.

As these industries evolve to use larger structures, in-process inspection of bonding quality of joints begins to play a vital role in the unitization of structures. The quality arena is again challenged with the verification of joint quality, the understanding of contaminates, and the levels of acceptability. Methods to detect and verify them are being studied and expanded.

Adhesive bonding is a very complex arena; it has proven to be extremely difficult to gain acceptance in many of the high-tech markets. Many aspects of the bonding process come into play when analyzing structures for bonding compatibility, including bonding surface tension, surface preparation, roughness, contaminate levels, moisture content, and surface conditioning. In high-tech markets, all aspects have to be monitored and controlled to verify quality and to maintain and expand the use of composites for critical applications. For less-demanding applications, these aspects must be monitored to improve scrap rates and reduce returns.

Introduction to Quality Assurance

Grover Aaron Henson III, Design Alternatives Inc.

Quality Assurance for Commercial Applications

Composite materials are becoming increasingly common in commercial products, such as bicycles, baseball bats, golf clubs, tennis rackets, automotive parts, and high-performance water and land race vehicles. The commercial industry uses approximately 65% of the graphite fibers produced, with aerospace companies and airframe manufacturers using the remaining 35%.

Commercial market requirements on quality are normally less demanding than for aircraft and transportation businesses. Nevertheless, control of the processes is still very important in reducing scrap-related costs. Industries that use advanced materials systems to build products for aircraft and other transportation markets are driven by structural integrity requirements. These industries recognize the need for structural validation and the necessity of continuous advancements in nondestructive analysis. There have been great strides in understanding and characterization of flaws, increasing our ability to identify and locate delaminations, voids, matrix cracking, and porosity in composite structures.

Grover Aaron Henson III, Design Alternatives Inc.

Nondestructive Testing and Data Fusion

In year 2000, nondestructive inspection/test methods such as pulse-echo and through-transmission ultrasonics are the technologies of choice in determining composite quality. Continuous improvement research has developed additional inspection methods, such as leaky Lamb wave, polar backscattering, nonlinear acoustics, ultrasonic, radiography, computed tomography, and infrared thermography, to name a few. The continued development of these technologies could effectively make huge improvements in some markets.

Data fusion systems are designed to provide nondestructive analysis data from fabrication and assembly processes for each individual composite part. The importance of these systems cannot be underestimated; collecting this manufacturing data provides not only a historical record (traceability) for fabrication and assembly, but, when properly mined, can also provide an essential source of information for engineering process analysis. Material review boards can use this technology to provide a data-supported disposition for "reworked" or "accept-as-is" nonconforming conditions.

Data integration systems will someday provide a single source of process information that can be used to determine product quality acceptance. The vision is that this technology will allow for in-process product acceptance without operator intervention. Statistical process control tools will play a vital role in the implementation of this technology. The "key" controllable process parameters can be monitored to provide the opportunity to disposition potential nonconforming conditions at the "correctable" level in the process. This concept is the "adhesive" that will bind all process quality elements to one source.

Introduction to Quality Assurance

Grover Aaron Henson III, Design Alternatives Inc.

Conclusions

The articles in this Section have been written with the objective of sharing years of experience and technical knowledge. Many of the writers are renowned in their industries for being innovative and creative. Much of the technology is proven as of year 2000; however, some of the next-generation methods described are in their experimental state. The reader is encouraged to satisfy curiosity raised by this Volume by consulting the references cited in the individual articles that follow. The reader should endeavor to understand the level of maturity of the processes described and judge their merit for the application being considered. The future of composites quality will be guided by those who share and embrace the concepts described in this Handbook.

Resin Properties Analysis

John D. Russell, Air Force Research Laboratory

Introduction

MOST RESINS USED IN COMPOSITE MATERIALS are blends or systems of ingredients, each of which is added to give some desired benefit for processing or for properties of the cured composites. Tests are performed on the resin in all stages of composite fabrication, including individual component materials, mixtures of ingredients that later become part of the final blend, the blend in its final composition, b-staged resin on impregnated fabric, and cured resin in a composite laminate.

Polymers with chemically different functions are used to categorize resin families. Early industrial polymers were resole type phenolics and polyesters based on styrene condensation. Epoxy and bismaleimide-based polymers are the most common resins used today in the aerospace industry. Other systems including polyimides, cyanate esters, polysulfides, and vinyls are used for specialized applications. This article focuses on epoxy because this resin category has widespread use and because it is tested using quality control measures typical of most resin systems.

Resin Properties Analysis

John D. Russell, Air Force Research Laboratory

Component Material Tests

Since each component of a resin system contributes to the final properties of the composite, it is essential to identify the individual component properties, define acceptable measurement ranges, and use appropriate test methods to determine these properties. A typical resin system will consist of one or more epoxy resins, a curing agent (such as an amine or anhydride), and a catalyst to control the rate of reaction. In addition, fillers or additional modifiers may be used to alter specific properties. Typically, the resin manufacturer will perform testing on the individual components of a polymer blend.

Resins

Resins may be tested to determine chemical content, moisture content, thermal behavior, chemical functionality, and other characteristics.

Epoxy per Equivalent Weight (EEW). Epoxy resins are chemically reacted to determine the epoxide content per unit weight of resin by wet chemical titration. Epoxide content is a measure of potential crosslink density.

Hydrolyzable Chloride. Epoxy resins are frequently made from chlorinated compounds. Any residual hydrolyzable chloride compound can poorly affect the reactivity and therefore the cured resin properties. The chloride content is measured by titration of a soluble sample.

Moisture. Since epoxies are hygroscopic and since absorbed moisture affects reactivity, moisture content is measured by drying or by titration using a Karl Fisher apparatus.

Melting Point. The melting point temperature of the resin influences how it is processed, and it should be measured using a calorimetric or dilatometric technique.

Softening Point and Viscosity. Because the viscosity of the resin affects system processibility and can be a measure of average molecular weight, the point at which the resin softens should be measured using a technique such as a cone and plate viscometer, a Brookfield viscometer, or a dilatometer.

Infrared (IR) Spectroscopy. This test is a rapid method for identifying chemical functionality, which is useful in differentiating epoxies with similar EEWs. A thin film of resin is placed on a crystal, and IR light is passed through the crystal and film at varying frequencies. Functional groups absorb at certain defined frequencies. The test is usually qualitative, but because absorption is proportional to quantity and intensity, quantitative results are also possible. This technique can also identify impurities or advancement of the polymerization reaction that may affect overall reactivity or final resin properties.

High-Performance Liquid Chromatography (HPLC). This test is performed by dissolving the resin in a solvent and depositing it into a packed column. The resin is then eluted selectively using a polar-nonpolar solvent mixture. This selective elution occurs as the equipment changes the ratio of solvents in a closely programmed system, providing a highly reproducible chromatogram. The detector is usually either an ultraviolet or refractive

index technique. Separation is also possible by diverting selected fractions during elution. Like IR, this technique can identify impurities or advancement of the polymerization reaction that may affect overall reactivity or final resin properties.

Gel Permeation Chromatography (GPC). This test is similar to the HPLC test except that it displays separation by molecular weight groups rather than functional groups.

Other Techniques. Gas chromatography, mass spectrometry, and nuclear magnetic resonance (NMR) can be used in organic synthesis and to identify unknown organic mixtures but are not routinely used for quality control.

Curing Agents

Curing agents can be liquids or powders. An amine equivalent test should be performed in which liquid or solid amine curing agents are dissolved in a liquid media and titrated to determine the number of reactive hydrogens per unit weight. Techniques are available to determine primary, secondary, or tertiary amines. Reactivity decreases as the available hydrogen atoms move from primary to secondary. Only ammonia has an available third hydrogen. However, amines form what is known as quaternary salts with an anion, which can change the behavior of the material. Other analytical and chemical tests, such as IR, ultraviolet analysis, GPC, and melting point determinations may be used to determine the quality of the curing agents.

Catalysts

Many catalysts of epoxy reactions are molecular complexes with a Lewis acid, which is usually BF_3 and a tertiary amine. The complex is a quarternary salt, with the BF_3 acting as the anion and the amine acting as the cation. Tests include atomic absorption to quantitatively determine boron concentration; moisture to assess water content, which tends to degrade the complex; and IR, to identify the amine form.

Fillers and Modifiers

Fillers are often used in the form of ground or pulverized inorganic materials to improve dispersion and reactivity or provide increased surface area for flow control. Screens of increasing size are stacked to separate the particles by size. Finer particles can be evaluated by particle analysis, whereby the sample is dropped in a liquid and the rate and quantities of falling particles are measured optically. Very fine particles can also be analyzed in a column of controlled dry gas, using a sensitive balance to plot weight gain versus time.

Typical modifiers include:

- Flow control agents, such as finely divided silicon dioxide, clays, and high molecular weight polymers
- Tack enhancers, such as low molecular weight resin or polysulfide, a naturally tacky resin
- Adhesive ingredients, such as soluble rubbers, polysulfides, and dienes
- Flame retardants, such as halogenated resins with cobalts, phosphates, and other inorganic materials
- Color agents, such as pigments and dyes
- Toughening agents such as thermoplastic particles

Resin Properties Analysis

John D. Russell, Air Force Research Laboratory

Mixed Resin System Tests

After the components are mixed, tests are performed to document the presence of each ingredient and to ensure that the proper chemical reaction state has been obtained. These resins can be used to make preimpregnated

reinforcing fibers (prepreg) or to infiltrate a fiber preform via resin transfer molding, vacuum assisted resin transfer molding, or resin film infusion. Testing on the resin blends are performed by either the resin manufacturer or the end user.
Gel Time and Viscosity. Gel is defined as the point when a three dimensional polymer network is formed. At this point, the viscosity of the polymer is essentially infinite, meaning the resin will neither flow nor wet out the dry or precured surfaces. Various techniques are available, including a Brookfield viscometer with thermocel, a cone and plate viscometer, and a rheometer type viscometer using oscillating parallel plates. Knowledge of gel time and viscosity is useful for predicting resin shop life and for determining resin cure characteristics.
Moisture tests are performed on neat resin using a titration method known as Karl Fisher. A moisture meter with P_2O_5 is also available to measure moisture.
HPLC and IR. Both chromatographs and spectrograms are used to "fingerprint" the resin blend. These techniques are also used to identify impurities or polymerization reaction advancement that may affect overall reactivity or final resin properties.
Solids and Volatile Content. When the resin is in a solution impregnation, the solids level is measured by evaporation of the solvents in an explosion-proof oven.
GPC. A chromatograph is used to define and fingerprint the molecular weight distribution of the resin. Reaction advancement can also be determined by this method.

Resin Properties Analysis

John D. Russell, Air Force Research Laboratory

Prepreg Tests

Resins that have been impregnated onto fibers are placed there via a solvent bath or by melt infusion. In either case, the resin can be heated, resulting in advancing the polymerization reaction to some degree. The resulting resin is referred to as ***b-staged*** resin. Both the manufacturer and the user typically run these tests to ensure that the prepreg contains the proper amount of acceptable component materials to meet user specifications.
Gel Time and Viscosity. Knowledge of gel time and viscosity is useful for predicting resin shop life and for determining resin cure characteristics. It is also useful for looking at an increase in molecular weight caused by resin advancement during the prepreg process.
IR Spectroscopy. This test is repeated on the resin after impregnation to ensure that no major change has occurred. Although the test is usually qualitative, techniques can be developed to obtain quantitative results.
HPLC. This test provides a signature of the components, separated by chemical functionality. Both quantitative and qualitative results can be obtained.
Atomic Absorption. When inorganic ingredients are used, they can be measured at low levels by atomic absorption.
Resin content. The amount of active resin, including the volatiles, is determined using acid digestion or by burning the resin off of the fibers. This test is used to determine if there is enough resin available to form suitable composite components. The quantity of active resin is expressed as a percentage of the total weight.
Volatile Content. For epoxies, the volatile level is usually less than 1% and results from residual solvents in any upstream process as well as absorbed water. Some resins, such as phenolics and polyimides, contain substantial volatiles in the form of water and alcohol reaction by-product or high boiling point solvents such as n-methyl pyrrolidone. Generally, a sample of prepreg is heated for a specified period of time at or near the temperature where volatile by-products are evolved. The weight before heating is compared to the weight after heating. Volatile content is expressed as a percentage of the original weight.
Fiber Areal Weight. This parameter is the weight of dry reinforcing fiber in the prepreg per unit area. The fiber weight, in conjunction with the resin solids content, allows the manufacturer and user to predict the theoretical ply thickness and the resultant fabricated part thickness. This property is obtained from the same sample as the resin content.

Resin Flow. Samples of plied product are exposed to pressure and heat (sometimes with bleeder) to measure the resin lost because of the flow of the resin at a specified temperature and pressure condition.
Tack. This test evaluates a subjective sticky characteristic of the prepreg. The most widely used test requires that a ply of prepreg be "tacked" to a tool and that subsequent plies be tacked to the first ply. The normal requirement is that the second ply shall be capable of being removed and repositioned if necessary. Tack is affected by many factors, including type of resin, resin content, and degree of resin advancement; temperature, and humidity (most epoxies are hygroscopic, and absorbed moisture increases tack). Therefore it is important to specify the conditions and methods of evaluation. Tack causes more problems for both the manufacturer and user than any other prepreg characteristic.
Drape. Like tack, drape is subjective. It is also greatly influenced by tack. Drape is the ability of a prepreg to be formed around defined radii and stay tacked to the tool for specified periods of time.
Room Temperature Out Time. This parameter is the period of time at ambient temperature for which a prepreg can maintain enough tack and drape to be used to make components in the production environment. This is important for building large parts by laying up prepreg. This could take several days depending on the part, and the resin must not have advanced beyond a usable level.
GPC. This technique is used for resin control after prolonged out time or storage to determine whether the resin has advanced beyond a usable level.

Resin Properties Analysis

John D. Russell, Air Force Research Laboratory

Cured Resin and Prepreg Mechanical Properties

Mechanical properties that are typically measured during the development and use of an epoxy resin system are shown with the appropriate test methods in Table 1. Because these properties form the basis of subsequent composite properties, the tests are often performed on composite samples as well as neat resin samples. These properties are also frequently measured after exposure to moisture saturation, to chemical exposure, to thermal exposures, and to impacts at a known energy level.

Table 1 Typical resin and prepreg property tests

Property	Test
Tensile strength, modulus, and strain	ASTM D 651 for resinASTM D 3039 for composite
Poisson's ratio	ASTM E 132
Compressive strength, modulus, and strain	ASTM D 3410
In-plane shear strength, modulus, and strain	ASTM D 3518
Flexural strength and modulus	ASTM D 790
Impact toughness	ASTM D 3398
Fatigue	ASTM D 256 or user defined test
Density	ASTM D 1895
Thermal properties, including glass transition temperature, coefficient of thermal expansion, and weight loss at temperature	User defined
Chemical exposure to acetone, chlorinated solvents, oils, hydraulic fluids, jet fuel, body fluids, alcohol	User defined
Moisture effects	User defined
Flammability	User defined

Many test procedures are defined by ASTM methods. Any prior conditioning parameters are typically defined by the ultimate end use to which the composite will be subjected in actual service and are specified by the user.

Tooling and Assembly Quality Control

Introduction

TOOLING AND ASSEMBLY METHODOLOGIES for advanced composites have steadily improved as a result of advancements in materials, through the use of computer-aided design/computer-aided manufacturing (CADCAM) technology, and through application of sophisticated design for manufacturing and assembly concepts. This article reviews techniques and technologies that are used to control the quality of tooling and assembly methods for composite components.

Tooling Quality Control

Jeff L. Ware, Lockheed Martin Aeronautics Company—Fort Worth

Fabrication methodologies for advanced composite tooling have benefited from advances in tooling materials and through the use of CADCAM technology. The thermomechanical properties of tooling materials have evolved such that they more closely match those of the production part to be fabricated. In addition to improvements in materials properties, today's tooling materials offer lower fabrication and materials costs. The advancements in CADCAM models have also provided opportunities for improved fabrication and inspection methods.

The use of CADCAM (also known as three- dimensional, or 3-D, engineering) technologies have helped to eliminate many of the conventional tooling methodologies once widely practiced up until about 1990. Conventional tooling methods of hand fairing plaster or plastic faces over aluminum lofting templates for fabrication of master models and then producing secondary control tools from reverse splashes are being replaced with electronic master models that exist in a computer-generated engineering tooling model. The 3-D engineering models provide all the control surfaces and coordination points to fabricate tooling associated with the engineering part. The 3-D engineering part model provides the tooling fabricator with the ability to design, plan, and program the data as needed. Often these data are fed into recognition databases that support numerically controlled fabrication and inspection work centers, including multiaxis machining and cutting centers, and high-precision measurement systems.

The advancements in electronic modeling, and the use of 3-D engineering models have shifted the conventional inspection methods from the inspector to the machinist or toolmaker. The inspector's role in relation to dimensional criteria has been greatly reduced, and in many instances, placed with the operator. The requirements for quality control are still as prevalent today as they were in the past, but the emphasis on quality control for the tool has shifted from a check of the end product quality to one of in- process monitoring. The use of sophisticated software and optimization programs along with modern fabrication and inspection systems means that the owner of a particular task (for example, designer, numerical control programmer, machine operator, or toolmaker) can readily inspect his or her own work by comparing the actual measured data to an engineering model. Toolmakers can fabricate and assemble details, perform and record in-process inspections of their own work, and provide inspection reports showing the actual tolerance conditions for acceptance by the inspector or auditor.

The tooling inspector's role is changing from one involving conventional hands-on dimensional and process inspection to that of an auditor. These new responsibilities include verifying engineering data for compliance through electronic configuration management systems, performing visual inspection according to preestablished inspections criteria, performing random in-process inspections, verifying traceability of materials certifications, and assuring that the quality records for the tool meet the company and customer requirements.

Due to the complexity of some inspection systems, a company may elect to have a quality inspector or auditor perform the inspection while operating equipment such as coordinate measuring machines and laser imaging systems. The following sections in this article cover typical quality control points that an inspector or auditor would review during the fabrication of a tool used for curing advanced composites.

Documentation

The tooling inspector's or auditor's role in assuring quality control documentation of the tool fabrication process is mostly confined to the tool planning sheet or tool shop order. The planning sheet or shop order may be documented on a paper system or may reside on an electronic retention system. In the case of large or complex tools, a tooling logbook is used in conjunction with the tool planning sheet or shop order. The tooling logbook contains the complete work history of the tool, including changes that occurred after the tool was fabricated and any periodic inspections. It should remain with the tool or should be filed in the tooling shop office. The logbook is a good resource when trying to determine what has happened during the life of a particular tool. A third form of quality control documentation is a separate inspection buy-off sheet, which is used when a detailed planning sheet or shop order is not provided to build the tool. In the fabrication of a composite tool, whether graphite-epoxy prepreg or a wet lay-up is used, certain checkpoints can be universally used as inspection verification points through the fabrication of the master model, the pattern taken from it, and the composite tool made from the pattern.

Hand-Faired Master Models

When building a master model from plaster or hand-faired epoxy, the primary areas of concern to the inspector or auditor should include the following:

- *Base plate:* The base plate should be flat and without twist; this should be verifiable using a coordinate measuring machine (CMM) or manual measurement method.
- *Templates:* Each should be within tolerance on its contour.
- *Reference system:* If scribed on the base plate, it should be correct and within tolerance. If an optical reference system is used, it must be verified, and the date of optical equipment calibration must be checked.
- *Rigging:* The riggingshould be checked to verify that the rigged templates are located properly and are vertical (not bowed or twisted).
- *Faired surface:* The surface should be free of flat spots, dips, and irregularities.
- *Scribe lines:* Trim and reference lines should be verified and checked for sharpness.
- *Final contour check:* It can be verified in its entirety through the use of a CMM.
- *Master documentation and identification:* These are the final items to be checked.

Machined Master Models

The inspection process is streamlined considerably when inspecting master models that have been machined on a computer numerically controlled lathe or mill. The inspector or auditor basically checks to confirm that no gross programming errors (such as the slip of a decimal point) have been made, and determines whether any items should be added to the tool after machining, such as scribe lines and identification. On smaller and simple machined master models, hand-held precision instruments, such as dial calipers and height gages, can be used to check dimensions. Templates are used to show any discrepancies in contours. A CMM, if available, can be used to check contours, hole locations, and scribe lines.

On large or complex machined master models, the contours can be checked with templates or with a CMM. To verify the proper location of tooling holes, scribe lines, and reference point templates, a CMM or optical measuring equipment can be used.

Second-Generation Patterns

When a pattern is to be taken from the master model, the inspection is similar to that for a plaster splash, plastic-faced plaster, or epoxy laminate. This is true for inspection both before and during fabrication of the pattern.

Before releasing the master model in order to make the pattern, the inspector or auditor may verify that:

- The surface of the master model is in an acceptable condition. It should be free of chips, cracks, or other surface blemishes that will affect the surface of the pattern.
- The required reference lines are clean and complete.
- The master reflects the latest engineering changes verifiable through the company or customer's configuration control management system. If the master model does not incorporate the latest engineering changes, it may be futile to fabricate any tooling from it.

The inspector or auditor may also verify that the toolmaker has the correct location on the master model taped off for his pattern and that it is large enough to make a tool, as determined by the tool-planning sheet. During pattern fabrication, the inspector or auditor should be concerned with each of the areas described subsequently.

Release. The master model should be released properly because it is critical that its surface be preserved for future tooling. A poorly released tool will usually result in destroying the master model tool face and destroying the transfer tool.

Fabrication. If a company or the customer has a formal fabrication procedure and requires that all patterns be fabricated according to the procedure, then the services of the inspection department are to ensure that the quality requirements of the company or customer are met.

Preremoval Inspection. Before the pattern is removed from the master model, an inspector/ auditor should verify that the pattern has received the proper cure time and is tight to the surface of the master model. This indicates that no warping or twisting of the pattern occurred during cure. If it is difficult to see the edge where the surface of the master model and the pattern meet, the inspector can use a 0.05 mm (0.002 in.) feeler gage to determine if the pattern has lifted off the master.

Cleanup and Scribe Lines. After the pattern has been pulled from the master model, its surface should be cleaned of any release residue, and the scribe lines, which are now high male lines, will have to be reversed back into the surface of the pattern. This reversing procedure is critical and should be monitored to verify that the scribe lines are within the tolerance of the original lines. This can be accomplished by leaving 6.4 mm (0.25 in.) long male witness lines every 75 to 100 mm (3 to 4 in.). After verification, these lines are then reversed.

Composite Tooling

Graphite/epoxy or high-temperature glass cure tools generally fall into two categories:

- Wet lay-up tooling
- Tooling consisting of prepreg face sheets with a composite laminate eggcrate or tubular back-up structure

The inspection criteria are generally the same for both except that wet lay-up tooling requires a gel coat. The inspector or auditor may inspect the gel coat for thickness and proper gel time prior to the application of the first ply of fabric by the toolmaker.
The inspector or auditor must check or verify the following items:

- Quality of the control tool through the use of a CMM or by some other method before lay- up begins
- Control surface finish
- Scribe line depth and uniformity
- Bushing installation
- Identification of tools, thermocouple connectors, vacuum connectors, tooling and control bushing holes
- Vacuum integrity while under vacuum, service temperature, and autoclave pressure
- Compliance of the tool to the design and/or to fabrication specification manual
- Materials certifications
- Materials out-time logs
- Documentation regarding waterjet or laser cutting of support structure
- Surface control data forms high-precision measurement equipment
- Fabrication planning for compliance of each operation and completeness in the tool build process

Tooling and Assembly Quality Control

Metallic Tooling

Metallic tooling made from Invar (a low- expansion iron-nickel alloy), steel, aluminum, and electroplated materials are becoming more popular for production composite cure tools. Metallic tools generally cost more than a composite wet or prepreg lay-up tool, but offer some advantages by eliminating the need for control/ transfer tools, by extending service life, and by providing higher durability characteristics.
The inspector or auditor is responsible for checking or verifying the following items for metallic tooling:

- Surface finish through the use of visual or manual means
- Scribe line depth and uniformity
- Bushing installation
- Tool identification and identification of thermocouple connectors, vacuum connectors, and tooling and control bushing holes
- Vacuum integrity of the tool while under vacuum; service temperature and autoclave pressure
- Materials certifications
- Weld and weld heat treatment quality assurance through the use of penetrant, magnetic particle, ultrasonic, or visual inspections according to the relevant specification manuals or tool design requirements

- Surface control data from high-precision measuring systems
- Fabrication planning for compliance of each operation and completeness in the tool build process
- Compliance of the tool to design or fabrication specification manual requirements

There are other types of composite tools, such as bond, drill, trim, and assembly fixtures. Inspection of these types of tools will vary from type to type. The general responsibility of the toolmaker and of the inspector or auditor to build in quality will remain the same, regardless of the type of tools and the materials used. Technology advancement will continue in the development of software and support systems to assure compliance to design standards and to facilitate the involvement of all development and fabrication personnel in the quality process.

Tooling and Assembly Quality Control

Composites Assembly Quality Control

Robert Moore and Dennis Bowles, Northrop Grumman Corporation

Composite assembly methods often rely on the use of metallic fasteners for joining composite details and assemblies. Fastener installation usually requires hole drilling and countersinking of the composite material, which necessitate attention to quality issues such as delamination around holes and hole surface quality. The continued use of complex and costly "old school" assembly tooling and fixturing technology further complicates quality assurance of assembly operations. However, the on-going implementation of "up stream" assembly process enhancements has provided significant benefits in the areas of design and detail fabrication. Process improvements include, but are not limited to, the use of co-cured laminates, co-bonding of details, and the development of liquid molding processes. These improvements benefit assembly processes by enabling the incorporation of part details into larger subassemblies, thus reducing "down stream" assembly requirements. The best way to ensure the quality of assembly operations is to reduce or eliminate the need for mechanical assembly wherever possible.

Ideally, composite details and subassemblies would be designed and fabricated so that they can be assembled as snap-together modules. Thermoset composite materials that are not manufactured using resin transfer molding methods cannot normally meet the accurate, repeatable, and reproducible dimensional requirements for snap-together modules. However, composite parts can be designed and fabricated using localized "high-tolerance" tooling that will support self-locating assembly. This approach is affordable and allows the use of determinant assembly concepts (defined subsequently) without the aid of complex tooling and fixturing.

Tooling and Assembly Quality Control

Methods for Simplifying and Improving Assembly Operations

Design for manufacture and assembly (DFMA) methods can be used to advance the minimal assembly concept and otherwise improve assembly operations. The DFMA process brings together design and manufacture personnel at the critical initial concept level of a new program or project. The early interaction between the groups ensures a concurrent and collaborative development effort that takes into account the manufacturing and assembly issues at the design concept level. This approach replaces the traditional manufacturing industry practice of "throwing it over the wall," which often results in the inclusion of nonproducible details in part designs and production nonconformities. The end result is high tooling costs, long process flow times, and

significant design rework. DFMA tools are used to evaluate the product process from initial design through completed assembly. The DFMA process helps identify manufacturing and assembly quality issues and provides up-front engineering to avoid nonconforming process conditions. Process unity ensures products are designed with the correct form, fit, and function from the basic design to final product assembly. This process identifies and eliminates hidden costs and labor to benefit both the composite producer and customer.

Additional information about DFMA concepts and tools is provided in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

Determinant assembly (DA) involves the use of engineering-controlled, one-position molded-in or machined-in features on each individual composite detail. The one-position feature controls the fit and location of independent composite items to one another. The use of DA ensures that correct, quick, and accurate assembly of composite details and subassemblies is accomplished without the need for complex tooling or fixtures. Other DA process features include items such as engineering-controlled self-locating joints and numerically controlled (NC) machine-drilled holes and locating features. (It should be noted that when NC holes are used in the DA process, only a very limited number of holes are drilled in the details prior to assembly. These holes are used as an aid to provide accurate and repeated assembly capability. The holes may or may not receive fasteners as part of the assembly process, depending on other DA locating features.)

The DFMA and DA process concepts described previously support one of the major goals of the composites industry—toolless assembly. Assembly tooling will never be completely eliminated, but it can be minimized significantly by the use of DFMA and DA processes.

Flexible tooling is another concept that helps reduce the high tooling cost associated with composite assembly efforts. This tooling methodology is developed in concert with the engineering design phase to ensure the support of multiple configurations of the same part as well as parts in other component families. This concept must be an integrated approach, and it relies on high levels of “touch experience” and on the use of simulation software to identify quality concerns at the detail, subassembly, and assembly phases. Up-front dedication is mandatory from design, tooling, quality engineering, manufacturing engineering, and manufacturing groups for this process to be successful. Early identification of assembly quality issues results in reduced tooling cost and assembly time.

Assembly Process Monitoring

The process concepts and tools described previously also involve the application of functional real-time, operator-level, and decision-capable statistical process control tools. These tools must be employed to verify and maintain in-process control. Process monitoring must be nonintrusive at the operator level. Variable data collection of process parameters must occur at a point in the process where correction can be made. This is critical to minimize the creation of noncorrectable nonconformance conditions that require engineering disposition, possible repair, and schedule adjustment.

Quality concerns must be addressed, as the composite assemblies become larger. Verification requirements must be based on in-process performance, not after-the-fact detection of nonconformities, which may be uncorrectable. Nonconformance detection may result in significant repair cost and schedule delays or even total loss. Nonintrusive types of process control must be used to minimize the risk of process failure. Every effort should be made to use the process tools mentioned in this Volume to ensure all assembly and detail processes are conforming to engineering/customer requirements. These requirements must be evaluated at the design level and tailored by engineering to promote successful in-process verification and eliminate end- item evaluation/inspection requirements at the detail and assembly level. Additional information is provided in the article “Nondestructive Testing” in this Volume.

Outlook for Composites Assembly

Existing composite assembly methods are adequate for the types of structures currently being manufactured. However, new designs are implementing fewer details, larger sub-assemblies, and more self-locating final assemblies. Bonding of these assemblies will require application of more innovative design, manufacturing, process control, and assembly concepts. Manufacturing processes must develop to the point that if products are manufactured within statistically accepted process parameters, no final verification is required. The goal of eliminating the end-item verification step will require the application of advanced but easy-to-apply engineering and quality tools. Those who embrace the challenge of determinant assembly methods and design for manufacture and assembly concepts will benefit in the area of composite assembly.

Tooling and Assembly Quality Control

Acknowledgments

Portions of this article were adapted from material written by Steven F. Hanson, Composite Tooling International, Inc., for the previous edition of this Volume. Jeff L. Ware wishes to thank Greg Dean, Doug Bruner, and Andy Smith from Lockheed Martin Aeronautics Company—Fort Worth for their contributions to this article.

Reinforcing Material Lay-Up Quality Control

Barry P. Van West, The Boeing Company, Seattle

Introduction

IN-PROCESS INSPECTION during composite material lay-up is essential if the structural, dimensional, and environmental performance designed into a part is to be consistently achieved. The inspection techniques are usually based on governmental standards, company processing specifications, quality assurance requirements, and what are generally known as good shop practices. Although inspection techniques vary from one company or facility to another depending on prescribed contractual requirements, available equipment, level of personnel training, and documentation systems used, they all fulfill the following criteria. The materials to be used in part fabrication must conform to drawing and material specifications, must have been stored and handled properly, and must be within specified shelf life and processing out- time limitations. Processing aids used in the shop must comply with accepted material standards, and lay-up procedures must be controlled to ensure proper material handling and consistent dimensional accuracy of the completed laminate. The processing environment must conform to requirements for cleanliness, temperature, and humidity; also, equipment must be qualified and within specified calibration limits. To ensure the above requirements are met, the processor must develop a set of standards that control facilities and equipment operation, procedures, and training for the sequence of tasks associated with the lay-up process. Figure 1 is an abbreviated flow chart of tasks associated with the lay-up process covered by this section. Cure process quality control following lay-up is covered in the article "Cure Monitoring and Control" in this Volume. Figure 2 is a cause-and-effect diagram for defects in composite lay-ups that are described in this article.

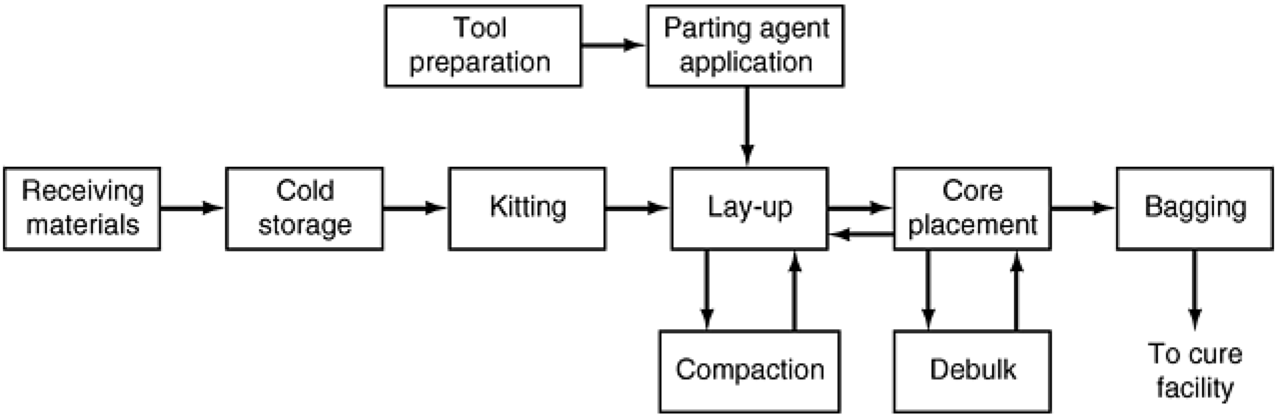

Fig. 1 Sequence of tasks associated with lay-up process

Reinforcing Material Lay-Up Quality Control

Barry P. Van West, The Boeing Company, Seattle

Facilities and Equipment

The facilities in which composite parts are laid up must meet requirements for cleanliness, temperature, and humidity. The requirements depend on the sensitivity to the environment of the materials being laid up, their limits on out-time and temperature, their tack, drapability, and tendency to absorb moisture. Dust particles must be limited because they become nucleating sites for void formation caused by moisture and entrained air. Aerosols and other contaminating materials must be avoided as they may act as releasing interfaces between plies, reducing the interlaminar strength of the finished part.

Controlled-Contamination Areas. Lay-ups must be performed in enclosed areas. All incoming air is filtered, and positive air pressure in the controlled-contamination area is required with respect to adjoining areas of lesser cleanliness. Compressed gas introduced into the area must be free of oil, condensed moisture, and

particulate matter. Doors that open directly outside the building are used only in emergency situations. The airborne particulate count must meet preset requirements and be monitored at set intervals. Temperature and relative humidity are monitored continuously. Typical temperature and humidity requirements are shown in Fig. 3. Contamination-controlled environments are classified according to the allowable airborne particulate count. The number used for identification of each class in FED-STD-209 (Ref 2) corresponds to the maximum number of particles 0.5 µm or larger, permitted in 0.03 m^3 (1 ft^3) of air. A typical lay-up-controlled area classification is 400,000, with requirements shown in Table 1. The international standard is ISO 14644 (Ref 3).

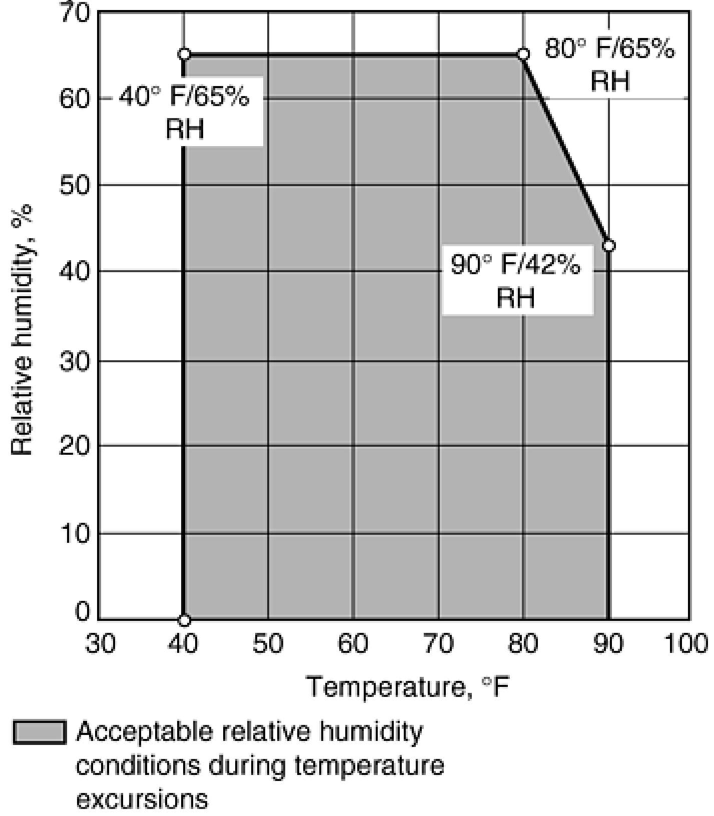

Fig. 3 Controlled-contamination-area temperature and relative humidity requirements

Table 1 Facility requirements and controlled area conditions

Controlled environment class	400,000 classification
Mass airborne particle count (≥0.5 µm)	**400,000 per 0.03 m^3 (per ft^3)**
Temperature	**22 ± 3 °C (72 ± 5 °F)**
Humidity	**30–60% RH**
Air pressure differential	**Positive pressure with respect to adjacent areas of lesser cleanliness**
Change rooms	**Not required**
Unidirectional air flow	**Not required**
Operation of internal combustion engines	**Prohibited**
Use of motors and equipment that spray or throw lubricants	**Prohibited**
Generation of nonvolatile residue	**Controlled**
Compressed gas use	**Controlled**
Cardboard	**Limited**
Exposed wooden surfaces	**Allowed if no visible damage and coated with smooth nonflaking finish**
Pencils and erasers	**Not allowed**
Carbon paper, paper pads	**Allowed**
Nonwork-related materials	**Not allowed**
Working in area	**Trained**

Cosmetics, perfume, cologne, aftershave, etc.	**Most allowed, but may not be applied in the area. Certain items, such as hair gels, not allowed**
Cleanroom clothing and shopcoats	**May be required**
Eating, drinking, and smoking	**Not allowed**
Dust, dirt, and debris	
Active work station	**Visibly clean from 0.6–0.9 m (2–3 ft)**
All other stations	**Visibly clean from 1.8–2.4 m (6–8 ft)**

Floors in the area are sealed or covered with nonflaking, easily cleaned material, such as plastic, paint, or vinyl tile. Walls and ceilings are covered with a high gloss or semigloss enamel. Autoclaves, ovens, and vacuum system equipment are generally not in the controlled area, but if so the outlets from this equipment are vented to the outside. Outlets are positioned or covered so that outside condensate cannot enter the outlet and are positioned away from air-conditioning intakes. Waste containers are emptied outside the controlled-contamination area, or liners are closed and removed from the container within the area. Cleaning schedules must be maintained within the controlled-contamination area. Cleaning methods are limited to water cleaning using mops, cloths, or rags, vacuuming with exhaust air vented outside the area or filtered to the same quality as the incoming air, chemical mopping using mops commercially treated with either propylene glycol, polyethylene glycol, or slightly tacky epoxy resin, and cleaning with water-based commercial glass cleaner. Protective clothing is worn over personal clothing when uncured parts are exposed to direct contact. If the protective clothing is removed from the controlled-contamination area, it is either cleaned or discarded. Requirements should be established concerning cleaning, frequency of changing, and storage of protective clothing. Protective gloves are worn when handling prepregs, adhesives, or precured details that will be bonded. The following materials or procedures are generally prohibited in the controlled-contamination area: materials, tools, parts, or equipment that have visible contaminants such as dirt, grease, or oil on their exterior surfaces; processes or operations that produce uncontrolled spray, dust, fumes, or particulate matter (i.e., grinding, machining, sanding or milling); uncured parting agents (liquid mold releases); hand-cream dispensers; unapproved aerosol dispensers; waxes; compounds containing uncured silicone or any material detrimental to adhesion; unapproved cleaning solutions or methods; operations that generate hydrocarbons; some personal hygiene items (especially hair gel products); smoking, eating, chewing tobacco, or consuming beverages; and the operation of internal combustion engines. Similar requirements are enforced in core machining areas.

Procedures that are allowed in the controlled- contamination area include solvent cleaning of cured composite surfaces and peel ply removal from cured parts at a distance from any uncovered prepreg or uncured film adhesive, removal of particles by vacuuming or solvent wiping, hand-sanding to prepare cured bond faying surfaces for bonding if done away from any uncovered prepreg or uncured film adhesive and the sanding particles are vacuumed, inkjet marking, the application of tackifier solution to tool surfaces with minimum overspray, spraying water- based commercial glass cleaner for cleaning away from uncovered prepreg, uncured film adhesive or contact-use material, and drinking from permanently installed drinking fountains. Portable vacuum systems must be approved and have special filters if outlets are within the controlled area.

During controlled-contamination-area shutdowns, uncured parts, prepreg, and film adhesive materials are placed in a sealed bag and stored in the freezer or in the controlled-contamination area if their temperature is monitored continuously and exposure units continue to accrue during shutdown periods.

Process and Equipment Qualification. The following steps in the qualification process are recommended. All equipment used to perform critical operations on deliverable materials should be qualified. Each processing facility desiring to manufacture parts should be qualified. Each family of parts to be manufactured at a facility should undergo preproduction verification.

A part/tool thermal profile should be performed after the processor's autoclave has been qualified, except for parts built on thin (less than 25 mm, or 1 in.) aluminum flat plates. The thermal profiling requires sufficient thermocouples to identify the leading and lagging temperature locations in the part during heating and cooling. This ensures that the heat-up rate, cure temperature, cure time, and cool-down rate of all areas of the part can be maintained within specification requirements in all future identical parts by referring to just leading and lagging thermocouples for process control. A permanent lagging thermocouple can be attached to the underside of the tool after thermal profile testing with multiple thermocouples ensures that this location represents the slowest heating area of the part. Insulation around the thermocouple can be used to increase lag time. The leading thermocouple can be placed in the excess at the edge of the laminate after the thermal profile testing with multiple thermocouples around the periphery of the part identifies the leading location.

All tools should receive leak checks after applying breather, vacuum bag sealing tape, and bagging materials to the tool in the same configuration that will be used in production. Each part should have an approved manufacturing plan, and a first-part qualification should be performed including a part inspection. Documentation from the first-part qualification should include a record of dimensional and nondestructive inspections, special engineering drawing allowances or exceptions, and cure records for vacuum, temperature, autoclave pressure, and pressure under the bag. The manufacturing plan includes definition of all operations related to part fabrication, including thermal processing, forming and inspection, and operations that ensure the correct orientation of prepreg fibers and core ribbon direction. Where automated processing uses computer controls, the processor must ensure software verification and security.

Equipment requiring qualification includes autoclaves, automated tape-laying machines, automated prepreg-cutting machines, drape-forming machines, inkjet-marking machines, and projection ply-locating machines. Qualification of an autoclave should include the determination of an upper limit on thermal mass that can be contained within the autoclave and still meet thermal rate requirements. Ovens, heat guns, and tacking irons need not be qualified, but must be calibrated and certified for temperature uniformity and control. Heat guns and tacking irons are certified not to exceed a maximum operating temperature that may be different for prepregs and adhesives. Heat blankets, used for repair and rework, must be calibrated and certified.

Reinforcing Material Lay-Up Quality Control

Barry P. Van West, The Boeing Company, Seattle

Material Control

One of the most significant areas in which quality-control personnel can be effective in preventing production problems is in material control. Controls must be in place to ensure arriving materials are to specification, to provide material traceability, to ensure conformance to shelf-life and out-time limits, and to ensure that handling procedures comply with specified practices. A quality-control manual must contain details on how to enforce these controls and verifications.

The purpose of receiving inspection is to ensure that each lot of material falls within key chemical, processing, and end-product parameters. For prepregs these include component percentages (such as resin, fiber, and catalyst), contents of impurities, volatiles and voids, resin flow parameters, and gel time. The temperature at which the material was shipped must be confirmed. For core materials, receiving inspection would include density measurements. Materials requiring end-product property testing must be laid up into panels and mechanically tested. Typical tests include compression, tension, and short-beam shear strengths.

Unused rolls, precut kits, partially laid-up parts, or partially used rolls of prepreg or adhesive materials are stored in sealed moistureproof bags or containers. Identification labels accompanying the material should contain the following information: supplier name, material specification number, material type, class, grade or style, batch number, lot number, date of kit preparation, and date of material manufacture. For precut kits, a means of providing traceability of the above information to each kit is necessary. Uncured lay-ups are bagged when transported outside of the controlled-contamination area.

A record must be kept of accumulated times in and out of refrigeration. When removed from refrigeration for use, the material must remain sealed until it reaches near-ambient temperatures such that no condensation forms

on the outside of the film wrapper when wiped dry. Both handling life and mechanical life accumulate from the date and time the material is removed from the freezer. Handling life accumulates until the material is formed to final contour. If forming operations such as hot-drape forming are required, the handling life requirements continue until those forming processes are completed. Mechanical life accumulates until the autoclave cure is initiated. Typically, air-temperature excursions above the required freezer storage temperature are allowed as long as the excursion does not exceed specified temperature and time limits. Exposure units do not have to be added to accumulated life for temperature excursions within these limits. Figure 4 shows the relationship among storage, handling, and mechanical lives of a prepreg. The refrigeration temperature is usually -18 °C (0 °F) or lower.

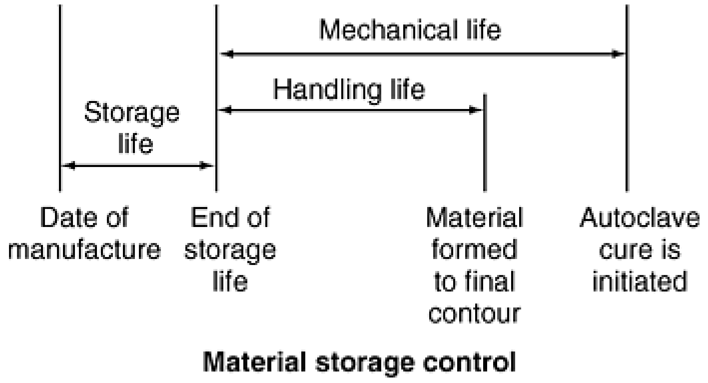

Fig. 4 Relationship of storage, mechanical, and handling lives of a prepreg. Prepreg and adhesives may be returned to storage one or more times provided their handling lives have not been exceeded.

Honeycomb core is packaged and stored in a manner that does not cause damage or contamination from water, grease, oil, dirt, or other foreign material detrimental to bonding. It must be identified using materials that will not contaminate subsequent core bonding.

Reinforcing Material Lay-Up Quality Control

Barry P. Van West, The Boeing Company, Seattle

Lay-Up

The lay-up process involves the handling of materials, the use of processing aids and equipment, the prevention of contamination, the use of procedures to control sequences and tolerances, and the upkeep of records. A set of operating regulations should be developed by the processor, describing the lay-up process and process-control methods, controlled-contamination area requirements, in-process inspection methods, and a training program. All personnel, including supervision and maintenance personnel who are working in the controlled-contamination area must receive training on the area requirements and on the special requirements for handling processing aid-materials.

Processing aids that come into contact with or are in the vicinity of the materials being laid up must not contaminate them. Processing aids are categorized as contact-use materials approved for use in direct contact with the part lay- up, and noncontact-use materials approved for use as aids to processing but not in contact with the lay-up. Contact-use materials include parting films, mold release materials, protective gloves, marking pens and pencils, rigid and flexible sweeps, peel ply, protective clothing, aprons and shoe-covers, ink-jet marking inks, and backing plates. Some tapes may be approved for contact use. Noncontact-use materials include vacuum bags, solvents, breathers, sealing compounds, pressure-sensitive tapes, identification marking labels, photogrammetry targets, alkaline cleaners, and absorbent wipers. Noncontact materials may contact the part outside of the net trim line. Table 2 lists commonly used materials. Special care should be taken when using processing-aid materials to ensure they are not inadvertently incorporated into the lay-up. It is important to make sure all film materials (backing paper, peel ply, nylon bagging films, etc.) are removed. Some of these

materials are not detectable during end-item nondestructive inspection. The main issues that reduce detectability are: thin materials are less detectable than thicker materials, materials that absorb prepreg resin or bond well to resin are less detectable than those that do not, and all foreign materials are more difficult to detect when porosity (even at acceptable levels) is present in the cured laminate.

Table 2 Processing aid materials for prepreg lay-up

Contact-use materials
Peel ply:
Nylon and polyester fabric, fiberglass with release coating
Parting films:
Fluorinated ethylene propylene (FEP), polytetrafluoroethylene (PTFE), or tetrafluoroethylene (TFE), polyvinyl fluoride (PVF), polyethylene, polymethylpentene, Teflon-coated glass fabric
Gloves:
Latex rubber, polyethylene, cotton.
Rigid sweeps:
Polyethylene, polyacetal, polyurethane, nylon
Flexible sweeps:
Tedlar and polyethylene film, supercalendared silicon-coated paper
Protective clothing:
Nylon net caps, reusable low-lint shopcoats, pants, boots, sleeves, coveralls, disposable polypropylene and olefin
Noncontact use materials
Vacuum bags:
Nylon, polyethylene, latex rubber, silicon rubber, neoprene
Solvents:
Methyl ethyl ketone (MEK), acetone, toluene
Breathers:
Fiberglass fabric, polyester mat and fabric mesh, embossed blankets, Dacron, porous TFE-coated fiberglass, paper

In-Process Control. Prepregs, adhesives, partially laid-up materials, and uncured parts removed from refrigeration are kept in sealed, moistureproof containers until they have thawed and warmed to room temperature. Protective gloves, clothing, and footwear (when required) are worn by material handlers. Prior to part fabrication, tool surfaces that come into contact with prepreg, resin, or adhesive during cure are either covered with nonperforated parting film or prepared with a release agent. Each section of unrolled material must be visually inspected prior to incorporation into a part. Material suppliers commonly attach markers identifying discrepant areas within an individual roll of material. Fiber breakage and resin-poor areas are among the most common defects encountered.

Prepreg materials may be warmed to facilitate manufacturing operations. In addition to the handling and mechanical life allowances, prepreg materials may be exposed to an external heat source within temperature and time limitations. The time accumulated from each exposure is defined as the time from initial application of heat to the time the prepreg material has cooled to the temperatures allowed for normal handling. The use of automated tape-laying heated guide chutes or heat guns and tacking irons for heating prepregs is exempt from the cumulative time limit requirement, and exposures resulting from this use need not be monitored. Film adhesive materials should not be exposed to temperatures in excess of approved temperatures prior to cure except when heating the adhesive using heat guns and tacking irons certified for use on adhesives. The heat guns and tacking irons are kept in motion in small circles over the area to be tacked, at least 76 mm (3 in.) away from the adhesive surface. Prepreg plies may be removed for repositioning by using portable filtered cold- air blowers, compressed cold-air guns, or other cold sources but without lowering the temperature of prepreg material to a point where visible condensation forms on the part.

When trimming and laying up new plies, precautions must be taken not to cut previously applied materials. For example, protective metal strips can be placed under material being cut with a blade, or the ply can be marked, partially lifted, and cut with scissors. Compaction is recommended after lay-up of several plies and for the ply preceding core lay-up. Compaction is suggested for each ply in a tape laminate part that has been laid up by

hand. For sandwich parts, once core is in place, it is recommended to limit subsequent use of compaction vacuum to a maximum of 33.8 kPa (10 in. Hg), primarily to prevent core movement. Debulking may be performed in an autoclave under vacuum, pressure, and heat. For typical sandwich parts, pressure is limited to 310 kPa (45 psig). The debulk temperature should not exceed 65 °C (150 °F) for 30 min, but may be less if resin properties require it.

The following information is recorded for each part: composite prepreg and adhesive specification numbers; material manufacturer's batch number, roll number, date of manufacture, and total accumulated exposure units of handling; mechanical and storage life; autoclave load or run number; part number; tool identification number; traceability to the cure cycle information; and discrepancy corrections accomplished. Similar traceability must be established for core material.

Peel ply is usually required on surfaces that will be adhesively bonded and on surfaces that are cured against breather and bagging materials. Peel ply is optional on surfaces cured against tooling substrates that will impart an untextured, smooth finish (e.g., metal, composite, or elastomeric surfaces). Cured laminates that have a textured surface (which comes from being cured against breather mats) are difficult to adequately prepare for bonding by sanding because the sandpaper tends to just hit the peaks.

Cleaning of honeycomb core may be accomplished by dust collection during machining, removal of dust and machine debris by vacuum cleaning and blowing with dry filtered air (electrostatic attraction of dust during machining and cleaning operation must be eliminated), or honeycomb core washing or vapor degreasing using solvents to remove oils or other visible contaminants.

Quality control of the lay-up process must verify that tool surfaces have been prepared, that materials are per specification and within time- history limits, that parts are fabricated in accordance with approved procedures, in particular that no foreign material contamination exists in the lay-up, that information is maintained for each part, that discrepancies that are accepted or reworked meet requirements, that rework is performed in accordance with the approved methods, that bagging is done correctly, and that thermocouples are placed at the correct locations.

Draping. Tools frequently have an orientation rosette marked on them at which point ply lay- up is initiated at the orientation specified on the drawing. On compound curved tools the fiber orientation will vary away from the initiation point, as shown in Fig. 5. This variation is the result of the kinematics of the draping process and cannot be avoided without inducing wrinkling or bridging. Wrinkling and bridging may occur anyway if the contour is severe enough, and darting and splicing are necessary to force the ply to conform to the tool surface. Darting and splicing are also used to limit the deviation in orientation of the fibers, in effect creating gores. The locations of darts and splices are critical to the strength of the part and must be approved by stress analysis. Software is available that simulates the draping process and defines the lay-up initiation point and orientation, predicts where wrinkling and bridging will occur, and shows how the introduction of darts and splices alleviates wrinkling and bridging problems (Ref 4, 5).

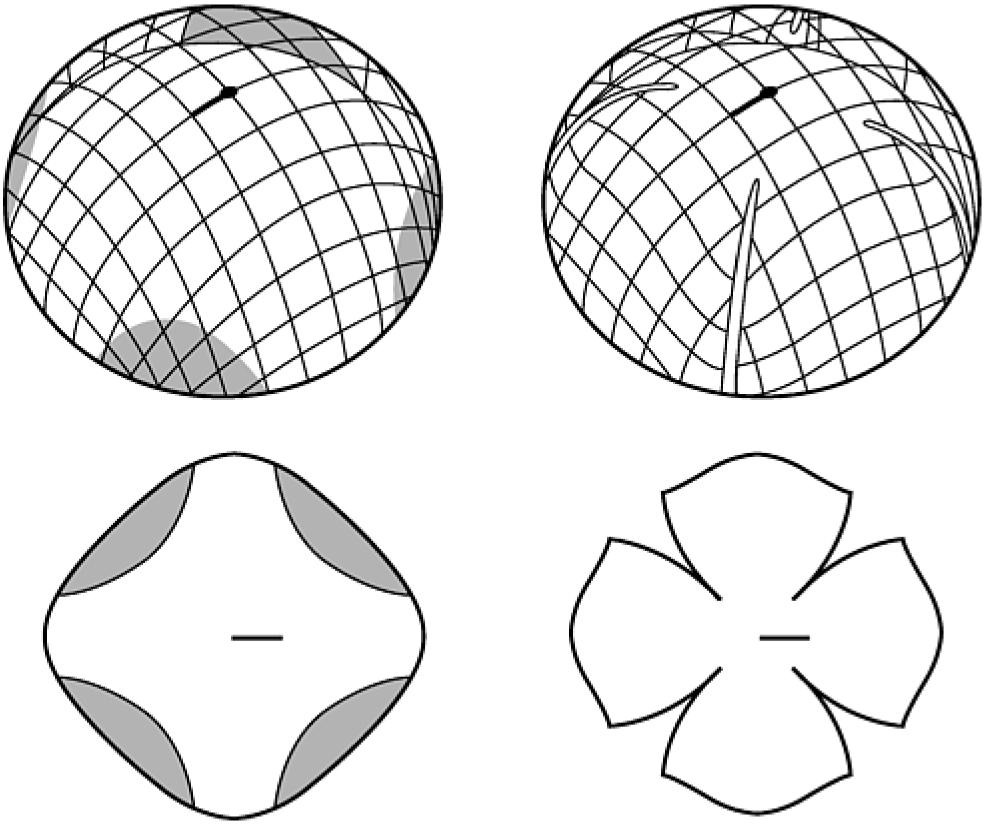

Fig. 5 Variation of fiber orientation with location on a compound-curved surface. Orientation will change if darts are cut and spliced to create gores. Flat patterns will also change. (Courtesy of Composite Design Technologies, Inc., Waltham, Mass.)

Voids form by mechanical entrapment of gases or by nucleation. Gases can be trapped by the resin-mixing operation, as a result of ply bridging and wrinkling, near wandering tows, fuzz balls, and broken fibers, and at ply drop- offs, overlaps, and splices. Nucleation occurs within the resin or at resin/fiber/particle interfaces. Water vapor, air, volatiles, and foreign particles can provide void nucleation sites in prepregs. Vacuum pressure sealed in honeycomb core can lower the hydrostatic resin pressure locally, allowing volatiles to emerge from solution. Lay-up and bagging procedures must ensure these imperfections are minimized. First-ply adhesion to the tool surface is especially important in female radii locations. Periodic compaction will consolidate plies and remove air if done correctly. Care must be taken not to trap air in the compaction process.

Vacuum Bagging. Wrinkles in the vacuum bag film frequently transfer to the part surface. Inadvertent wrinkles in the bag film should be avoided. When pleats are used to help the bag conform to part contour, they should be positioned to minimize effects in the part surface or provided with extra padding to prevent transferring to the part surface. Sharp contours must be padded to minimize the risk of bag failure. Breather materials must allow vapors to flow freely through the resin to escape as vented gas. An unrestricted vacuum path must be allowed to all areas of the part. The part should be left connected to an active vacuum source after completion of the bagging procedure. Leaving parts disconnected from vacuum for extended periods of time may result in ply wrinkles, voids, and other defects. Before starting the cure cycle, each vacuum bag is checked for leaks while connected to the autoclave system. A minimum vacuum of 74 kPa (22 in. Hg) is applied, and then vacuum sources are shut off. The vacuum gage reading should not drop more than 17 kPa (5 in. Hg) in 5 min.

Thermocouples are positioned in the lay-up for connection to the autoclave junction box. At least one thermocouple in the part must be identified as the lagging or slowest thermocouple during heating and cooling, and at least one must be identified as the leading or fastest thermocouple during heating and cooling. The thermocouples are electrically checked, and identification and locations are recorded. The combined accuracy of the thermocouple junction box and recorder should be ±3 °C (+6 °F) or better from 38 to 185 °C (100–365 °F).

Tolerances. The fiber orientation and location of each ply must be verified during lay-up. Precision templates can be constructed to aid in the alignment and positioning of plies. The templates for flat parts are commonly made of Mylar, rubberized fabric, or other flexible but inextensible material, and molded fiberglass is used for contoured parts. Eyebrow cutouts in the templates mark the edges of core and plies, and indexing holes fit over

pins in the tool to establish orientation. Figure 6 shows examples of flexible and rigid templates. There are two scenarios for the use of these templates, one involving rough-cut plies and one involving plies cut on a ply-cutting machine. If a ply is rough cut and laid up with excess at the edges, the template is placed on the ply and the cutouts are used to hand mark the edge of ply on the ply itself, followed by cutting it to shape in place. The ply must have been marked with an orientation line that is lined up with marks on the tool edge or a rosette. If the ply is precision cut to net shape using flat pattern software, it can be laid up on the previous ply or tool surface, which has the outline and orientation of the ply hand marked on it using the template. In lieu of using templates, plies can also be inkjet marked by the cutting machine with the outline and orientation of the following ply. Optical lay-up templates using scanning laser lines projected from overhead are increasingly being used to project orientation and positioning information as a lay-up aid and for inspection. Tolerances depend on the specific program requirements. Typical values are shown in Table 3. Full plies are generally oversize to allow for trimming of the cured part. All splice joints should be offset from any other splice joint among any six consecutive plies through the thickness of the lay-up. Wrinkles are generally not permitted in fabric plies, which must be smoothed out. Tape splices should have no cut fibers; that is, the splices should be parallel to the fiber direction. Splices may cross within a lay-up except as specified by the drawings. There should be no overlaps in areas that will become faying surfaces, as shown in Fig. 7.

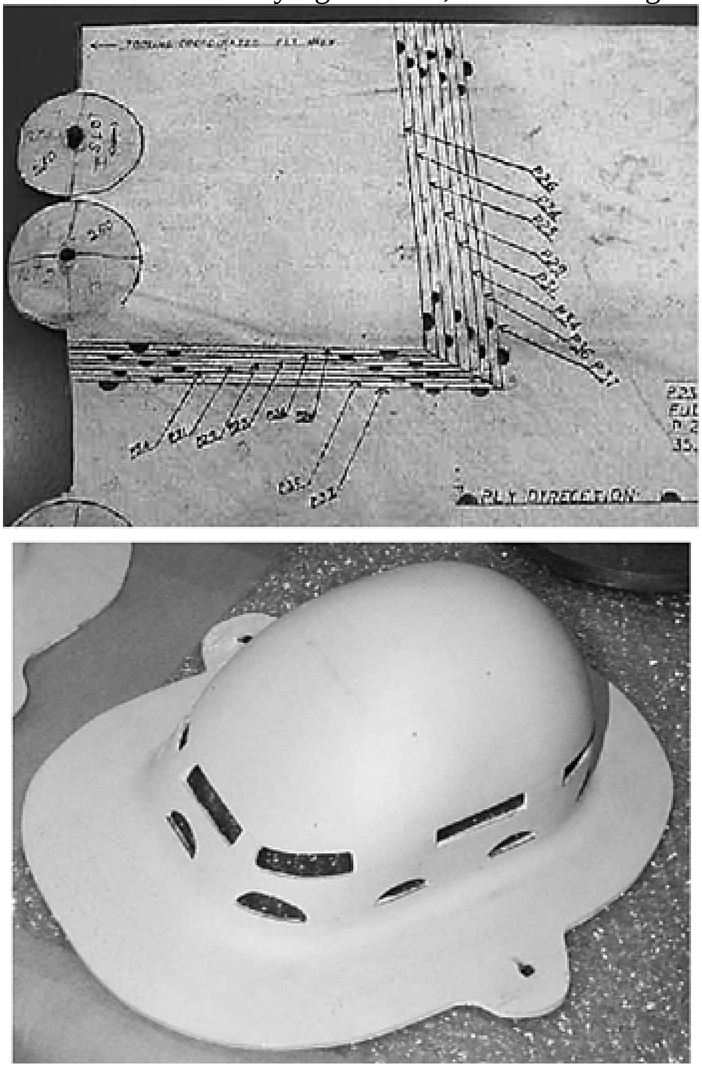

Fig. 6 Flexible and rigid ply locating templates with indexing cutouts denoting edges of plies and honeycomb core. Templates are used as lay-up guides and inspection tools.

Table 3 Typical tolerances for lay-up

	Tolerance
Orientation	
Fabric	±5°
Tape	±3°

Core (ribbon direction)	±5°
Position	
Full plies	**Oversize**
Partial plies and doublers	**±0.25 mm (±0.010 in.)**
Splicing	
Fabric	
Butt	**No overlap, to 2.5 mm (0.10 in.) gap**
Overlap	**13–25 mm (0.5–1.0 in.)**
Offset	**25 mm (1.0 in.) min**
Tape (no cut fibers)	
Butt	**No overlap, to 2.5 mm (0.10 in.) gap**
Overlap	**None**
Offset	**13 mm (0.50 in.) min**
Film adhesive	
Butt	**No gap**
Overlap	**0–25 mm (0–1.0 in.)**
Core	
Thickness	
Up to 50 mm (2 in.)	**±0.15 mm (±0.006 in.)**
50–100 mm (2–4 in.)	**±0.25 mm (±0.010 in.)**
Over 100 mm (4 in.)	**±1.6 mm (±0.063 in.)**
Position	**±0.25 mm (±0.010 in.)**
Chamfer angle	±3°

Note: Actual tolerances depend on specific program requirements.

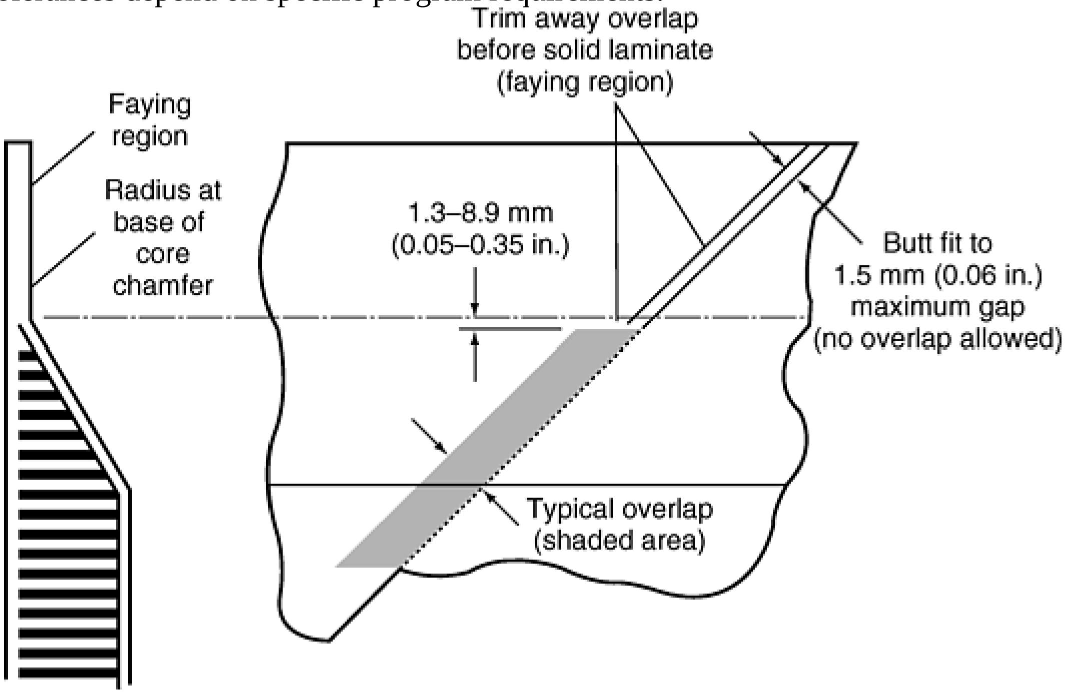

Fig. 7 Overlapping splices cut back to form butt splices in the faying region, maintaining a smooth faying surface

Discrepancies in prepreg material during lay- up include cuts, wrinkles, and fabric distortion. Typically, cuts should not exceed 2.5 mm (0.10 in.) in length in any 0.9 m (3 ft) of material and may be patched with an overlay of material 13 to 25 mm (0.5–1 in.) around the cut. Wrinkles may be up to 305 mm (12 in.) in length, but must be removed by smoothing with no fiber damage. Yarn deviation in fabrics should be less than 6 mm (0.25 in.) from nominal path, but may be more if the length of deviation is greater than 10 times the deviation.

Discrepancies in honeycomb core include cell tear-out (Fig. 8), frayed or burred areas, edge waviness, node bond separation, and core surface depressions. Typical discrepancy acceptance criteria are shown in Table 4.

Discrepancies may be reworked by filling damaged areas or sweeping the surface with potting compound or by splicing in new core.

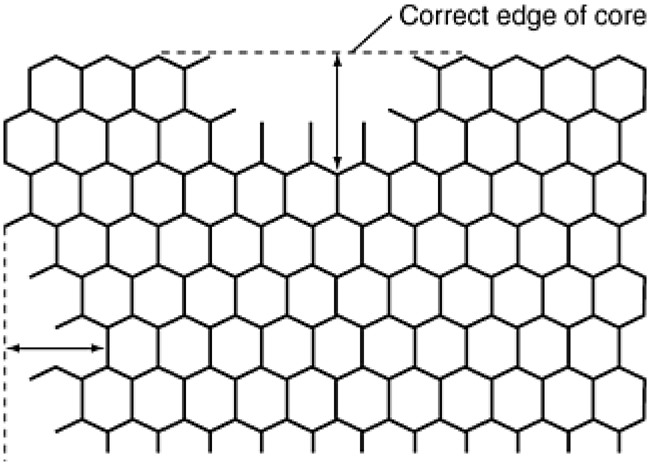

Fig. 8 Cell tear-out in honeycomb core

Table 4   Typical honeycomb core discrepancy limits

Discrepancy	Acceptable limits
Multiple discrepancies	**No two within 152 mm (6 in.) and a maximum of 10% core area**
Cell tear-out	**161 mm^2 (0.25 in^2) max area or 13 mm (0.5 in.) max width from edge**
Frayed or burred areas	**No fiber fuzz after sanding**
Edge waviness	**Within 1.3 mm (0.05 in.) of nominal core edge**
Node bond separation	**Number of nodes: <10% partial and <1% total separation**
Surface depressions	**0.5 mm (0.02 in.) deep, 13 mm (0.5 in.) long**

Actual limits depend on specific program requirements.

Statistical quality control may be used to apply statistical methods to determine the acceptance of ply lay-up operations with a minimum of inspection effort. Key characteristics and process parameters must be determined on which to base a quality appraisal. Key process parameters (KPP) include those parameters in each stage of the manufacturing process that have the greatest influence on the key characteristics and the performance of the final product. A nominal target value and control limits for each KPP must be established as well as the inspection method and monitoring frequency. The frequency of monitoring is a variable that depends on the acceptance rate of previously inspected work. In a simple example, if a specified number of consecutive plies are found to be within location and orientation tolerances, then only one of every m plies needs to be inspected. If a specified number of those are acceptable, then only one of every n plies needs to be inspected (with $n > m$), and so on. If discrepancies are found, the inspection rate reverts to previous levels of frequency.

A program of manufacturing self-examination may be instituted whereby the personnel doing lay-up tasks are specially trained to perform quality examinations of their own work according to specific procedures. This does not eliminate the need for auditing inspections, but reduces the workload on inspectors who would otherwise be required to inspect every ply for a number of tolerance parameters. This program is coupled with statistical quality control to determine the inspection rate.

Automated Tape Laying and Fiber Placement

Automated tape laying and fiber placement are prepreg lay-up processes that automatically control fiber orientation, ply position, and shape. With automated tape laying, a wide band of tape is drawn from a spool and laid down under pressure by a heated head, whereas with fiber placement individual prepreg tows of material are drawn from spools within a controlled-temperature chamber and collated into a single band of material at the head of the machine. Gentle contours can be laid up by tape-laying machines with deviations from a flat plane of more than 20°. Complex contours can be laid up and individual tows of material terminated and added due to the steering and cutting capability of fiber- placement machines. The processes still require hand lay-up of peel ply, fabric plies, small doublers, and isolation fiberglass for which ply sequence and orientation must be verified and lack of moisture and defects confirmed. The locations for these plies may be marked using an optical lay-up template or the machine-mounted laser.

In the fiber-placement process, gaps larger than a specified width and length are filled by manual insertion of tow to fill the gap, by removal and reapplication of the defective tow, or by manual adjustment of adjacent tows. Gaps resulting from tow convergence must be limited in width. Spliced ends are overlapped at least 25 mm (1 in.). Tow splices must be offset from other splices along the length of a tow and laterally from other splice locations. Each ply of the lay-up is visually examined for defects such as missing tows, wrinkled tows, fuzz balls, contamination/inclusions, or other defects. Nonconforming areas have the individual tows replaced by hand or the machine or the entire course replaced by the machine. Wrinkled tows and puckers are limited in width perpendicular to the fiber direction and in area. Folded and twisted tows are acceptable if the ply meets gap requirements. Bridged tows in the fiber direction are acceptable up to a maximum specified length.

Reinforcing Material Lay-Up Quality Control

Barry P. Van West, The Boeing Company, Seattle

Numerically Aided Lay-Up

Modern lay-up processes are progressing toward automation that utilizes computers to facilitate each step of the process. This reduces error due to human intervention, reduces cycle times, increases the consistency of the finished parts, and reduces material waste and part rejections. The part is designed using a CAD system that defines part geometry, ply shapes, orientations, and sequences. For parts other than those made on automated tape laying or fiber-placement machines, such as parts made of fabric with a high degree of contour, an orientation rosette, and its location on the tool is defined. The design dataset is fed to a flat pattern simulator, which does a kinematic analysis of the plies being draped on the tool and computes the flat pattern shape for each ply. These data are fed to a nesting program that determines the least wasteful arrangement of plies within the bounds of the broadgoods from which the plies are cut. The nesting program provides instructions to a cutting machine to cut the nested plies. Each ply is marked with a part or ply number and reference points or lines to aid in initiating the draping process. Although not commonly utilized at present, pick-and-place machines can pick up individual plies and store them in specific locations for later retrieval. More likely, the plies will be kitted and stored by hand. At the time of part lay-up, an overhead laser projection system scans lines onto the tool and ply surfaces, defining the ply boundaries, orientations, and starting points, and compensating for any complex contour in the lay-up geometry and for the change in surface elevation due to ply and core thickness. The ply is laid up by hand with the aid of sweeps, using the laser projections as guides. Variations can occur in the way a ply is laid up due to the actions of the operator doing the lay- up. Variations

in the sequence in which areas of the ply are swept onto the surface or the amount of stretching force applied to a fabric can cause variations in the resulting fiber paths. To minimize this variation, the sequence and technique of lay-up should be defined with marked or projected lines and the operators trained accordingly. In lieu of hand lay-up, pick-and-place machines could be used to select and position plies on the tool, using a vision system that can identify ply boundaries or reference points on the ply to control and verify position and orientation. Diaphragm-forming cells are used to form the ply or plies to the tool surface, although this process is currently limited to simple or gentle contours. Such a fully automated system would reduce quality-control requirements to first-part qualification, limited process monitoring, and final inspection.

The use of automated tape-laying or fiber- placement machines further automates the process by continuing the numerical process through the final lay-up and eliminates the need for flat patterns, nesting, precutting, marking, kitting, laser projection, and pick-and-place operations. Quality inspection requirements are reduced accordingly. However, automated tape laying and fiber-placement processes are restricted by part contour limitations.

Cure Monitoring and Control

Dirk Heider, Roderick Don, and E.T. Thostensen, University of Delaware; Kirk Tackitt, U.S. Army Research Laboratory; John H. Belk, The Boeing Company; Thomas Munns, ARINC

Introduction

ACHIEVING PERFECT PARTS every time is an elusive goal. Industry has responded by choosing its battles carefully, gradually increasing its abilities by creating new materials and processes aimed at improved production of parts of increasing complexity and difficulty. Now that many variations on these few processing approaches have been mastered, it may be time to go to the next level. Composites manufacturers are now quite good at making a few kinds of parts with few defects at acceptable cost. If composites manufacturing is to be extended to more types of parts and into more markets, the technical capabilities of manufacturers will need to be expanded dramatically.

One way to enable this expansion is to further monitor the process as it unfolds, making in-process decisions as opposed to making only post-manufacturing inspection-based decisions. This will enable manufacture of more difficult parts by tuning the process for a particular part with a particular material on a particular day.

Generally, this takes the form of modeling the process, modeling the part, modeling the chemistry and kinetics, and attempting to combine all this information into something that can be used on the shop floor. This article deals with the current attempts of industry to create sensing approaches for this vision and includes those currently in use and some of the sensing approaches that are being investigated but have a reasonable chance at adoption. The reader should note that all of these sensing approaches share one key ingredient: all are based on the philosophy that sensors are valuable only if there is something to control.

Due to its current use and rising importance, dielectric sensing is covered in detail. Also, microwave curing is covered in somewhat more detail than the reader might expect. This is in part due to its potential near-term importance, but it also serves as a general conceptual model for electron-beam curing and ultraviolet curing, which are therefore not covered in any substantial detail as a result.

Cure Monitoring and Control

Dirk Heider, Roderick Don, and E.T. Thostensen, University of Delaware; Kirk Tackitt, U.S. Army Research Laboratory; John H. Belk, The Boeing Company; Thomas Munns, ARINC

Process Control

Process control requires a sufficient knowledge of the entire manufacturing process to make the correct choices at the correct times. Recipe- based control requires sufficient knowledge of previous parts to extrapolate a plan that will, for the most part, result in a good part. Recipe-based control has worked very well for a long time and will continue to play a valuable role, especially in batch-based processes. On-line real-time process control will simply add new capabilities, allowing more part types, additional materials, and the ability to correct for variations in real time.

How will this process control work? It consists of modeling, sensing, and then control. Good models must be available for the parts, materials, tooling, and processes before one can hope to generate a recipe or build a control system. Fortunately, composites manufacturers know how to make good models of all these and simply need to tie them together and learn how to make and carry out good decisions.

Sensing is most useful when placed in the overall context of the manufacturing process, including part design, tool design (including locations of inlets, outlets, thermocouples, resin runners, etc.), cure cycle design (accounting for both the part and any tooling), and the infusion plan (including control of the process). Many of these interrelated elements must feed the infusion and cure process to be controlled. Sensing should not be intrusive to the part and should not affect part dimensions or properties. In addition, sensing must not significantly increase the difficulty of part manufacture or the overall part cost, after the decrease in scrap or increase in quality is factored in.

Numerous customized aids have been produced to facilitate efficient production of these designs and plans, including the Automated Tooling Manufacture for Composite Structure (ATMCS) design package (Prescient Technologies, Inc., Boston, MA). Another such aid is autoclave batch filling software in the form of COBRA (Lockheed Martin Corp.) and cure codes in the form of both COMPRO (University of British Columbia) and Computer Aided Curing of Composites (CACC) (McDonnell Aircraft Company) (Ref 1), all developed primarily for autoclave processes. These are of course in addition to the more common computer-aided design programs and various finite element packages that start the design process. As the composites industry migrates toward larger, more complex integrated structures, there will be a more pronounced need for process control because the industry simply cannot afford to throw away even one large part.

There are a host of properties that can be measured for use in real-time control, including tool or part temperature (Ref 2), pressure, vacuum level, resin viscosity, flow rate, resin position, degree of gelation, degree of cure, moisture content, and residual stress and strain. For each of these there are multiple sensors that might be considered in a control scenario, depending on the specifics of the manufacturing process and the level of confidence required.

For liquid molded parts, including those made via resin transfer molding (RTM), SCRIMP (TPI Technology Inc., Warren, RI), or vacuum-assisted RTM (VARTM), resin flow paints much of the picture. Current sensor-based process control procedures use dielectric sensing (Ref 3, 4), which would readily transfer to liquid molding applications.

Resin Cure Sensing

Several methods exist to begin the process of curing a composite resin system. Of course the most common is application of heat. However, several alternatives are finding niches or showing promise including ultraviolet (UV), electron beam (EB) (Ref 5), and microwave curing. Microwave curing is rising in importance and is used here to illustrate non-direct-heat approaches. Electron beam curing is discussed in the section "Dosimetry-Based Resin Cure Sensors" in this article to illustrate how non-direct- heating approaches can be addressed in cure- sensing schemes.

Microwave Curing of Thick-Section Composites

Microwave heating has been shown to minimize difficulties during thick-section composite cure through in situ volumetric deposition of energy (Ref 6). Thermal gradients during the ramp segment can be minimized and, because microwave heating is instantaneous, heat generation due to microwaves can be precisely controlled. Therefore, temperature excursions in the cure cycle can be minimized, and undesirable spatial solidification can be eliminated. Current research results indicate that microwave heating can substantially reduce the cycle time required to obtain an *inside-out* cure. Microwave cure cycle times are approximately one-third of the required cycle time for autoclave curing.

Research on curing of thick-section composites focuses on numerical process modeling and experimental investigations of microwave and conventional, autoclave curing. The process models combine aspects of transient heat transfer, microwave/materials interactions, and chemical reaction kinetics to model cure behavior in microwave and conventional processing (Ref 7). Models for the interaction of microwaves with laminated composites were developed to account for the influence of fiber orientation on the internal electric field within the composite. Numerical and experimental work focused on a model system of a cross-ply glass/epoxy laminate. Experimental investigations were conducted to develop a cure kinetics model (using epoxy resin

EPON 862/curing agent W) for input into the numerical simulation and for validation of the numerical simulations through manufacturing experiments in a conventional autoclave and a state-of-the-art microwave furnace.

To compare the thermal and cure behavior of thick composite laminates during conventional and microwave curing, numerical simulations were performed for 25 mm (1 in.) thick cross- ply glass/epoxy laminates subjected to the same cure cycle (5 °C/min, or 9 °F/min to 165 °C, or 330 °F, for 2 h). Figure 1(a) shows numerical results for conventional curing. As expected, a significant thermal lag between the center and surface of the laminate exists. From the transient cure behavior, it is clear that the thermal gradients result in differential curing where the surface cures faster than the center. There is also a significant exothermic overshoot due to heat liberated from the chemical reaction. These thermal gradients combine to create the undesirable *outside-in* cure. Figure 1(b) shows numerical results for the same laminate subjected to microwave heating. Volumetric heating due to microwaves results in elimination of the thermal lag. Because the laminate is exposed to free convection in the unheated microwave cavity, the surface of the laminate is cooler and these thermal gradients promote the desired *inside-out* cure. In addition, the ability to control instantaneous microwave heat generation eliminates the temperature overshoot in the cure cycle. Thus, direct, volumetric heating due to microwaves significantly improves control over spatial solidification temperature excursions in the laminate.

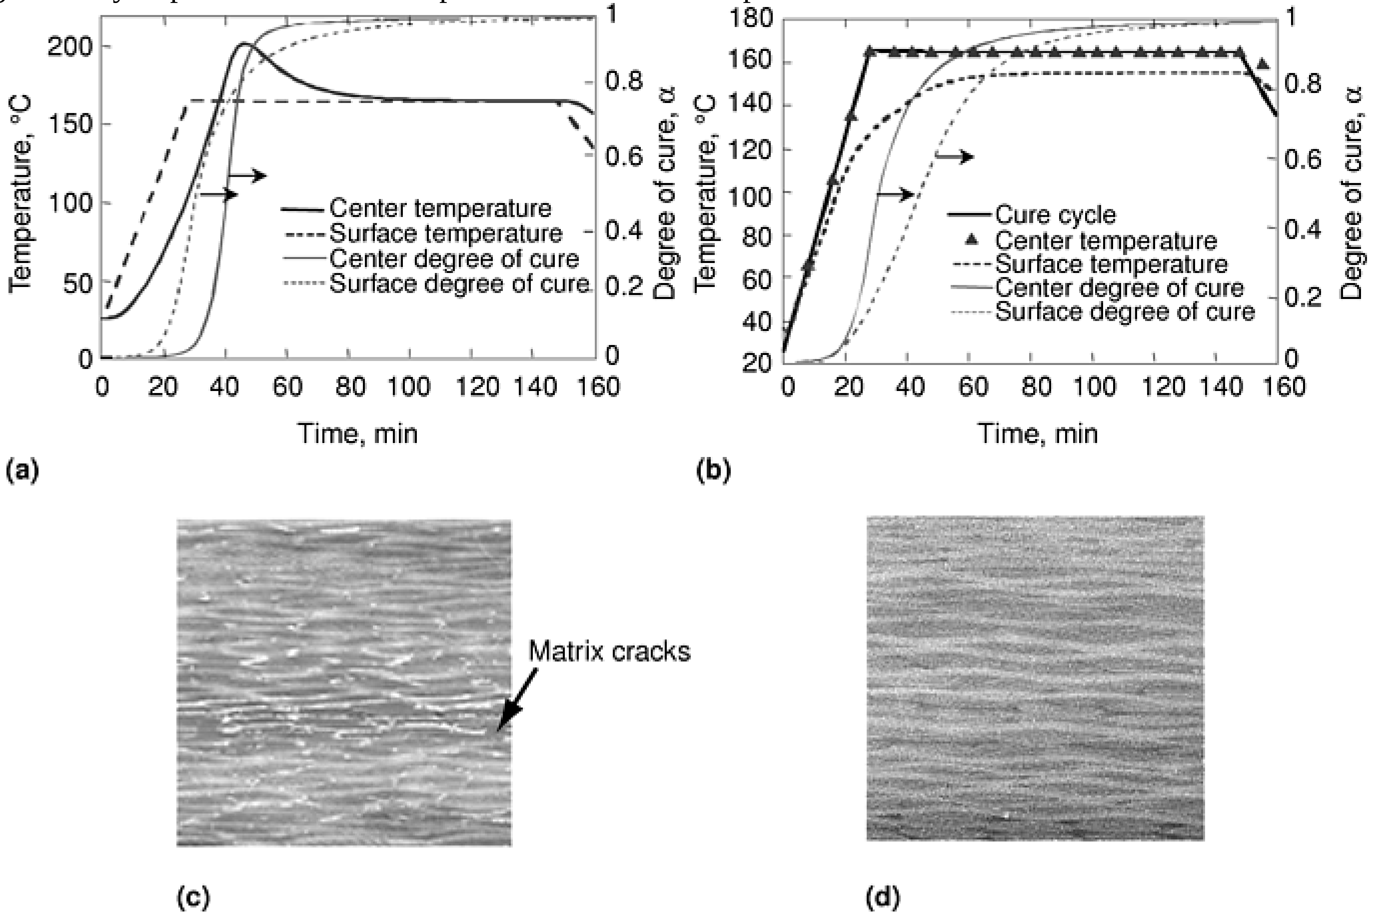

Fig. 1 Numerical results for (a) conventional and (b) microwave processing of a 25 mm (1 in.) thick glass/epoxy laminate and cross-sectional micrographs of (c) conventional and (d) microwave-processed laminates. Significant matrix cracking is seen in the autoclave-processed laminate, resulting from outside-in solidification stresses.

Figures 1 (c) and (d) show cross-sectional micrographs of autoclave- and microwave-processed laminates, respectively. The importance of controlled spatial solidification is clear. The *outside-in* solidification of the thick laminate results in significant matrix cracking. Stresses in the thickness direction result from the shrinkage associated with curing a thermoset. When surfaces of the laminate cure first, the shrinkage of resin in the center of the laminate is constrained and results in tensile stresses in the thickness direction. In microwave cured laminates, where the center cures first, there is no buildup of tensile stresses due to resin shrinkage because the surfaces have not solidified. This explains why the microwave-processed laminate is crack-free.

Resin Cure Sensors

For resin cure monitoring, a robust, embeddable, or standoff sensor is desired that is capable of interrogating for degree of cure with a resolution sufficient to discriminate between, for example, 90 and 95% degree of cure for military structures. Robust egress and relatively inexpensive readout of the signal appropriate for the production environment should also be available. Several methods that have been demonstrated in the past for resin cure monitoring are given in Table 1 and should be considered.

Table 1 Recently investigated cure monitoring technologies

Resin cure monitoring method	**Investigators**	Comments
Thermocouples	Stanford University and most others	**If you know the temperature history, you can predict degree of cure.**
Dielectric	Micromet Instruments; Beijing University of Aeronautics and Astronautics (China); NASA-Langley; College of William and Mary; Lockheed	**The standard method at this time. See text for more.**
Ultrasonic	Micromet; Rockwell (laser based)	**No part contact required; stitches can return anomalous signals.**
Frequency dependent electromagnetic sensing (FDEMS)	NASA-Langley; Virginia Polytechnic Institute and State University; College of William and Mary; U.S. Air Force Materials Directorate; Hughes	**Similar to dielectric**
Fluorescence	National Institute of Standards and Technology (NIST); Johns Hopkins University; McDonnell Douglas (now Boeing); Duke Engineering Group; Northwestern University	**This gets to the heart of the chemistry but sometimes requires dopants to get sufficient fluorescence of the host resin.**
Acoustic waveguides (AWG)	Westinghouse Science and Technology	**This is an offshoot in many respects of ultrasonic methods. "Leaky" AWGs interrogate part.**
Fiberoptic index of refraction	Brunel University, Northrop Grumman, NIST	**…**
Fiberoptic strain sensors	Naval Research Labs; McDonnell Douglas (now Boeing); Lockheed Martin	**Uses various relatively expensive fiberoptic sensors to measure strain at points.**
Fourier transform infrared (FTIR) spectroscopy	NIST; Foster-Miller, Brunel University	**This also gets to the heart of the chemistry but uses expensive fiber that you cannot reuse because it is embedded. Lower cost fibers are becoming available.**
Near infrared (NIR) spectroscopy	Northwestern University, Brunel University	**This builds on FTIR approach but works with telecom fiber. Uses neural networks to interpret data.**
Direct current conductometry	University of Delaware; University of Dayton; General Electric; ASC Process Systems; Hughes Aerospace; U.S. Air Force Materials Directorate; U.S. Army Research Laboratories	**Often requires ionic doping to decrease resistivity. Can be combined with SMARTweave resin flow monitoring.**
Dosimetry	Adherent	**For EB processing, film coatings or coated optical fiber versions indicate exposure levels by color changes in the film layer. See text for more.**

Nuclear magnetic resonance (NMR)	**Boeing**	**Rising in importance for fiber placement**

The manufacturing process greatly affects the choice of sensing approach. The only approaches available commercially as part of commercially available control systems are thermocouple and dielectric. Dosimetry and nuclear magnetic resonance approaches have specific process alignments that may bring them to fruition in the near future.

Dielectric Cure Sensors. Dielectric measurements have been used for many years to characterize the electrical properties of materials and to study chemical reactions (Ref 8, 9 and 10). Since they are the only readily available method for monitoring the cure process at this fidelity, this method is discussed here in detail. Readers must decide whether their needs warrant developing one of the other approaches listed previously or whether dielectric sensors will suffice. For organic polymer systems, dielectric measurements have been shown to strongly correlate with various quantities such as molecular mobility, dynamic moduli, extent of crystallization, viscosity, the buildup of glass-transition temperature (T_g), and the extent of cure. These correlations have resulted in increased interest in applying dielectric methods for process monitoring and control during the cure of composite materials.

Dielectrometry is commonly performed using either matched parallel plate or comb electrodes that may be embedded in the bulk material or located on the sample surfaces. An alternative probe technology is the microdielectrometer, which consists of an interdigitated electrode deposited on a semiconductor substrate. To determine the dielectric constant, a time-varying voltage is applied and the output voltage or current waveform is measured. The excitation voltage is usually a sinusoid in the frequency range from 10^{-4} to 10^7 Hz. In general, the material will cause an attenuation of the output signal with an accompanying phase shift. The severity of these effects is determined by the sample conductance and capacitance, from which the complex dielectric constant may be determined via a model that incorporates the electrode geometry and an appropriate equivalent circuit representing the material under test. For polymers, the equivalent circuit is typically a collection of capacitive and resistive elements connected in parallel and/or in series. A basic example of this type of representation is given in Fig. 2. In this circuit, circuit C_1-C_2-R models the dipolar relaxations, and the addition of R_{ion} in parallel models ionic conductivity.

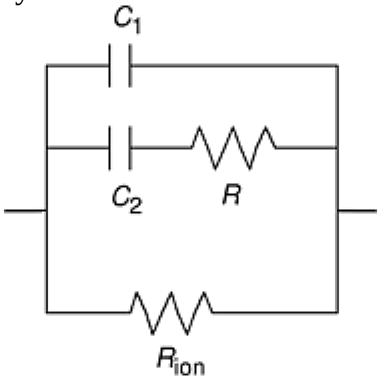

Fig. 2 Schematic of an equivalent circuit for a conducting polymer resin

Dielectric Constant. The complex relative dielectric constant, ϵ^*, is a measure of how much electromagnetic energy can be stored within a material and how much energy is absorbed or lost. The term “relative” in this instance comes from the fact that ϵ^* is referenced to the permittivity of free space, so that $\epsilon^* = \epsilon/\epsilon_0$, where $\epsilon_0 = 8.85 \times 10^{-14}$. Farads/cm. Equation 1 defines ϵ^* and shows the real and complex components, which are the dielectric permittivity, ϵ', and the dielectric loss, ϵ'', respectively.

$$\epsilon^* = \epsilon' - i\epsilon'' \qquad \text{(Eq 1)}$$

For polymers, ϵ' represents the polarizability of dipoles plus additional capacitance due to ionic charge accumulation and ϵ'' represents the losses associated with both dipole orientation and ionic conduction. Expressing this fact mathematically gives:

$$\varepsilon^* = (\varepsilon'_i + \varepsilon'_d) - i\,(\varepsilon''_i + \varepsilon''_d) \qquad \text{(Eq 2)}$$

where ϵ'_i and ϵ'_d are the respective ionic and dipolar contributions to ϵ', and ϵ_i and ϵ_d are the respective ionic and dipolar contribution to ϵ''.

Dipole Polarization. When a time varying voltage is applied to a sample, dipoles that are attached to polymer-backbone molecules will rotate to align themselves with the field. The time required for dipoles to align fully with the field is a characteristic of the dipole mobility and is referred to as the relaxation time, τ. The relaxation time is influenced by the following factors: temperature, viscosity, dipole size, dipole distribution, and the mobility of the segment to which the dipole is attached. In general, as temperature and segment mobility increase, τ decreases, and when dipole size or viscosity increase, τ increases. In reacting systems, for example, epoxy- amine, τ typically starts out low but then begins to increase as the reaction continues due to the motion-hindering mechanisms.

If a reacting system without any conducting ions were to be monitored versus time with a single frequency, the permittivity would be seen to remain initially at a constant level while the loss would be low. Early in the reaction, dipoles have sufficient mobility to quickly orient themselves to the applied field so full polarization can be achieved. Little energy is lost through alignment. As the reaction progresses, the permittivity would decrease, and the loss factor would increase to a maximum before falling again. This behavior is related to the increase in τ that results from the increased restriction of the dipole mobility due to the developing network. The point of maximum loss in this situation corresponds to the point where the period of the excitation voltage equals τ. Debye was the first to develop an analytical expression to describe hindered dipole motion in systems that possess a single relaxation time. Incorporating ionic conduction effects on the dielectric constant with the Debye model gives the following:

$$\varepsilon_i' = \frac{A}{\omega^{n=1}}\left(\frac{\sigma}{\varepsilon_0}\right)^2 \quad \text{(Eq 3)}$$

$$\varepsilon_d' = \varepsilon_u + \frac{\varepsilon_r - \varepsilon_u}{1 + (\omega\tau)^2} \quad \text{(Eq 4)}$$

$$\varepsilon_i'' = \frac{\sigma}{\omega\varepsilon_0} - \frac{B}{\omega^{n=1}}\left(\frac{\sigma}{\varepsilon_0}\right)^2 \quad \text{(Eq 5)}$$

$$\varepsilon_d'' = \frac{\omega\tau(\varepsilon_r - \varepsilon_u)}{1 + (\omega\tau)^2} \quad \text{(Eq 6)}$$

$$\varepsilon'' = \frac{\sigma}{\omega\varepsilon_0} + \frac{\omega\tau(\varepsilon_r - \varepsilon_u)}{1 + (\omega\tau)^2} \quad \text{(Eq 7)}$$

$$\sigma = \sum_i z_i q n_i \mu_i \quad \text{(Eq 8)}$$

where A and B are constants dependent on the electrode/material interface and electrode polarization, ω is the excitation frequency in rad/s, σ is the ionic conduction in $(\Omega/\text{cm})^{-1}$, z_i is the valence of the *i*th ionic species, q is the electron charge, n_i is the concentration of the *i*th species, μ_i is the ionic mobility, ϵ_r is the relaxed dielectric constant (defined as the value ϵ^* reaches when the maximum possible dipole polarization has been achieved for the given conditions), and ϵ_u is the unrelaxed dielectric constant (defined as the value of ϵ^* at infinite frequency, i.e., the base value of ϵ^* without dipole or charge migration included).

While Debye's model is sufficient for systems with one relaxation time, for example, a monodisperse, single-component monomer solution, real polymers typically exhibit a distribution of relaxation times. Therefore, the strict Debye equations no longer apply. For systems with a distribution of relaxation times, the Havrlik-Nagami (HN) equation is often used:

$$\varepsilon^* = \varepsilon_u + \frac{\varepsilon_r - \varepsilon_u}{\left[1 + (i\omega\tau)^{1-\alpha}\right]^{\beta}} \quad \text{(Eq 9)}$$

where α is a parameter describing the width of the relaxation, and β is a parameter that describes the asymmetry of the relaxation. These shape parameters can be calculated by fitting Eq 3 to experimental data.

Ionic Conduction. Many of the resin systems used for composite materials, for example, epoxy-amine, contain impurity ions or are easily ionizable. The ions present in the resin will move under the influence of the applied

electric field and absorb energy. As Eq 3 shows, the absorbed energy contributes to the dielectric loss. For highly conductive resins, the contribution of σ to ϵ'' can completely mask the losses due to dipole orientation. For these systems, the dielectric loss is given by Eq 10.

$$\varepsilon'' = \frac{\sigma}{\omega\varepsilon_0} \quad \text{(Eq 10)}$$

If ionic concentration does not change during cure, then the resin conductivity is a direct measure of the ionic mobility. The dependence of σ on ion mobility provides a powerful tool for monitoring the extent of cure, as the movement of ions through the polymer network will decrease as the network densifies. Prior to gelation, ionic mobility is high, and the conductivity is, in general, inversely proportional to the viscosity. At the gelation point, the macromolecule forms, viscosity becomes essentially infinite, and ionic mobility is drastically reduced. However, after gelation, ionic conduction does not become constant, as would be expected if viscosity were the sole determining factor. Instead, σ remains finite with a gradual decrease. This behavior corresponds to the further densification of the network that occurs as vitrification is approached. The existence of a measurable conductivity suggests that the local motion of polymer chain segments on the order of the ion size is sufficient to allow for conduction. Ionic conductivity is the most widely used parameter for cure monitoring because it is sensitive to the polymer viscosity, the concentration and type of molecular species present, and the microstructure of the polymer over a wide range of the cure. Measurement of ionic conductivity is typically accomplished through measuring the dielectric loss. Figure 3 shows a schematic of a typical plot of dielectric loss versus frequency, and Fig. 4 shows the typical behavior versus curing time.

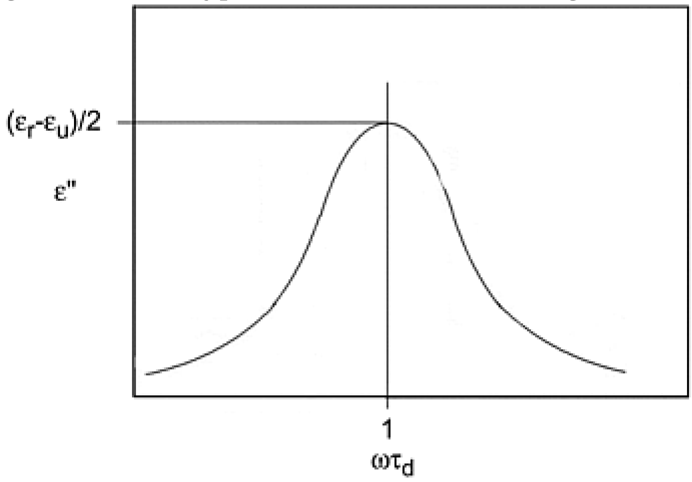

Fig. 3 Dielectric loss versus frequency for a typical epoxy resin

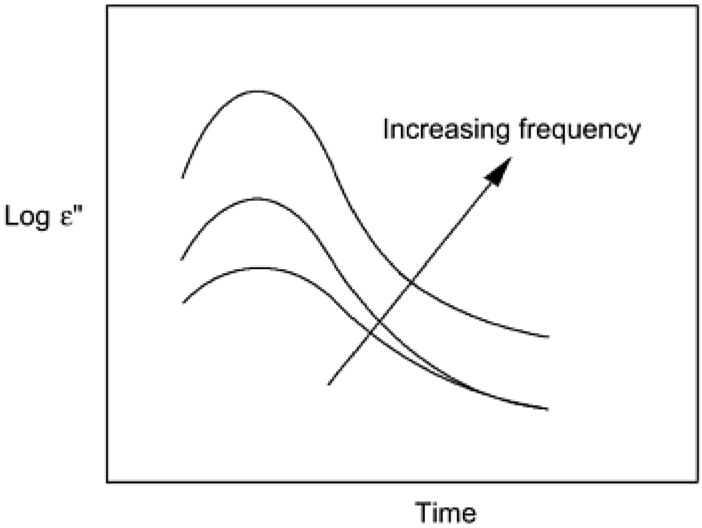

Fig. 4 Dielectric loss versus cure time for typical epoxy resins

Electrode Polarization. The analysis of dielectric data for cure monitoring can be difficult to interpret due to a phenomenon known as electrode polarization. This effect, which manifests itself under direct current conductivity measurements or low-frequency dielectrometry, is the result of the accumulation of ionic charge at

the electrodes. Due to the blocking nature of the electrode/polymer interface, the accumulated ions cannot discharge, thereby creating a charged boundary layer that adds to the specimen capacitance. This increased capacitance adds to the permittivity and lowers the apparent loss. The electrode polarization effect can be modeled by adding two capacitances in series with circuit C_1- C_2-R from Fig. 2, as shown in Fig. 5, where these two capacitances are combined into a single capacitor of thickness $2t_b$. Assuming that the permittivity of the blocking layer is the same as the material, the blocking capacitance, C_b, is given by:

$$C_b = \frac{\varepsilon_0 \varepsilon' A}{2t_b} \quad \text{(Eq 11)}$$

where A is the area in cm^2, and t_b is the thickness of the polarized layer in cm.

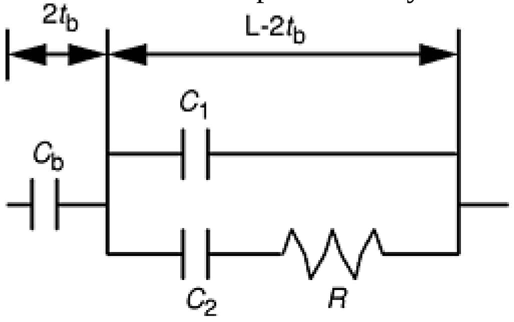

Fig. 5 Schematic of an equivalent circuit for a polymer sample of length *L*, with blocking layers

Electrode polarization may become significant when the admittance of the equivalent circuit, 1/ R, becomes greater than ωC_b. If this situation is avoided, then the sample behaves as a simple dielectric. However, if this situation occurs, for example, for highly conductive resins, then charging of the electrodes through R masks other circuit responses. When $1/R$ becomes large, electrode polarization becomes significant when the following inequalities are satisfied:

$$\cot(\varphi) > 1 \quad \text{(Eq 12)}$$

and

$$\cot(\phi) > \frac{L}{2t_b} - 1 \quad \text{(Eq 13)}$$

where L is the specimen length in cm. Experimentally, electrode polarization effects can be seen through the linearization of the plot of frequency versus loss factor, illustrated schematically in Fig. 6.

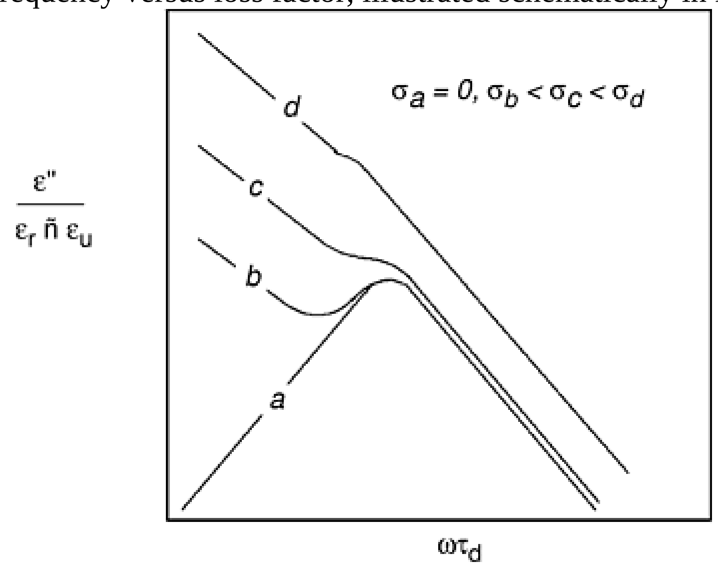

Fig. 6 The effect of ionic conductivity on the dielectric loss versus frequency

In composite materials, the presence of fillers such as fiber reinforcement may act as additional blocking interfaces that become polarized. These interfaces exhibit Debye-like phenomena known as the Maxwell-

Waner (MW) relaxation. Heterogeneous systems that produce MW relaxations can be modeled as multiple-layered heterogeneous capacitors.

The Cole-Cole Plot. A convenient tool for displaying dielectric data is the Argand, or Cole- Cole, plot. This diagram is constructed by plotting ϵ'' versus ϵ' for various frequencies. For a resin with no ionic conductivity and a single relaxation time (Debye behavior), the Cole-Cole plot is a semicircle with its center on the axis and intercepts at ϵ_u and ϵ_r as Fig. 7 illustrates. A distribution in the relaxation times would transform the plot from a semicircle to a more complex trace that can be described via the HN equation (Eq 9). From a Cole-Cole plot, the effects of multiple relaxation times, conductivity, and electrode polarization can be quickly and easily determined.

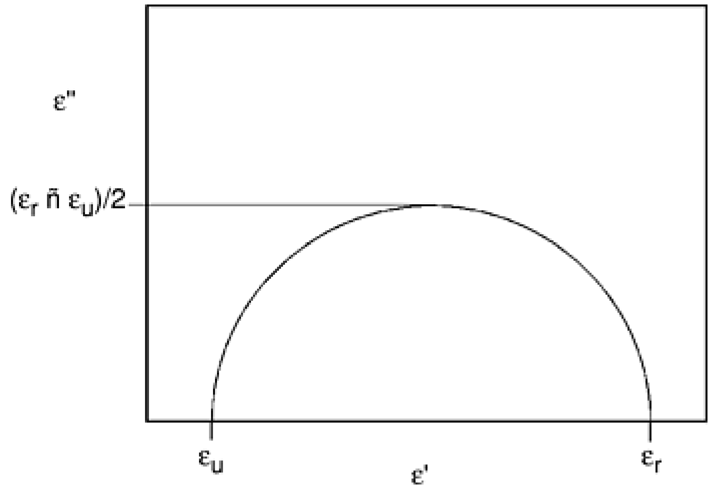

Fig. 7 A Cole-Cole plot

Ionic conduction and the presence of blocking layers will alter the Cole-Cole plot. High levels of ionic conduction will result in an almost linear plot (Fig. 8). The effect of electron polarization is opposite to the effect of ionic conductivity. The presence of blocking layers causes the Cole- Cole plot to become semicircular, mimicking a single Debye relaxation. Figure 9 shows the effect of boundary layer thickness on the Cole- Cole plot.

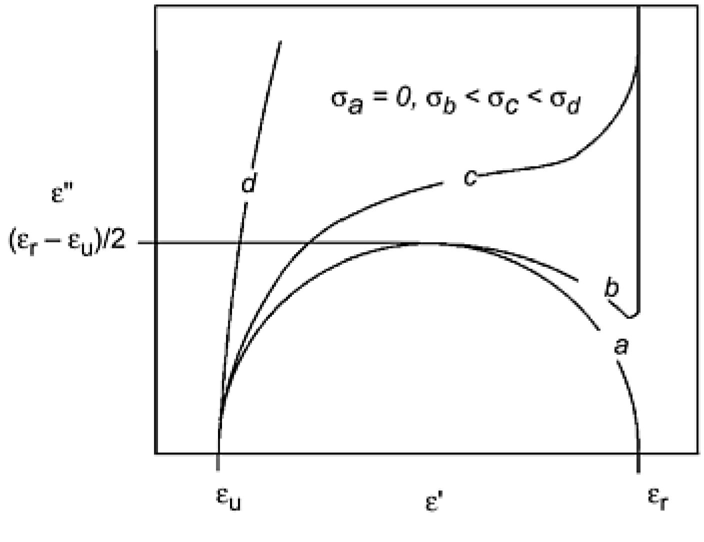

Fig. 8 Cole-Cole plot showing the effects of ionic conductivity

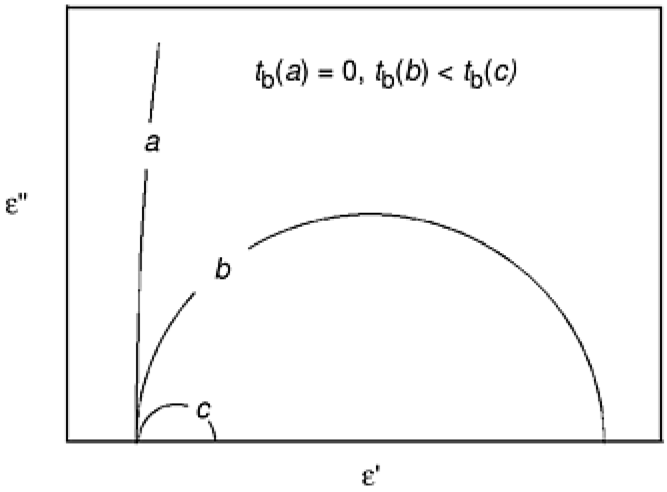

Fig. 9 The effect of boundary layer thickness on the Cole-Cole plot

Fiberoptics-Based Resin Cure Sensors. Fiberoptics may offer an inexpensive, robust method of monitoring resin-cure sensing. Various optical fiber approaches have been investigated, including monitoring the chemical changes within the resin via fluorescence, infrared spectroscopy, near-infrared spectroscopy, evanescent wave transmission (Ref 11), and tracking strain and temperature. All have been achieved at a level appropriate for laboratory use but none have really gained widespread acceptance.

The most simple of this class of sensors uses inexpensive optical fiber to monitor the changes that occur during cure in the index of refraction of the resin. Optical fiber with removable cladding (the part of the fiber that surrounds the light-carrying core of the fiber) has its cladding replaced in sensing locations with a high-refractive-index material, higher in index than the resin it is to be embedded within. This provides a large change across the entire cure but as the cure approaches completion, its index changes very little. For aerospace parts, this approach does not offer the resolution needed in the range desired but it may offer a low cost method for other industries.

The setup for achieving this comprises a laser, a power source for the laser, an optical detector, and some means of performing data collection and analysis. This approach has been done by several researchers in the past and recent availability of optical fibers with removable cladding may renew excitement over this approach.

Ultrasonics-Based Resin Cure Sensing. Ultrasonic techniques can be applied to monitoring the changes in mechanical response that result from the cure of thermosetting polymer matrix resins. Most of the techniques have focused on monitoring changes in viscosity in epoxy resins and composites undergoing thermal cure.

Fundamentally, ultrasonic cure monitoring methods involve introducing a pulsed ultrasonic signal to a curing system and measuring transit time for the signal to reach a receiving transducer. A signal velocity (and attenuation) is calculated from the transit time, amplitude, and distance. Changes in the ultrasonic signal velocity are analytically related to the density, thickness, and stiffness at the interface between the matrix and the transducer or waveguide.

Figure 10 shows a typical signal velocity trace for a carbon/epoxy composite under representative processing conditions (Ref 12). These basic relationships have been observed for a number of ultrasonic techniques with different coupling geometry (Ref 13, 14). An initial decrease in signal velocity is attributable to the decrease in viscosity of the matrix resin resulting from initial heating. This transition ends when the signal velocity reaches a minimum, corresponding with minimum viscosity. Then, the signal velocity increases as the effects of the cure reaction dominate the process (i.e., gelation and increasing cross-link density). Finally, the response levels off as cross-link density reaches a steady state.

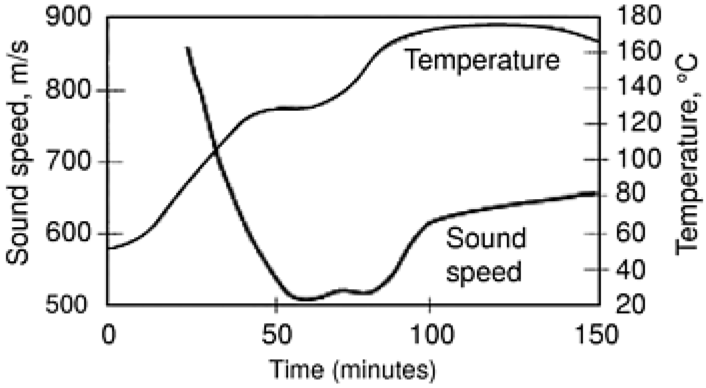

Fig. 10 Changes in ultrasonic signal velocity during processing of a compression molded carbon/ epoxy prepreg laminate. Source: Ref 12

Fiber ultrasonics is a technique that uses embedded filaments as sensing elements to characterize interfacial properties. The technique is based on guided-wave ultrasonics that were developed almost 60 years ago, when ultrasonic waves were used to propagate along transmission lines (Ref 15). When a high-frequency ultrasonic pulse (typically 0.5 MHz to 10 MHz) impinges on a rod, the ultrasound travels along the rod as a guided wave at specific velocities characteristic of the material properties of the rod. Analogously, if an ultrasonic pulse is applied to an unconstrained small-diameter fiber and the frequency of the ultrasound used for interrogation is chosen such that the corresponding wavelength is much smaller than the diameter of the fiber, the ultrasound will propagate along the length of the fiber as a guided wave. The properties of the ultrasonic wave propagation are characteristic of the fiber material properties (Ref 16, 17).

In cases where the fiber is constrained along its axial radial boundaries, the guided ultrasound leaks from the fiber to the surrounding media, thereby altering the observed ultrasonic response. The rate and nature of the ultrasonic leakage is a function of the density, thickness, and stiffness of the fiber-matrix interface region (Ref 18, 19). Therefore, analysis of the waveguide propagation provides a direct measure of the fiber-matrix interfacial characteristics.

The primary advantage of this method is that it offers a direct measure of stress-wave transfer within the material, which could enable both in- process material characterization and in-service condition analysis. In addition, a reinforcing fiber can be directly used as the primary sensor in the structure. Although there has been specialized application of guided-wave ultrasonic cure monitoring (Ref 20), fiber ultrasonic techniques that employ reinforcing fibers as the waveguides are still in development.

In conclusion, ultrasonic cure monitoring technologies allow the state of cure to be monitored without intrusive sensors. Commercial systems are available (Ref 12), even though most applications have been in research and process- development environments. Ultrasonic cure monitoring is being evaluated for production implementation for a range of composite processes.

Dosimetry-Based Resin Cure Sensors. Electron-beam curing of carbon fiber composite materials promises to be very economical while providing significant manufacturing options that are not possible with the conventional autoclave cure process. Advantages of EB curing include dimensional stability of cured parts, potential for secondary bonding after partial cure, speed of cure operation, lower cost, compatibility with complex assemblies, and low-cost tooling. If this technology makes it to maturity, conventional cure sensing approaches will not suffice because EB cure processes must be monitored for accumulated dose values to determine if adequate levels of radiation have penetrated the laminate being cured. This is a significant departure from current practice in autoclave and liquid molding processes.

This monitoring is currently performed as a post-process verification using film as the verification medium. This does not allow for the collection of in-process control data nor in-process adjustment of the process to ensure conforming results. The film is developed and the density compared to a known reference standard to determine the amount of accumulated radiation that has passed through the laminate. If the value is below or above the specification level, a nonconformance is generated and engineering must disposition the part. The cost of this nonconformance is determined by the type. Overcured laminates normally do not require any additional curing. Undercure nonconformances normally require additional post curing at a nominal temperature. The undercure and overcure are an inherent risk of using the film method of monitoring degree of cure in EB laminates.

Fiber optic dosimetry holds the potential to be used to predict cure-acceptance parameters, in- process and real-time. This capability would provide manufacturing the visibility of the cure process to partial cure laminates to specific glass-transition temperature (T_g) values. This partial cure capability should be predictable, repeatable, and reliable for production level EB curing operations. Current fiber optic dosimeters (Ref 21) have a limited life based on current technology development, but their cost appears to be dropping rapidly based on the sharing of development costs with the medical industry.

Reducing the need for post-EB cure physical verification such as T_g could also be accomplished by developing a statistical database that correlates the accumulated cure dose to the appropriate thermal T_g value. Once the correlation is established, the risk of a cure nonconformance could be eliminated except for catastrophic process failures such as equipment failures or blatant operator error. This concept becomes increasingly important as the unionization of composite parts into large structures continues and manufacturing nonconformance risks increase. Using the accumulated dose as a method of determining the degree of cure also improves the manufacturing process flow by eliminating the hold time for testing. Support labor cost will also drop due to a lack of post-process verification requirements.

Resin Cure Control

For autoclave, RTM, SCRIMP, VARTM, and other heat-activated cure processes, control is exercised over the temperature or pressure or both. None of these should require extreme measures to increase the overall degree of cure unless the cure is sufficiently nonuniform that a global cure cannot be performed. For other processes where energy is supplied via UV, microwave, or EB energy, additional exposure would be used to increase the degree of cure in localized areas.

Flow Sensing

As resin infiltrates the fibers in any of the infusion processes, it must follow a path that completely fills the part. This is more difficult than it appears due to variations in the permeability of the materials along its path. The most obvious problems are encountered when resin finds an easy path along the edge of the cloth in what is termed racetracking. The resin front path can be modeled, mapped, and, to some degree, controlled.

Flow Modeling

Resin-flow front mapping is useful for locating and identifying problems, but its full value cannot be achieved until the identified problem is fixed and the reasons for the sensed abnormalities are understood and accounted for in future components. Resin-flow modeling must be used in coordination with design and modeling to minimize the occurrences of flow-related problems and to optimize inlet and outlet locations as well as runner size and location. The University of Dayton Research Laboratory, the U.S. Army Research Laboratory,

Stanford University, the University of Connecticut, and the University of Delaware all were active in flow modeling at the time of publication.

Flow Mapping

Process control will require improved resin- flow-front sensing methodologies tuned to the needs of high-quality composites. These flow mapping technologies must of course be mated with models and controls systems in the rest of the process to achieve the best part quality and cost. But the first step in achieving flow control is being able to track resin flow. Most of this work has concentrated on SMARTweave (developed by the Army Research Laboratory and licensed to Holometrix Micromet, Bedford, MA) but there has been some work in fiberoptic and infrared flow mapping that may well become important in the near future. SMARTweave and methods of a similar electrical nature have been found to work quite well in nonconductive materials, and some work has been done to extend this approach to carbon-fiber-based composites. Infrared flow monitoring has been demonstrated on heated tables but lags significantly in utility in the other bagged processes like VARTM and SCRIMP. Optical flow-front monitoring has also been demonstrated with various schemes to fill air gaps in the fiber with resin, but none have made it anywhere near production. At this time, the only method that has shown significant development and promise is SMARTweave.

SMARTweave for resin-flow front mapping was developed to monitor resin-flow-front progression and provide data for control of resin flow in large RTM fiberglass parts. The SMARTweave resin-flow-front monitoring process is well developed and commercially available for most current composites manufacturing processes. It consists of a grid of conductors, half of which are located between two plies in one orientation. The other half are located between two other plies and oriented orthogonally. The resistance between two conductors gives an indication of resin presence or absence at the point at which the conductors are closest. For carbon fiber composites, the fibers themselves are conductive, and so care must be taken to insulate the SMARTweave grid from the surrounding reinforcement. The U.S. Army Research Laboratory and the University of Delaware Center for Composite Materials have demonstrated that this can be accomplished by using a sensor grid composed of overbraided copper wires. Research has also shown that the SMARTweave technique can be accomplished using carbon tows as sensor elements to reduce the impact of the sensing grid on material performance. However, the use of carbon tows does not reduce the number of electrodes that must egress from a mold or vacuum bag.

While generally not a concern for processes that are not sensitive to minor pressure loss, resin loss, or air infiltration and embedded wiring, the point of egress of each sensing and excitation wire are potential resin or air-leak paths for VARTM and other highly vacuum-sensitive processes. Therefore, care must be taken to mitigate this risk. A potential solution has been found by reducing the number of wires needed to perform the multiplexing of the sensor grid to a three- wire set coupled to a signal-processing circuit board. These modifications to the process allow SMARTweave to be implemented on aerospace- quality structures as long as the wiring dimensions do not result in unacceptable strength degradation.

To further the acceptance of SMARTweave for monitoring the manufacture of strength critical components, further studies are needed to demonstrate that this method can be implemented without deleterious effects on structural performance. However, this technology has demonstrated sufficient reliability and performance that Micromet Inc. (Bedford, MA) currently offers commercially available SMARTweave resin- front tracking systems based on the systems originally conceived by the U.S. Army Research Laboratory (Ref 22) and further developed by the University of Delaware Center for Composite Materials (Ref 23).

Resin Flow Control

There are currently no methods to modify the resin-flow front beyond altering the application of resin pressure at various inlets or the incoming resin temperature. For many cases, adjusting resin pot temperature or pressures works well, and controlling inlets and temperature is mostly straightforward. However, localized disturbances in the flow field cannot currently be addressed except by introducing more resin or cycling the resin to remove any pockets that are created. This is a known and identified gap in available technology.

Practical Issues in Sensing Resin Cure and Flow

Tool-Mounted Sensors. Most resin-cure- sensing efforts have either placed a sensor under the bagging material in autoclave processing or passed a sensor through the tool in RTM processing. Either of these tends to result in a mark of some sort in the surface of the part. Tool- mounted sensors tend to have less trouble with the wires or fibers moving or breaking. Tool- mounted sensors also tend to meet some resistance due to increased tool costs or fear that cleaning the tool surface will damage the sensor. Both of these objections have indeed been overcome in some instances (Ref 24), so tool mounting is still considered a viable option for production composite part manufacture.

Ingress/Egress. Sensors must have power to work. Usually they use electrical power; sometimes they use optical energy instead. In either case, any sensor that is in contact with the resin system must have available electrical or optical energy that will typically pass through the tooling or bagging used to contain and shape the part. This presents a major obstacle, especially when this is not considered until late in process design.

Resin under pressure tends to find a way out of the bag or tooling at these ingress points unless care is taken to seal the resin in over the entire temperature and pressure range. This thins the part or allows gasses to enter or collect. The designer must also consider that the fibers and resin will move during processing, sometimes shearing off the lead in wire or fiber so carefully designed into the tool. Both optical and electrical sensors have been used successfully in situ, but the designer must account for this as early as possible in the design of the tooling and, preferably, the part.

Nondestructive Testing

ASM International Committee on Nondestructive Testing of Composites*

Introduction

COMPOSITE MATERIALS, because of their nonhomogeneous, anisotropic characteristics, pose significant challenges for defect detection and materials property characterization. Throughout their life cycle, composites are susceptible to the formation of many possible defects, primarily due to their multiple-step production process, nonhomogeneous nature, and brittle matrix. These defects include delaminations, matrix cracking, fiber fracture, fiber pullout, and impact damage. Table 1 shows some of the defects that may appear in composite laminates and their effect on the structural performance. While the emphasis of most practical nondestructive evaluation (NDE) is on detection of delaminations, porosity, and impact damage, Table 1 shows that other defects can also have critical effect on the host structures.

Table 1 Effect of defects in fiber-reinforced composite materials

Defect	Potential effect on structural performance
Delamination	**Catastrophic failure due to loss of interlaminar shear strength. Typical acceptance criteria require the detection of delaminations with a linear dimension larger than 6.4 mm (0.25 in.).**
Impact damage	**Loss of compressive strength under static load**
Ply gap	**Strength degradation depends on stacking order and location. For $[0, 45, 90, –45]_{2S}$ laminate, strength is reduced 9% due to gap(s) in 0° ply and 17% due to gap(s) in 90° ply.**
Ply waviness	**For 0° ply waviness in $[0, 45, 90, –45]_{2S}$ laminate, static strength reduction is 10% for slight waviness and 25% for extreme waviness. Fatigue life is reduced at least by a factor of 10.**
Porosity	**Degrades matrix-dominated properties. 1% porosity reduces strength by 5% and fatigue life by 50%.**
Surface notches	**Static strength reduction of up to 50%. Strength reduction is small for notch sizes that are expected in service.**
Thermal over-exposure	**Embrittlement and reduction of toughness up to complete loss of structural integrity**

This article introduces the principal methodologies and some advanced technologies that are currently being applied for NDE of composite materials. The primary discussion and examples are for fiber-reinforced polymer-matrix composites. Many of the techniques have general applicability to other types of composites, such as metal-matrix composites and ceramic-matrix composites. However, there may be specific application differences and limitations that are not addressed.

Nondestructive Testing

ASM International Committee on Nondestructive Testing of Composites

---

Ultrasonics

The most common method of NDE for composite materials is ultrasonic inspection. The measurement of ultrasonic parameters can provide a wealth of information on the quality of composites. Ultrasonics can generally detect delaminations, inclusions, matrix macrocracks, and voids in composites structures. The ultrasonic method itself uses longitudinal, shear, Lamb, Rayleigh, or guided waves for various measurements on composite materials. Wave parameters, including acoustic attenuation and speed, can be used to determine materials properties and characteristics, such as void fraction, stiffness, and, if the density is known, moduli. The reader is referred to other texts and articles to obtain detailed information on the fundamental aspects of ultrasonics as well as advanced methodologies for measurements using ultrasound (Ref 1, 2, 3, 4 , and 5).

The acoustic impedance of the media and frequency of the vibrations determine the ultrasound propagation through materials and the behavior at interfaces. The acoustic impedance (Z) of a material is defined as:

$$Z = \rho c \qquad \text{(Eq 1)}$$

where ρ is the material density, and c is the acoustic velocity in the material. The frequency and wavelength are related by the equation:

$$f\lambda = c \qquad \text{(Eq 2)}$$

where f is frequency, and λ is wavelength. At interfaces, the sound energy transmitted or reflected depends on the acoustic impedance of each media. The transmission (T) and reflection (R) of sound energy from media 1 to media 2 for a normal incidence sound beam is given by:

$$T = 4Z_2 Z_1/(Z_2 + Z_1)^2 \qquad \text{(Eq 3)}$$

and

$$R = [(Z_2-Z_1)/(Z_2+Z_1)]^2 \qquad \text{(Eq 4)}$$

respectively, where Z_1 and Z_2 are the acoustic impedances of media 1 and media 2. Table 2 provides some typical acoustic characteristics of materials, and Table 3 gives the relative wavelength as a function of the frequency. For example, at the interface between water and a graphite/epoxy interface, the transmission and reflection of sound energy will be 152% and 52%, respectively. The sound energy in the composite material will be greater than in the water. At an interface between graphite/epoxy and air, the transmission is 0.017%, and the reflection is 100%. It is this change in the acoustic impedance that allows ultrasound to be used to detect defects in materials. Delaminations and cracks represent air interfaces that transmit very little sound and provide a large reflection. Inclusions must have a sufficient difference in acoustic impedance from the composite material in order to be detected.

In solid homogeneous material, both longitudinal (compression) and transverse (shear) waves can be created and monitored independently. In composite materials, however, the separation of longitudinal and transverse waves is much more difficult. Composites are anisotropic media. The plane waves moving through the anisotropic media are often only quasi-longitudinal or quasi-transverse (containing both longitudinal and shear characteristics), because of the wave interactions at the many matrix and the reinforcing material interfaces. In fiber-reinforced composites, the ultrasonic waves can travel along fibers, and therefore, the technique can be highly sensitive to the fiber orientation in the structure. This feature can be used as a means of characterization of the structure (Ref 6). However, for the general inspection of fiber-reinforced composites, the most common inspection is with ultrasonic waves perpendicular to the fiber tape or fabric planes.

As the ultrasonic beam passes through a material, it will be attenuated due to scattering, absorption, and beam spreading. The anisotropic properties of composites can make them strong scatters of ultrasound, depending on the wavelength. As shown in Table 3, for ultrasonic frequencies between 1 and 10 MHz, the wavelength will be between 0.3 and 0.03 mm (0.01 and 0.001 in.). Features in the composite larger than one-tenth the wavelength will contribute to scatter. Features smaller than this will not be detectable. Absorption occurs due to the conversion of the sound energy into heat. Beam spreading is due to the geometric principles of the ultrasonic beam size, frequency, angle, and distance. Considering the attenuation due to scatter and absorption, the sound pressure of a plane wave in the far field can be represented by:

$$p = p_0 e^{-\alpha d} \quad \text{(Eq 5)}$$

where p is the end pressure, p_0 is the initial pressure, α is the attenuation coefficient, and d is the distance traveled. The attenuation coefficient in dB/m is obtained from Eq 5, such that:

$$\alpha d = 20 \log (p_0/p) \quad \text{(Eq 6)}$$

where 20 log (p_0/p) is the ratio in decibels of the initial-to-final pressure. The use of the logarithmic dB parameter is customary for attenuation or gain in ultrasonic inspection, because it allows significant ranges to be measured. A change of 6 dB represents a factor of 2 between the initial pressure and the end pressure; a change of 20 dB is a factor of 10, and a change of 80 dB is a factor of 10,000. Figure 1 shows an example plot of the attenuation of a fiber-reinforced graphite/epoxy material as a function of thickness measured at 5 MHz. Actual attenuation coefficients will vary as a function of the fiber, matrix, and lay-up. The acoustic attenuation for the example shown is on the order of 1300 dB/m (33 dB/in.).

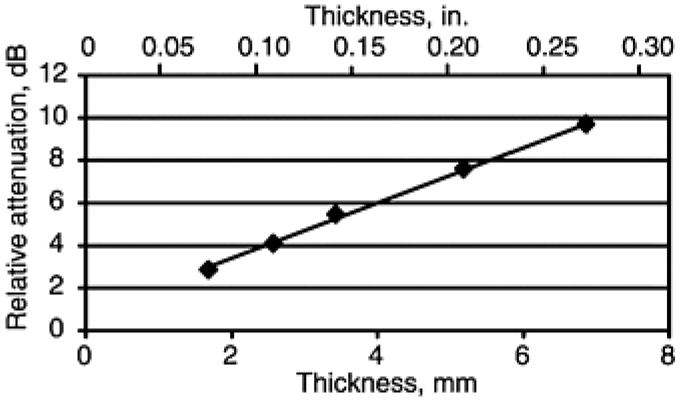

Fig. 1 Acoustic attenuation at 5 MHz for a graphite/epoxy composite as a function of material thickness

The most common inspections of composite structures are through-transmission (TT) ultrasonics and pulse-echo (PE) ultrasonics. The TT method uses two transducers, one on each side of the part, to measure the acoustic attenuation through the structure. One transducer is the transmitter and is electronically pulsed to produce an ultrasonic signal, and the other transducer is the receiver, typically aligned opposite to the pulser. The coupling media of the ultrasound to the composite is usually water. This may be performed by immersing the sample in a water tank or by using water-squirter systems. For TT examinations, the pulser often employs a tone burst (several cycles of the waveform), so that significant ultrasonic power is available. Through transmission is the most common ultrasonic examination method for fiber-reinforced composites. Trough transmission is relatively simple to implement, much more forgiving than automated PE on alignment of the transducers to the part under test, typically has a wide dynamic range (>120 dB on some systems), and easily detects problems in multilayered structures. By comparing TT signal loss in adjacent good areas, porosity,

unbonds, wrinkles, delaminations, and most inclusions can be detected. In the case of porosity, the signal loss can be correlated to standards. For example, porosity in the 1 to 2% range corresponds to a change of 4 to 8 dB in signal level for approximately 6 mm (0.25 in.) of graphite/epoxy material at 2.25 MHz. Through transmission methods cannot determine the depth or layer of detected defects. This must be accomplished using pulse-echo ultrasonic methods. However, data from TT methods are normally presented in the C-scan mode, which presents an image of the part with gray scale or color values relating to the attenuation experienced. This is perhaps the easiest ultrasonic presentation to interpret.

Pulse-echo ultrasonic methods typically use a single transducer as both the pulser and receiver of the ultrasound signal. The ultrasound is commonly coupled into the part using a couplant, such as water, glycerin, and other materials. Typical noncontact systems used to couple PE transducers to the parts are hand-held devices, immersion tanks, water-bubbler systems, or water-squirter systems. Any of these systems can be automated.

The advantages and limitations of the coupling methods for automated water-coupled systems are summarized in Table 4.

Table 4 Advantages and limitations of automated system water-coupling methods

Method	**Advantages**	Limitations
Immersion systems	Excellent signal quality, no moving water, very clean and stableGood spatial resolution at a prescribed focal zone of the transducerLarge stand-off distances are possibleCan be used in TT and/or PE modeBest resolution available using focused transducers	**Buoyancy and loading stresses on the part must be considered.Part size, plus tooling and viewing the test under water, are issues.Tank depthScanning speed**
Water-squirter systems	No immersion required (buoyancy not a problem)Large stand-off distances (e.g., 200 mm, or 8 in.) are possible.Resolution/power transfer of TT sound can be tailored for the application.Fastest scanningCan be used in TT and/or PE mode	**Manipulator systems can be complex to maintain surface alignment.Water squirters must be properly designed and matched to the transducer application.Scan quality can suffer due to water splash and air in squirter system.Cannot effectively use focused transducers**
Bubbler/dribbler systems	**Excellent signal qualityLow implementation cost**	**Edge/cutout inspection limitations, due to the contacting nature of the bubbler scans, cannot cover the full part surface.Speed limitations. Bubblers have been used at up to 50 cm/s (20 in./s) surface speed. Squirters are used up to 100 cm/s (40 in./s).Cannot effectively use focused transducersCan only be used in PE modeNot effective for parts with complex shapesLimited penetration capability**

For PE inspection, the sound is reflected from the front and back surfaces of the composite material as well as from internal defects. Usually, a narrow electronic spike pulse is used in PE inspections to generate a short burst of ultrasound, so that a time-based waveform display (A-scan) can show the difference in the interfaces. While this presentation is not as intuitive as the C-scan, it has the advantage that defect depths can be determined and also, for a trained inspector, provides some information about the nature of the defect. Figure 2 shows a PE ultrasonic waveform at 5 MHz of composite structure. The first pulse is the front surface echo of the part (the interface between the coupling media and the part). The second pulse is the back surface echo of the part. Any reflective defects will show up as echoes between the front and back surfaces. The height of the echo correlates to the size, depth, surface geometry, and impedance mismatch of the defect to the composite. Delaminations (air interfaces) will essentially block all sound from going any further into the composite. Therefore, PE is usually limited to detection of the first occurring defect. By knowing the wave speed in the composite part, or through the use of reference standards, thickness or defect depth can be measured.

Carbon/epoxy composite materials have a characteristic wave speed of around 3.2 mm/μs (0.125 in./μs). This can vary by as much as 5% in parts of the same material, so care must be used when using PE ultrasound for absolute thickness measurements. Automated PE inspection usually generates plan-view images of the time of flight from front surface to the next significant reflector (back wall or defect). Different colors or gray scales indicate part thickness or depth. Amplitude images can also be generated by gating on the back wall, a reflector plate, or gating after the front reflection. Parts with varying thickness have to use the latter method. Care must be taken in evaluating PE amplitude images, because defect reflections or multiples of the defect can occur within the gate. Porosity detection with PE amplitude is usually more sensitive than TT, due to the back-wall reflection having gone through the part twice. Also, the dynamic range (~35 dB) in PE mode is usually limited, due to sound continuing to reverberate in the good layers of the composite. For these reasons, porosity over 1 to 2% usually cannot be quantified in PE mode.

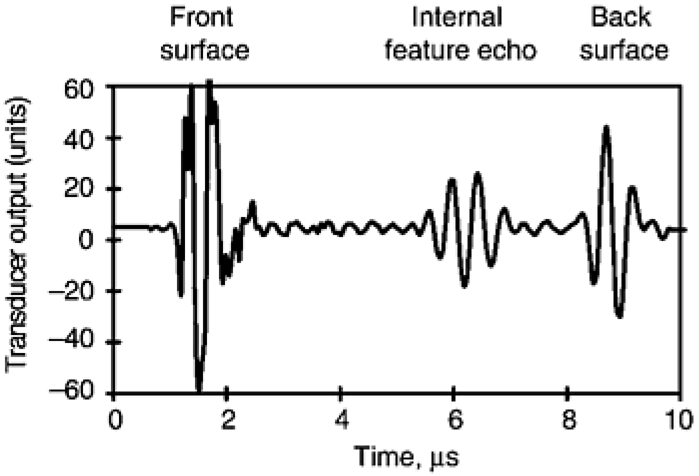

Fig. 2 Example ultrasonic waveform in a composite sample

Pulse-echo ultrasound is very sensitive to angle of the transducer to the part under test. The rule of thumb is that the transducer should be within 2° of normal to the composite. Maintaining 0.5° alignment provides better data quality (less variation) and is highly recommended. In comparison, TT data can be evaluated with up to about 10° of part misalignment. Automated systems for PE scanning thus usually require more axes of motion and more complex motion software or require contact with the part surface, with the transducer mounted in a free-gimbaled bubbler (which limits inspection near the edges). Pulse-echo is mainly used in the industry when access is limited to one side or when film-type foreign material inclusions are possible. These foreign materials have acoustic impedance very close to the composite and thus do not cause much difference in TT attenuation (less than 0.5 dB). However, these materials will generate significant reflections (20 to 30% of front wall) in PE mode. For automated PE inspection of thick composite parts (>13 mm, or 0.5 in., thick), time-corrected gain (often called distance amplitude correction) is required to keep PE defect sensitivity constant throughout the composite thickness. The electronic gain applied to the raw ultrasonic signal is increased as a function of time to compensate for the natural attenuation of the composite. Thus, defects near the back wall of the composite are brought up to the same amplitude as a near-surface defect. Newer-generation systems allow the operator to tailor this curve to the specific composite and lay-up in use.

In the aerospace industry and other industries as well, automated ultrasonic inspection is the principle inspection method for testing and accepting fiber-reinforced composites. Automated scanners are employed that acquire TT, PE, or combined ultrasonic measurements over an entire structure at high speed.

Automated ultrasonic scanning systems take many forms and sizes. They range from small tabletop immersion tanks to large overhead gantry systems. Figure 3 shows a small, flat panel scanner where the parts under test are suspended on a cable bed. The cables are smaller in diameter than the defect class size required. This is a TT-only water-squirter system and uses two channels of TT data to decrease inspection time. For more complicated composite structures, ultrasonic systems have been developed to track part contour. Figure 4 is a large overhead gantry system, with nine axes of motion to follow part curvature in two directions. The part contour is programmed, taught, or brought in via computer- aided design surface data. The mechanism moves the system over the part surface, following and keeping the squirters normal to the part contour. The system indexes at the end of each scan pass. For laminate composites, data is typically acquired at 1 mm (0.04 in.) spacing in the scanning direction and 2 mm (0.08 in.) spacing in the index direction. The transducers are pulsed at each 1 mm

(0.04 in.) interval, and the ultrasonic signals are received, converted to digital data, and stored in a computer file. Imaging software is provided to view the data on a computer screen in shades of gray or color.

Fig. 3 Automated ultrasonic two-channel flat panel through-transmission system

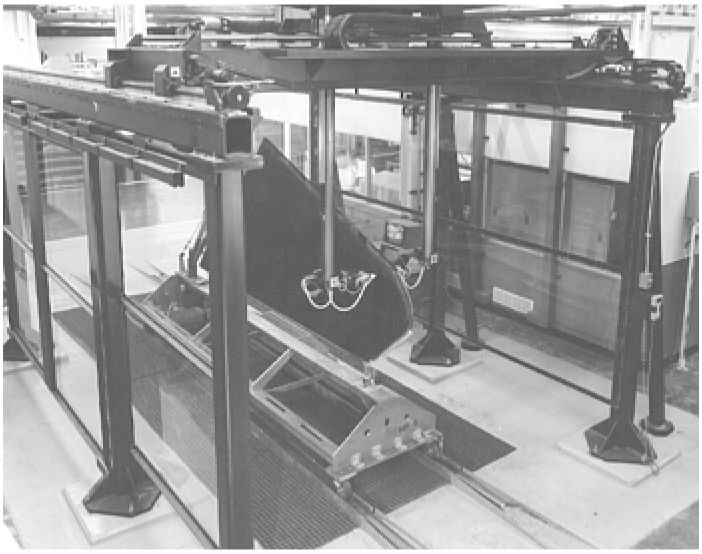

Fig. 4 Overhead gantry automated ultrasonic scanning system

Most large gantry systems have maximum scan speeds of 76 cm/s (30 in./s) for flat parts. Part contour can slow motion down to the 38 cm/s (15 in./s) range. This provides for overall scan speeds in the 2.3 to 4.6 m^2/h (25 to 50 ft^2/ h) range. On relatively flat parts, a second set of squirters (and the associated electronics) can be added to double this rate to 9.3 m^2/h (100 ft^2/h). These rates are calculated at 2 mm (0.08 in.) per index. When comparing methods, the data resolution must be considered for proper comparisons. Current-generation scanners and the associated acquisition electronics can scan at up to 100 cm/s (40 in./s) while maintaining 1 mm (0.04 in.) data spacing in the scan direction.

For round or nearly round composite parts, the most cost-effective ultrasonic scanning method is obtained by placing the part on a rotating turntable fixture under a gantry system. If the system is properly designed, the turntable should be able to rotate continuously to maintain 100 cm/s (40 in./s) movement of the squirters over the part. Turntables, combined with dual nozzles, can therefore provide 190 ft^2/h of scan speed at 1 by 2 mm (0.04 by 0.08 in.) data spacing. Figure 5 shows a turntable scanner system.

Fig. 5 Automated ultrasonic inspection system with a turntable

The latest generation of automated ultrasonic scanners has gone to independent machines on each side of the part to be tested. Advantages to these types of scanners are independent surface following from each side, much improved “reach-in” capability, overall stiffness, and reduced ceiling height. An example is shown in Fig. 6.

Fig. 6 Independent side automated ultrasonic scanning system

An important feature when choosing an ultrasonic scanning system is the ability of the system to provide 1 to 1 flaw sizing on complex curved structures. Figure 7 shows a TT image of the internal structure for the composite C-17 landing gear pod fairing shown in Fig. 6. The data have been acquired such that the two-dimensional image accurately represents the three-dimensional surface of the part, similar to map layouts. The lighter areas are laminate-only areas (less attenuation); the darker areas are fiber-honeycomb buildup areas. With the TT dynamic range of this system, both types of areas can be inspected with a 5 MHz transducer frequency. Honeycomb areas are typically scanned at 1 or 2.25 MHz. Multilayer (septumized) honeycomb or foam-filled structures are scanned at 250 kHz, 500 kHz, or 1 MHz. Because resolution suffers at lower frequencies, parts are generally scanned with the highest frequency that can provide penetration through the part. Laminate-only parts are generally scanned at 5 MHz for both TT and PE. In thin PE applications, 10 and 15 MHz are sometimes used.

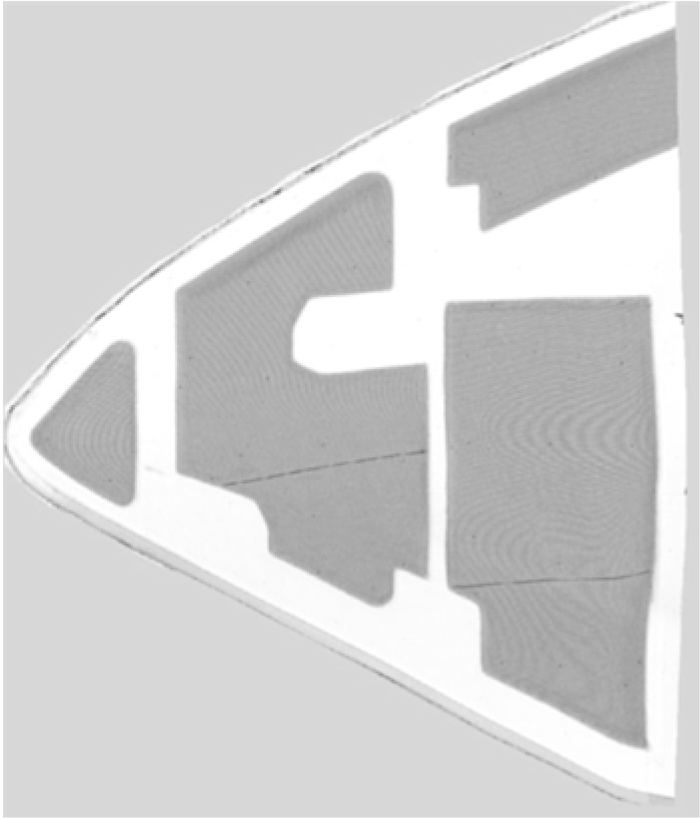

Fig. 7 C-17 pod fairing through-transmission ultrasonic data image

The terms A-scan, B-scan, and C-scan are used throughout the nondestructive testing (NDT) industry to describe the types of data images being acquired. Figure 7 is considered a C- scan image, which is a plan view of the part. The colors or gray scales of a C-scan image can represent TT amplitude, PE depth, PE amplitude, and numerous other data types. An A-scan image is a single ultrasonic waveform display, as shown in Fig. 2, where the horizontal scale represents time, and the vertical scale represents amplitude. A B-scan image is a plot of distance along the surface of the part on the horizontal axis, with time plotted vertically and amplitude data represented in gray-scale shades or colors.

A- and B-scans are generally not acquired for production inspections of composite structures. The magnitude of data storage requirements for acquiring the full waveform data required for A- and B-scans has limited production applications—1 to 3 C-scan parameters per pixel (image files in the megabytes) versus 512 to 2048 waveform samples per pixel (image files in the gigabytes). Very critical composite and bonding applications, such as high-bypass fan blades and shuttle solid rocket motors, are where waveform acquisition is currently used in production. As computing and disk capacities increase, more systems will provide waveform capability at production inspection speeds. The advantage of waveform acquisition is verification and quantification of defects without separate inspection processes (such as hand A-scan).

Figure 8 shows A-, B-, and C-scan image examples. The C-scan image is the background image. This particular C-scan is PE amplitude data from the interface between a laminate and honeycomb substructure. The line over the defect in the upper right of the C-scan image shows the location of the B-scan image, which is shown in the left inset. The top sets of lines in the B-scan image are the front surface-part reflection. Below that are echoes from the internal composite structure. The defect shows up as a much stronger echo than the surrounding good area. The right inset is an A-scan trace over one point of the defect. The front and defect echoes are readily seen. Flaw detection is much easier using C-scan imaging, because the gray or color image provides a view of the defect and surrounding good areas for easy comparison.

Air-Coupled Ultrasonics

In many instances, it is beneficial to inspect some types of composite materials without contacting the surface with water or other coupling liquid used in the standard ultrasonic inspection system approach. One method to accomplish this is with air-coupled ultrasonic testing (UT). The technique can be used very effectively on composite materials, such as laminates, honeycombs, and foams. Air-coupled ultrasound inspection has been performed using frequencies from 50 kHz to 5 MHz (Ref 7, 8, 9, and 10). While the attenuation of ultrasound by air is an issue at high frequencies (at 1 MHz it is over 100 dB/m), it is the large acoustic impedance difference at the air- solid interfaces that has the greatest influence on the signal amplitude at the receiving transducer. As noted earlier, the transmission of ultrasound from graphite/epoxy composite to air is only 0.017%; whereas the transmission of ultrasound from graphite/epoxy composite to water is on the order of 93%. This nearly 4 orders of magnitude difference in transmission characteristics requires some significant differences in air-coupled UT systems from conventional equipment.

Materials with lower acoustic impedance (generally lower-density materials) are well suited for air-coupled UT inspection. Thick or multilayered sandwich panels with foam or honeycomb core construction are good examples. It is not unusual to find air-coupled UT effective through structures such as these that are 150 to 200 mm (6 to 8 in.) thick or more, using frequencies of a few hundred kilohertz. For solid laminate material and higher-frequency inspection, it is necessary for the ultrasonic transducers and electronics to have very high sensitivity.

Air-coupled UT can be performed with piezoelectric transducers or with microelectromechanical (MEM) transducers (Ref 10, 11, 12, and 13). The MEM transducers typically exhibit a significantly lower acoustic impedance than piezoelectric transducers and so provide a better acoustic match to air (Ref 12). However, MEM transducers are relatively new and have not yet been implemented in commercial instruments. The use of impedance matching layers for piezoelectric transducers has been demonstrated to transmit ultrasound through air with only 30 dB signal loss, compared to conventional contact transmission (Ref 9). The development of the efficient acoustic matching layers, high-intensity tone burst generators, and low-noise electronics allows the high interface losses in the air-coupled approach to be overcome with adequate sensitivity for air-coupled piezoelectric transducer application (Ref 14).

The use of high-power tone-burst operation and the reflection of most of the energy at the first interface back to the transducer suggest that air-coupled UT implementation should use the TT ultrasound or pitch-catch operational modes. Figure 9 shows the configurations commonly employed. The transducer is usually positioned close to the part (within an inch at frequencies above 400 Hz and within several inches for lower frequencies), with the beam focused in the part. Figure 9(a) shows the TT method. Figure 10 shows a comparison of a 400 kHz air-coupled inspection and a 5 MHz water-coupled TT inspection of a composite bonded assembly containing an internal void region. The air-coupled sensitivity to features in this application is very good. Figure 9(b) demonstrates a transducer setup using an angled beam. The angle beam can create shear waves in the part. The TT method, with the angle beam in particular, is an excellent technique on a number of materials inspections, such as honeycomb core structures where low frequency inspection (below 1 MHz) is necessary for penetration. However, for optimal signal levels, care should be taken on the selection of the angle to the surface. Because of the path of the shear waves in the part, an offset between the axes of the transducers is often necessary. The size of this offset will depend upon the type and structure of the composite and its thickness. Figure 9(c) shows one possible pitch-catch arrangement. A barrier is needed between the transducers to prevent direct communication of the transmitted acoustic wave through air. In fact, a common problem with air-coupled ultrasound is the need to protect against signals leaking around the edges of objects, limiting the quality of the inspection at those edges. Low-density foam can be taped along the edge to significantly reduce this edge effect. Figure 9(d) shows both a single- sided guided-wave technique and alternate two- sided configuration, with the second transducer on the opposite side. The single-sided pitch- catch technique is best for inspecting skins and skin-to-core bonds in sandwich panels, while the two-sided pitch-catch technique

works best for thin laminates. To produce plate waves, the transducers are set at a low angle to the part and relatively far apart (150 mm, or 6 in., or more). Most air-coupled inspections can be performed using hand-held yoke systems or with the transducers mounted on robotic scanners.

Laser Ultrasound

Laser UT is a method for evaluating materials properties based on the analysis of ultrasound that is generated and detected using lasers (Ref 15, 16). Although this field is very broad in terms of various implementation techniques and materials applications, this review is restricted to methods that are similar to conventional PE water-coupled UT systems and specifically applied to organic-matrix composite materials. Laser UT provides the same type of measurement information obtained with conventional ultrasonic systems, such as the presence of internal defects, bond integrity, part thickness, and other basic materials properties. The motivation for replacing conventional water-coupled piezoelectric transducers with laser-based systems varies with material types and the specific NDE requirements. In the aerospace industry, speed and flexibility are the primary benefits for testing composite materials with laser systems, while the noncontact remote-sensing feature is most important for process-control applications in the steel industry. For many composite materials and configurations, laser UT can be faster than other ultrasonic approaches and should be considered as an alternative to conventional water-coupled UT.

A brief introduction to the fundamentals is presented in this section, with a more detailed discussion to follow. Basically, laser ultrasonic systems use two lasers: one laser is used to generate ultrasound in the part by a mechanism called thermoelastic expansion, and a second laser is used to detect these vibrations as they return to the top surface (Ref 17, 18, and 19). A diagram of a typical configuration is shown in Fig. 11. In the thermoelastic generation process, the absorbed laser energy is converted into heat in the top 10 to 100 μm (0.0004 to 0.004 in.) of the surface. The resulting temperature rise creates a local expansion of the material. If the heating laser pulse duration is short (10 to 100 ns), then the expansion will be in the frequency of ultrasound (1 to 10 MHz). The important feature is that the ultrasound will propagate perpendicular to the surface, independent of the laser angle of incidence. This allows generation of ultrasound in complex-shaped parts at angles as high as ±45° off-axis, compared to conventional water- coupled transducers that must remain within a few degrees of normal.

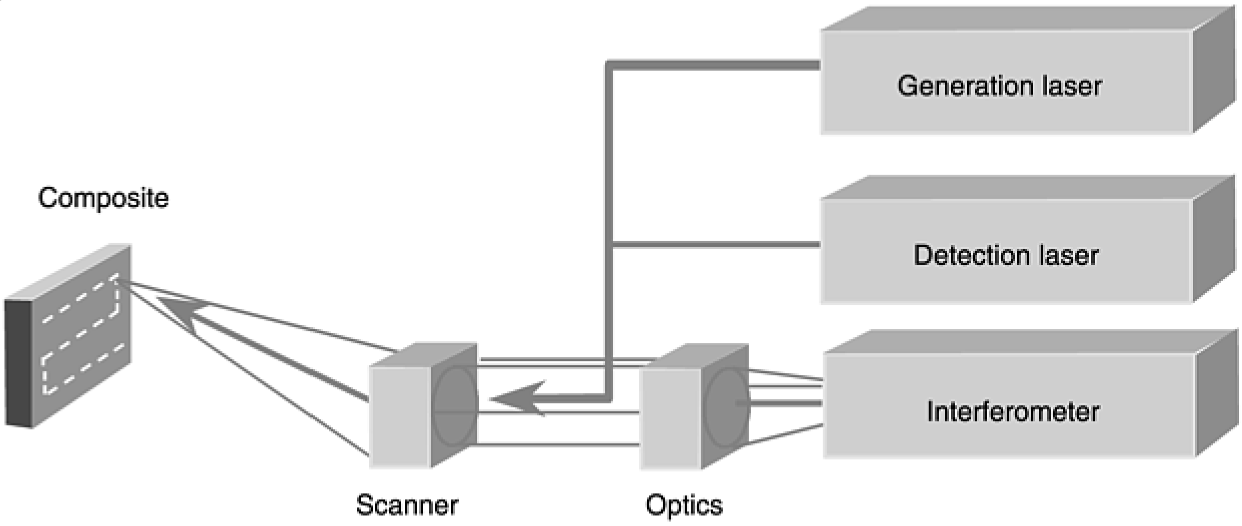

Fig. 11 A laser ultrasound system is composed of a generation laser, detection laser, interferometer, optical scanner, and computer controller.

The detection laser is coaxial with the generation laser and illuminates the same point where the ultrasound is produced. Unlike the generation laser that is ideally absorbed by the composite, this laser is scattered off of the composite surface. The collected scattered light is analyzed by an interferometer to extract the ultrasonic signals that are “imprinted” on the laser as phase and frequency modulations caused by the moving surface. The ultrasonic signals extracted are basically the same as those obtained with conventional systems and can be

analyzed using similar methods. Finally, the two laser beams are indexed over the composite surface with an optical scanner to produce standard C-scan images.

Laser Generation. The detailed mechanism of ultrasound generation by a laser pulse is relatively straightforward to illustrate (Ref 20). The key variables that determine performance are the laser pulse temporal duration, optical wavelength, energy, and the properties of the composite structure being tested. Figure 12 shows how absorbed laser light causes a temperature rise and therefore, a localized expansion of the composite material. If the pulse is temporally short, then the thermal expansion will generate ultrasonic waves, as shown in Fig. 13. The signal-to-noise ratio (SNR) of the resulting data improves linearly with the amplitude of the ultrasound; thus it is important to consider how to optimize generation methods.

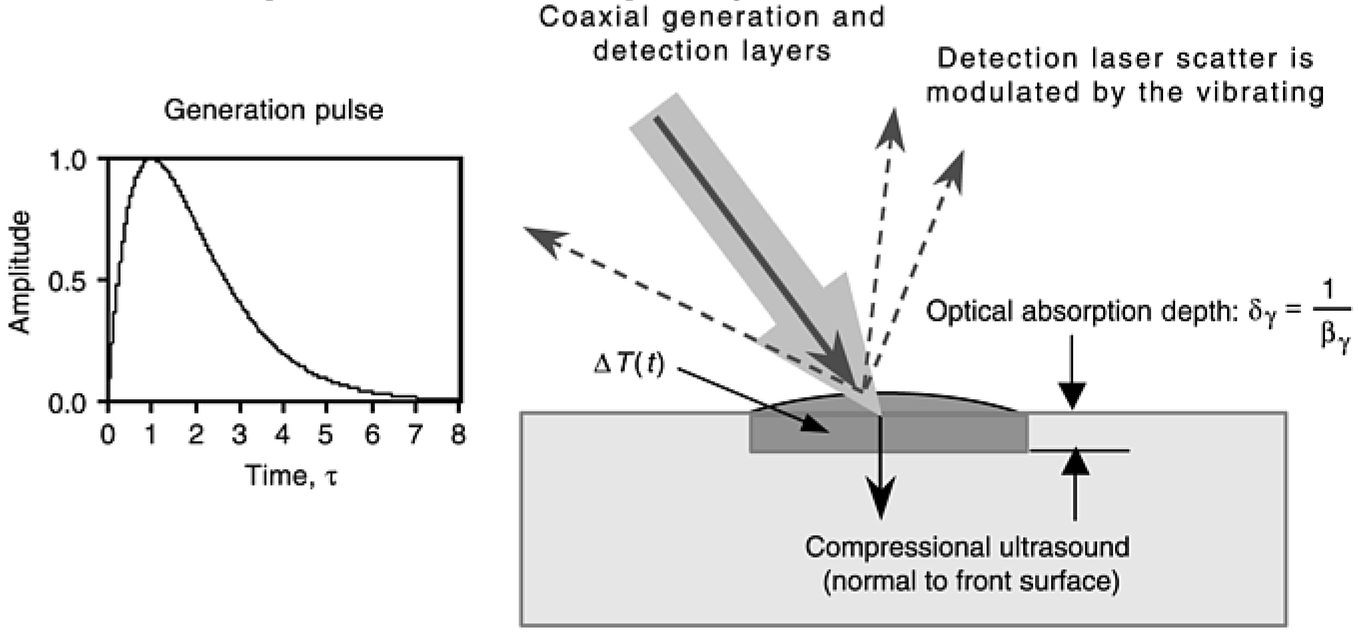

Fig. 12 Ultrasound generation by laser pulse. Ultrasound is generated in an organic composite by the absorption of energy from a pulsed laser, and the resulting surface vibrations can be monitored with a detection laser and sensitive interferometer. The resulting signals are equivalent to conventional pulse-echo ultrasonic signals. τ, rise time; β_λ, wave-length-dependent optical absorption coefficient.

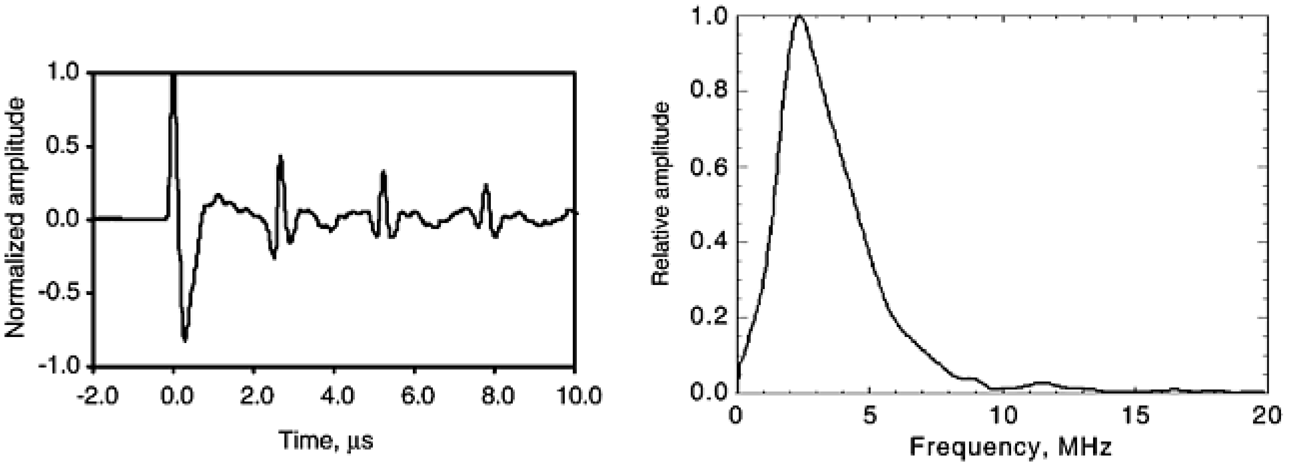

Fig. 13 Laser ultrasonic signal from a 3 mm (0.12 in.) thick graphite/epoxy composite showing the front surface signal and a series of back surface echos. The frequency spectrum of a typical back surface signal shows a center frequency near 2.5 MHz, with most of the energy well below 10 MHz.

Ultrasound is generated in the small volume of material where the laser energy is absorbed. The objective is to generate as much ultrasound as possible without exceeding temperatures that could damage or alter the appearance of the material. In a composite, there are potentially two different absorption mechanisms,

corresponding to laser absorption within the polymer volume and absorption by the fibers. For a simple model that leads to most of the important considerations, consider two layers consisting of a resin layer over a fiber-resin layer. Laser light will penetrate into the resin and be absorbed at some rate, thereby creating a local temperature rise. If the resin is thin or particularly transparent to the laser wavelength, then any residual energy will be absorbed at the opaque resin-fiber interface. In the case where the light is primarily absorbed below the resin layer at the fiber interface this produces what is termed as a buried source. As a simplification of this general mechanism, buried sources will not be considered, but it is assumed that the light is exponentially absorbed in the resin layer only. Thermal conductivity can carry heat away, but is not significant over ultrasonic time scales less than 100 μs and may be ignored. Given these assumptions, the temperature profile can be modeled as:

$$T(x,t) = \frac{\beta_\lambda I_0}{\rho C_p} e^{-\beta x} \int_0^t f(t',\tau)dt' \quad \text{(Eq 7)}$$

where β_λ is the wavelength dependent optical absorption coefficient (m^{-1}), I_0 is the absorbed energy density of the laser (J/m^2), ρ is the material density, C_p is the specific heat, and $f(t'\tau)$ is the normalized laser pulse temporal profile with a characteristic rise time of τ. Some time after the laser pulse has deposited all of its energy, the peak surface temperature is reached. As a numerical example, the temperature rise would be about 80 °C (145 °F) for a typical epoxy resin with an absorption depth of 50 μm (0.002 in.) subjected to a 100 mJ laser pulse deposited over a 5 mm (0.2 in.) spot. For a volume absorber, the peak temperature, and therefore the maximum allowed energy density, is primarily influenced by β_λ and is independent of the temporal properties of the laser. The maximum allowed laser irradiation scales with energy density and not with peak laser power, which is an important point, because very short-pulsed lasers can be used without the risk of inducing surface damage for volume absorbers.

In addition to calculating the temperature rise of the surface modeled by Eq 7, a model is needed to predict how much ultrasound is actually generated in the material. The front surface displacement, u, is simply estimated as the product of the peak temperature rise, the coefficient of thermal expansion, α, and the optical penetration depth:

$$u_{max} = \alpha I_0/\rho C_p \quad \text{(Eq 8)}$$

As a numerical example, assume that 15% of a 100 mJ CO_2 pulse is in the first 100 ns, a 5 mm spot size, $\alpha = 5.5 \times 10^{-5}$/K, $\rho = 1250$ kg/ m^3, and $C_p = 1050$ J/kg · K; this produces a front surface displacement of about 32 nm. Equation 8 does not contain the optical absorption coefficient, which might lead one to interpret this as meaning that β_λ does not influence the amount of ultrasound produced, except by limiting how much energy can be absorbed without excessive heating. Also, the role of the temporal profile of the generation laser does not alter the maximum temperature or displacement—so how important is the shape of the laser pulse? To address these issues, the complete wave equation must be modeled along with the laser-induced temperature rise; this shows that the amplitude of ultrasound that propagates through the material is dependent on β_λ, the velocity of sound, v, and the characteristic rise time, τ, of the laser pulse. For the case of an absorbing layer of sufficient thickness, a general rule can be expressed so that, if satisfied, the strength of ultrasound produced will be a maximum for a particular material and laser combination:

$$\beta_\lambda \cdot v \cdot \tau \leq 1 \quad \text{(Eq 9)}$$

Large acoustic amplitudes require a short-pulse laser tuned for the absorption in the resin layer. The frequency content of the ultrasonic pulse will obviously not exceed that of the generation pulse, so a sufficiently fast pulse must be used to generate the frequencies of interest. A general rule would be to use a pulse such that $\tau \leq (4f_{max})^{-1}$. The ideal source laser would include the freedom to dynamically adjust the temporal and optical character of the pulse based on part material needs, which may be determined by thickness, defect nature, and the optical/mechanical properties of the part surface. A composite designer or manufacturer can improve laser UT results by assuring that the surface peel ply or resin depth is on the order of 100 μm or more. Figure 14 compares the relative amplitude of ultrasound generated for different surface conditions. As can be seen, different peel ply layers and paints can significantly alter the amplitude of the signals.

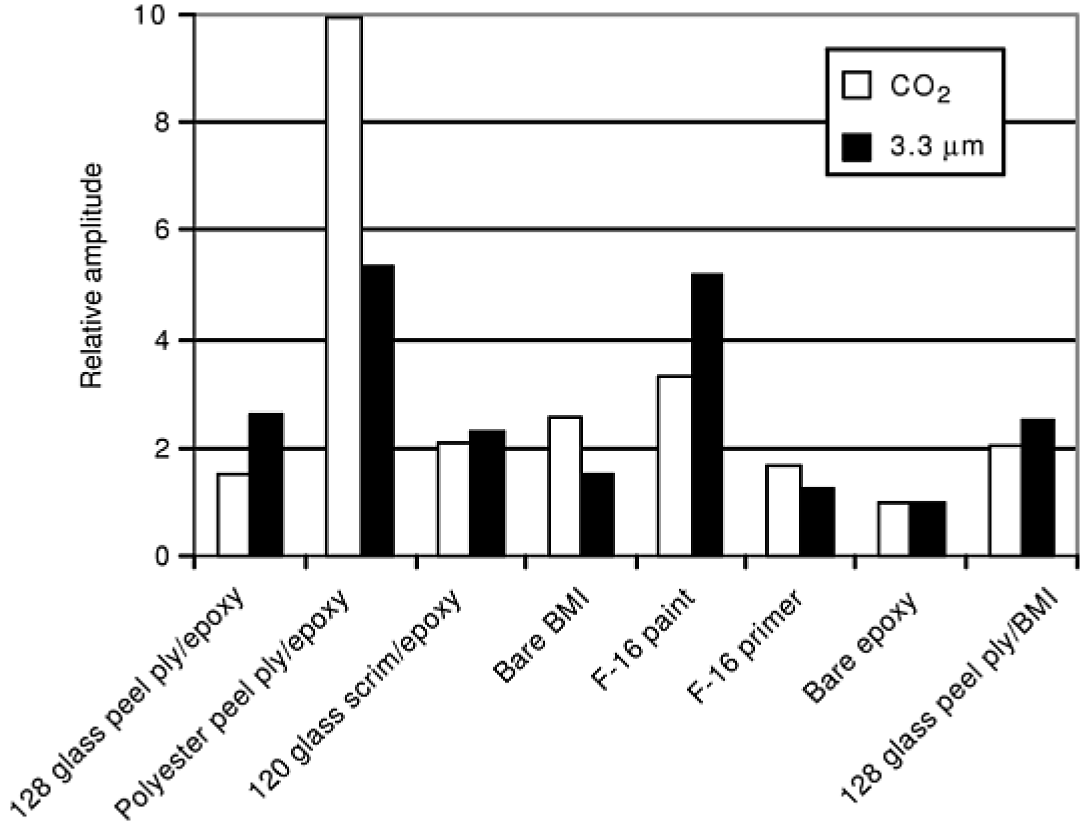

Fig. 14 Relative amplitude of ultrasound generated in a graphite/epoxy composite for various surface conditions. The data is normalized to the bare epoxy signal for both laser wavelengths (i.e., the CO_2 and 3.3 μm data cannot be directly compared). This shows there is considerable variance in signal strength for different surface conditions. BMI, bismaleimide

The short-pulse transversely excited atmosphere (TEA) carbon dioxide laser has made possible the inspection of many composite components (Ref 17, 18), because large longitudinal ultrasound pulses can be created without damage. However, carbon dioxide lasers do pose several problems, including the handling of gases consumed by the laser, the large size and cost of higher repetition rate units, and the problem that 10.6 μm radiation from the TEA carbon dioxide laser cannot be easily handled by fiber optics due to unacceptable attenuation. In addition, although the TEA carbon dioxide laser has been a popular choice, the optical wavelength and temporal pulse shape are not necessarily optimal (Ref 21). The temporal pulse width from an improved TEA carbon dioxide laser yields a useful energy for ultrasound generation in the first 100 ns that varies between 6 and 15% of the total energy.

Recent research has identified the use of mid- infrared lasers in the 3 to 4 μm (120 to 160 μin.) band, where the penetration depth corresponds to a volume absorption (Ref 22). A 3 μm (120 μin.) absorption arises from the OH molecular vibrational mode, which, while present in all composites, can vary widely by manufacturing and ambient atmospheric conditions. Instead, the 3.5 μm (140 μin.) CH vibrational mode is universal to polymer composites and does not suffer the same variations as the OH mode. Also, new fiber optic materials have been demonstrated with excellent propagation properties in the 3 to 4 μm (120 to 160 μin.) band, enabling the use of fiber delivery for remote access applications.

There are many lasers available that will provide surface absorption on the fibers, including the 1.06 μm (41.7 μin.) neodymium:yttrium-aluminum-garnet (Nd:YAG) laser and its doubled 0.532 μm (20.9 μin.) harmonic. While effective generators of ultrasound, these lasers have lower-energy damage thresholds for composites and are considered risky.

Laser Detection. An ultrasonic wave originating within the part that reaches the surface causes a small displacement—typically on the order of Angstroms (10^{-10} m) at frequencies of several MHz. Amazingly, these small displacements are detected routinely with piezoelectric transducers and can be detected with optical interferometers. In order to measure such small displacements, the quality of the detection laser and the interferometer are both critically important. The general detection scheme is to direct a bright laser at the part,

collect the scattered light, and use a interferometer to analyze laser photons to measure the small phase or frequency shifts caused by the vibrating surface. One of the first considerations is how bright the detection laser needs to be to detect the laser-generated ultrasound. To estimate this, one must consider the fundamental limits of laser detection of a vibrating surface. First, the photons obey Poisson statistics—the number, N, arriving in an interval has an uncertainty or shot noise of roughly $N^{1/2}$—while the signal is proportional to N, yielding a fundamental SNR proportional to $N^{1/2}$. In addition to shot noise, amplitude and phase noise are present on the detection laser, with a linear dependence on N. These last two sources of noise can be reduced by appropriate selection of an interferometer or careful specification of the detection laser. In practice, the part surface is not mirror smooth, and the interferometer must deal with optical speckle—the random variations in phase of the arriving light across the detection aperture, due to small variations in the optical path length. A general expression for the SNR of shot noise limited detection of ultrasound is given as:

$$\mathrm{SNR} = 4\pi u(f)S(f)\sqrt{\frac{P_{\det}QE}{2\lambda hcBW}} \qquad \text{(Eq 10)}$$

where $u(f)$ is the frequency-dependent surface displacement, λ is the detection laser wavelength, $S(f)$ is the response function of the interferometer (a Michelson interferometer has a $S(f)$ of 1.0), P_{det} is the laser power collected from the composite and delivered to the detector, QE is the detector quantum efficiency, h is Plank's constant, c is the speed of light, and BW is the detection bandwidth. Equation 10 shows the linear relationship of SNR with surface displacement, which was previously shown to be linear with the absorbed energy density of the generation laser. Assuming that an optimal generation laser is used, then only the response sensitivity of the interferometer, the detection laser wavelength, and the amount of detection laser power collected remain as important design variables. Note that the QE only varies over a small range for properly chosen detectors (40 to 90%), and the BW must be on the order of 10 MHz. Equation 10 can be inverted to solve for the minimum detectable displacement, which will give a good estimate of the sensitivity and dynamic range limit. As a conservative approximation, the root mean square (RMS) signal-to-noise ratio can be changed to a peak-to-peak value, where the noise is about 6.6 times the RMS value. Most UT systems operate on peak thresholds, so this is a valid approximation. Using a Nd:YAG 1.064 μm laser, 5 mW of detected power at a 50% QE, a 10 MHz BW, and a 50% interferometer sensitivity gives $u_{min} \approx$ 40 pm. If the induced ultrasound is on the order of 40 nm, then the amplitude dynamic range is 60 dB. This number is below many conventional UT systems, but is adequate for most aerospace composite testing requirements.

Next consider the amount of light collected from a diffuse target with a detection laser of power P_0, using a lens aperture of Φ_{lens} located a distance D_{target} away:

$$P_{\det} = \frac{P_0}{4}\left(\frac{\Phi_{\text{lens}}}{D_{\text{target}}}\right)^2 \eta_{\text{loss}}\,(1-A)\cos\theta \qquad \text{(Eq 11)}$$

where η_{loss} accounts for general system losses, A is the diffuse target absorption, and θ is the incident angle. Although this ideal diffuse model is an approximation to what is typically a much more complex reality, it does show that one would desire a powerful detection laser, a large collection aperture, and to operate close to the composite surface. For most detection systems, optical powers delivered to the interferometer in excess of a few mW are limited by laser noise, and additional power will not improve SNR. The required detection laser intensity can be estimated based on the particular application configuration. For example, collecting 5 mW of laser power using a 50 mm (2 in.) aperture positioned 2 m (6.6. ft) from an absorbing (90%) diffuse target tilted at 45° would require a peak power of over 900 W at the target, for a typical collection loss of 50%. Continuous-wave lasers of this power are impractical and would damage the surface, due to excessive heating. Therefore, long-pulsed (≈100 μs) detection lasers are used to produce high peak-power intensities during the short time interval of the ultrasonic event, while the average power remains at a safe level. The duty cycle for a 100 μs pulse at 400 Hz would make a 1 kW peak laser only 40 W in average power. Although the small aperture and large working distance of this example severely reduces the collected light level, these parameters establish an optical system with a large depth of field, allowing the system to scan complex parts without active focus control. Real composite surfaces do not behave as diffuse targets, but instead are mixtures of diffuse and specular (mirrorlike) properties. Specular surfaces can be several times brighter than a perfect diffuse reflector on-axis and then quickly drop off by a factor of 100 in intensity in just a few degrees off-axis. This extreme dynamic range requires both a large peak power detection laser and an active intensity control system to reduce brightness when operating on-axis with specular surfaces.

Multiple types of interferometers are possible, but two designs are of practical interest for remote scanning of rough parts. The confocal Fabry-Perot is the most important type of interferometer today, with excellent sensitivity, where $S(f) \geq 0.5$ from 1 to 10 MHz, and it has the ability to handle rough surfaces (Ref 23). The Fabry- Perot is a homodyne interferometer, consisting of two mirrors that form a resonant cavity that analyzes the phase and frequency of the returned light. A typical implementation is two spherical mirrors with a reflectivity of 95% spaced 1 m (3.3 ft) apart. This interferometer can be configured to reject common-mode amplitude noise produced by a less-than-perfect detection laser. The output of the interferometer is composed of light that has reflected back and forth 10 to 100 times within the cavity—achieving full sensitivity requires a single longitudinal mode detection laser with a sufficiently long coherence length. Either the Fabry-Perot cavity length or the laser must be adjusted dynamically to track the Fabry- Perot resonant pass band with the laser line frequency.

A new interferometer employing a photorefractive demodulator is emerging and may be important in the future (Ref 24). The photorefractive interferometer employs a nonlinear crystal to "correct" the speckled wavefront. The best designs today are within a factor of 4 of an ideal Michelson interferometer. The major benefits are the compact size (fitting within a 13 to 46 cm, or 5 to 18 in., rack mount package), robustness to vibrations, and potential tolerance of lower- quality lasers. The disadvantages are a loss of two times in sensitivity against the Fabry-Perot, and a requirement that the lateral velocity of the laser spot over the inspected part not exceed a value determined by the properties of the nonlinear crystal. The photorefractive interferometer performance will improve with additional developments, which may make it a preferred solution in the future. Additional interferometer types, such as the Michelson and Sagnac, exist but are limited to niche applications, such as laboratory measurements of materials properties, optical near-contact probes, and embedded as fiber optic sensors within structures.

LaserUT System. Any technology that is perceived as "new" must balance expectations with realistic performance. Although research and development have steadily progressed in this field since the invention of the laser in the early 1960s, there have been few practical implementations of this technology. One example of laser ultrasonics meeting expectations is the LaserUT system (Lockheed Martin), shown testing a complex composite duct in Fig. 15 (Ref 25). This system has been in full-time production use for testing composite inlet structures for the F-22 fighter since June 2000.

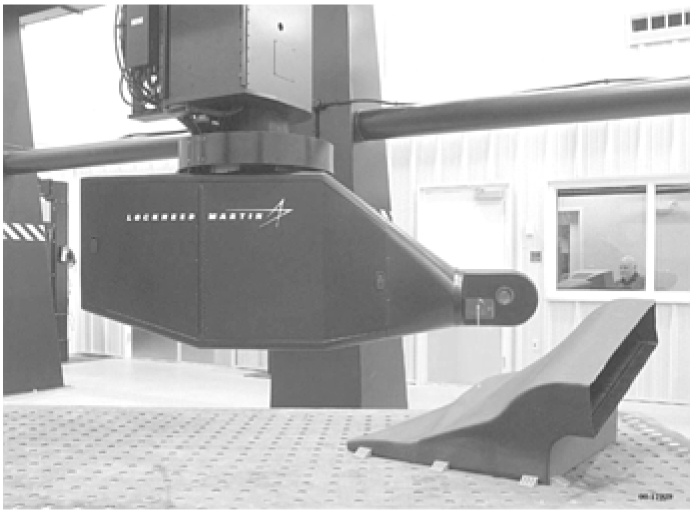

Fig. 15 Lockheed Martin Laser UT system testing a complex composite duct. This system routinely inspects parts ten times faster than conventional water-coupled UT systems and does not require expensive tooling to hold the part under test. The inspection head would be positioned above the part, approximately 2m (6 ft) away during a scan.

Lockheed Martin has developed two LaserUT systems, referred to as Alpha and Beta, for testing advanced aerospace composite structures. Both systems are similar in design, except that the work envelope of the Alpha gantry robot is much larger than that of the Beta robot. A short- pulsed TEA carbon dioxide laser generates ultrasound, and a long-pulsed, diode-pumped Nd:YAG laser with a dual differential confocal Fabry-Perot interferometer is used for detection. These lasers are optically combined to produce a coaxial beam that is about 5 mm (0.2 in.) in diameter at the composite surface. Inspection depth of field is fairly large and allows the part standoff distance to vary between 1.5 and 2.5 m (4.9 to 8.2 ft) from the optical scanner. Beam indexing (optical

scanning) is done with a two- mirror galvanometer scanner that has a 50 mm (2 in.) clear aperture. A five-axis gantry robot moves the inspection head to the best position for scanning each region of a part. Scan coverage can be as large as 2 × 2 m (6.6 × 6.6 ft) for a single inspection view. Parts with significant contour are typically sectioned into a series of smaller scans, such that each subsection remains within the constraints of the system. Scanning constraints can be material-dependent, based on generation efficiency and optical scattering properties, but typical values are ±45° angle of incidence and a nominal working distance of 1.8 m (5.9 ft) from the surface.

All ultrasonic waveforms are digitally captured, processed, and permanently stored as the inspection point is indexed over the composite surface. Figure 16 shows the graphical display from the system for a composite part with a series of inclusion defects. The current LaserUT system operates at a maximum inspection rate of 400 points per second and is limited by the pulse rates of the lasers. As faster lasers become available, the scan rate will improve accordingly. Inspection coverage rate is obviously related to the index step size required for the material under test, which is usually influenced by the size of defect that must be found. A conservative rule is to index at a resolution three times higher than the reject flaw size dimension. For example, an index size of 2.0 mm (0.080 in.) is typically used for a 6.3 mm (0.25 in.) flaw reject criteria. A 400 Hz scan rate at 2.0 mm (0.080 in.) steps gives a maximum area coverage of 6 m^2/h (64 ft^2/h). This system typically inspects complex composite parts ten times faster than the previous conventional water-coupled PE or TT methods, because part teaching and setup procedures are much less critical, and the inspection results are more consistent from part to part.

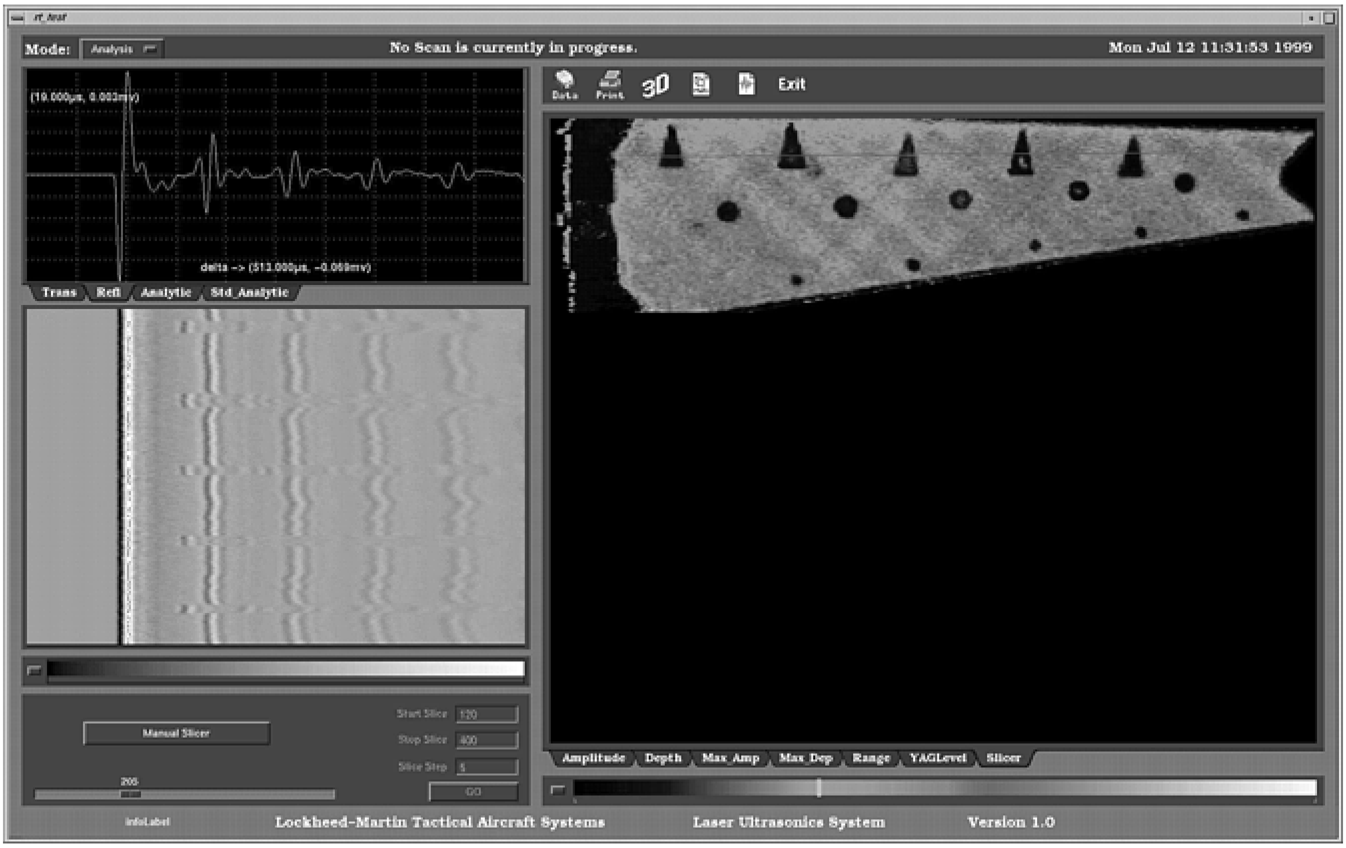

Fig. 16 LaserUT A-scan, B-scan, and C-scan images of a graphite/epoxy composite test part with inclusion materials. Each of the inclusions is clearly visible in the B-scan image.

If the need is to test large, flat composite panels, then conventional systems will operate as fast or faster and provide equivalent results. Conversely, if a component with even, gentle contour requires ultrasonic testing, then a laser system may be the most cost-effective method. Recall that the composite part must have at least a small layer of an organic material at the surface for efficient laser generation of ultrasound. If the surface is machined or totally resin-starved, then a laser system may have only limited success, unless some form of a surface treatment is applied. LaserUT will work better with some materials than others, based on the material type and the design of the system, and in all cases the candidate material should be evaluated to establish compatibility, both in terms of desired SNR performance and to verify that the surface is not damaged or visibly altered by the laser interactions.

Ultrasonic Spectroscopy

The primary use of ultrasonic spectroscopy is to evaluate the effect of changing wavelength on material interaction. Wavelengths that are large (low frequency) relative to a defect tend to be unaffected by it. However, wavelengths that are comparatively small (high frequency) tend to interact. The degree of attenuation or scatter is a function of the wavelength-to-defect size. In the simplest case of internal porosity of uniform size, the porosity will act as a filter that will pass wavelengths below a certain frequency, partially attenuate wavelengths over a frequency range, and completely block all wavelengths over a given frequency.

Traditional ultrasonic spectroscopy methods have used broadband ultrasonics to permit taking data over a range of frequencies in a single test (Ref 26). This allows determination of the interaction of various frequencies with the tested materials. Typical broadband ultrasonic methods use a short, narrow pulse as the input signal. This provides a limited range of frequencies to be transmitted through the materials being tested. The short length of the pulse limits the total energy. The low energy results in an output signal with low SNR. More-recent work has resulted in a method of ultrasonic spectroscopy that uses a swept-frequency input signal (Ref 27). The signal can cover a wide, user-definable range of frequencies without compromising energy. The higher energy results in an output signal with a robust SNR in the frequency domain. This method provides a SNR over ten times greater than the traditional pulse method. Also, the spectrum can be designed to provide a uniform input over the range of frequencies. With multiple layers of varying material, how the ultrasonic waves respond (transmit or reflect) at the interfaces will depend on the relative acoustic impedances of the materials. This can provide the ability to inspect multiple layers and evaluate the nature of the interface.

Another aspect of ultrasonic spectroscopy is the phenomenon of resonance. Resonance is the result of constructive and destructive interference of standing waves in an ultrasonic medium that can be locally modeled as a plate. Positive interference happens when an integral number of half-wavelengths occur in the medium, which will happen periodically throughout a typical spectrum. Destructive interference occurs at odd quarter-wavelengths. Where this interference occurs in the frequency spectrum is a function of the thickness and velocity of the inspected part. For a given velocity, the spacing between resonance peaks (harmonics) is inversely proportional to thickness. If material velocity is known, material thickness can be determined from resonance spacing, and vice versa.

Starting with the fundamental equation for relating velocity (v) to frequency (f) and wavelength (λ):

$$v=f\lambda \qquad \text{(Eq 12)}$$

Knowing that the fundamental resonance occurs when there is half of a wavelength in a plate, then twice the plate thickness can be substituted for wavelength in the equation. Further, because higher-order resonance peaks (harmonics) are spaced at integer multiples of the fundamental frequency, then the spacing of any two successive peaks can be substituted for frequency. Thus:

$$v = f2d \qquad \text{(Eq 13)}$$

where v is the longitudinal velocity of the plate, f is the fundamental frequency or the spacing of any two successive resonance peaks, and d is the plate thickness. The significance of this relationship is that a very precise thickness measurement can be made using ultrasonic spectroscopy simultaneously with the spectral evaluation.

The magnitude (peak height-to-width ratio) of the resonance in a spectrum is a function of acoustic impedance mismatch on each layer of the part being inspected. The greater the mismatch, the more energy reflects back into the part and the more pronounced the resonance peaks (higher impedance mismatch means sharper peaks). When multiple plates are stacked and inspected using ultrasonic spectroscopy, each plate in the stack will resonate according to its thickness and velocity. The intensity of the resonance for each plate will be determined by the impedance mismatch at the boundaries and by the effects of internal damping of that plate.

Ultrasonic spectroscopy can use the resonance behavior of each material in the frequency domain. It has proven to be a very effective inspection technique for debonds and kissing debonds in multiple-layer composites. Also, the resonance behavior provides an easier and more- accurate interpretation capability for thickness or velocity measurements in single or multiple- layer structures. This is shown in the case of a 19 mm (0.75 in.) composite liner bonded to a graphite/epoxy 3.8 mm (0.15 in.) outer layer, as illustrated in Fig. 17 and 18. One of the samples is well bonded, and the second has a kissing debond. In the well-bonded sample, the resonant behavior in the spectrum is dominated entirely by the silica phenolic inner layer (80 kHz spacing). The full spectrum penetrates the bond, resonates the inner layer, and penetrates the bond again. In the debonded sample, the spectra graph shows the resonant behavior of the outer layer only. The full spectrum of energy is not penetrating the bond to resonate the inner layer (Fig. 18).

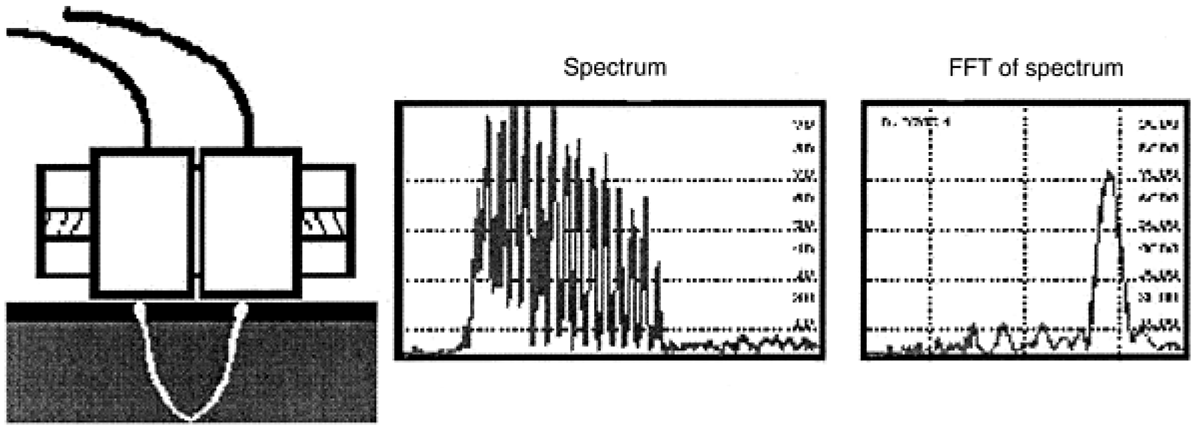

Fig. 17 Ultrasonic spectroscopy response of well-bonded multilayer composite. FFT, fast Fourier transform

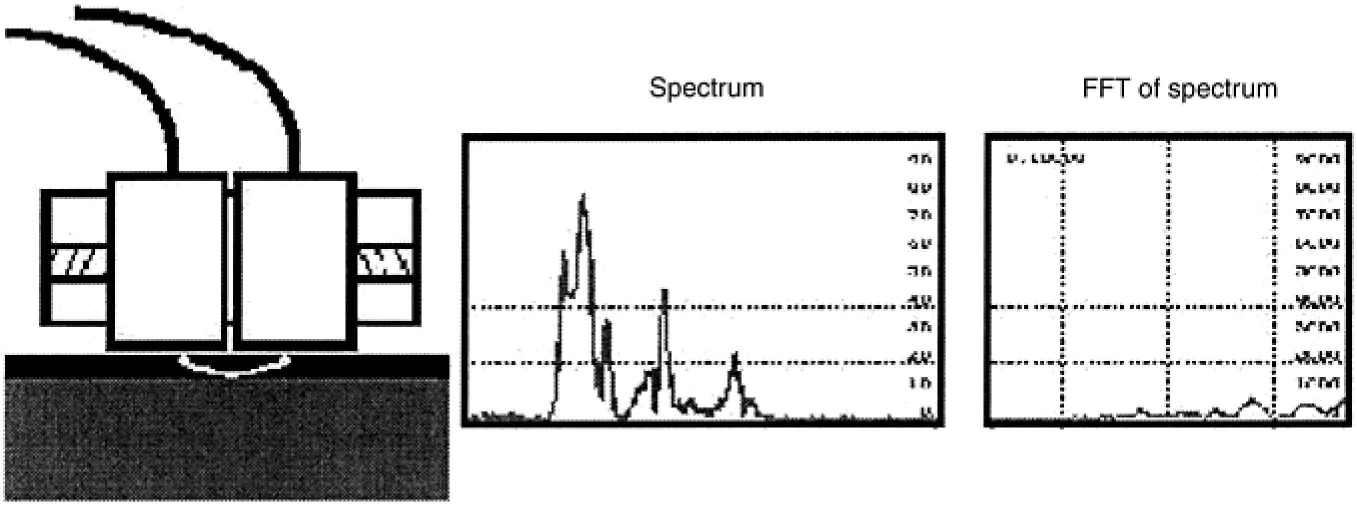

Fig. 18 Ultrasonic spectroscopy response of debonded composite. FFT, fast Fourier transform

Ultrasonic spectroscopy has the capability to define attenuation as a function of frequency, allowing the user to establish signatures for various materials. The signal of each new sample can be compared to these signatures and evaluated for atypical responses caused by microstructure changes, porosity, microcracking, cracks, delaminations, fiber volume fraction, velocity (elastic modulus), and so on. Figures 19 and 20 show composite samples containing different levels of microcracking. The frequency cutoff varies with severity of microcracking, and surface roughness value increases. The micrograph is shown with the corresponding signal.

Lamb Waves

Lamb waves, also known as plate waves, are wave modes that propagate through layered media with thickness that is only a few wavelengths. Lamb waves consist of a complex vibration that occurs throughout the thickness of the material. The propagation characteristics of Lamb waves depend on the density, elastic properties and structure of the material, as well as the thickness of the testpiece and the frequency. Their behavior in general resembles that observed in the transmission of electromagnetic waves through waveguides. There are two basic forms of Lamb waves: symmetric and antisymmetric. The form is determined by whether the particle motion is symmetric or antisymmetric with respect to the neutral axis of the testpiece. Theoretically, there are an infinite number of specific velocities at which Lamb waves can travel in a given material. Within a given plate, the specific velocities for Lamb waves are a complex function of the plate thickness and frequency. In symmetric (dilatational) Lamb waves, there is a compressional (longitudinal) particle displacement along the neutral axis of the plate and an elliptical particle displacement on each surface (see Fig. 21a). In asymmetric (bending) Lamb waves, there is a shear neutral axis of the plate and an elliptical particle displacement on each surface (Fig. 21b). The ratio of the major to minor axes of the ellipse is a function of the material in which the wave is being propagated.

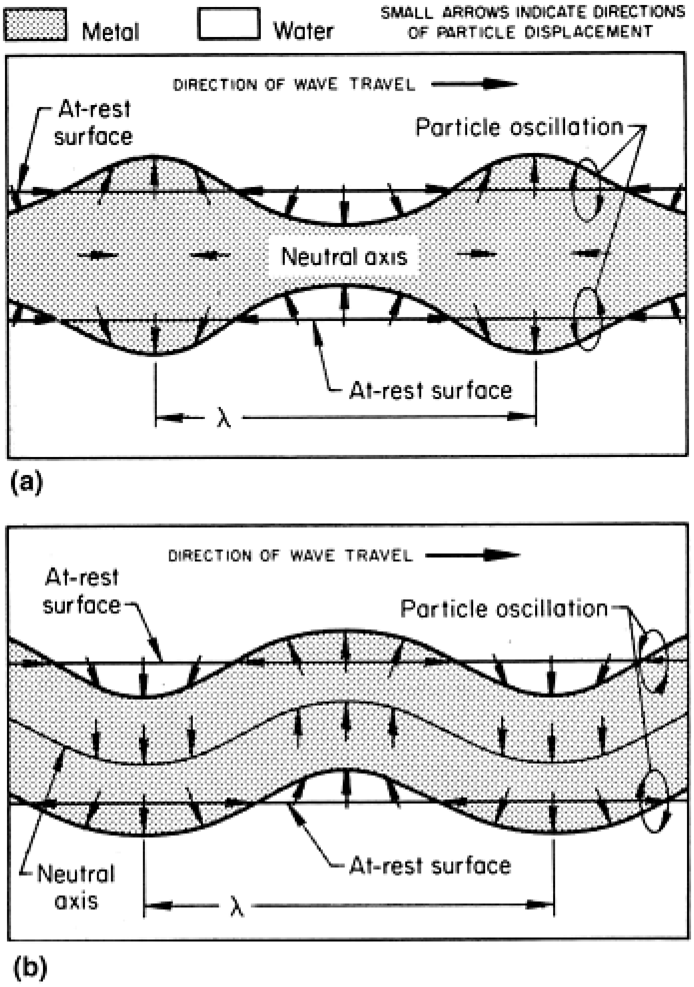

Fig. 21 Schematic diagram showing the two Lamb wave basic modes. (a) Symmetric. (b) Asymmetric

Lamb waves can be induced by contact transducers and received after traveling through the material over a known distance. In such a case, only the first one or two symmetric and antisymmetric modes may be induced. The signal can provide useful information about the integrity of the material over the traveled distance and may prove superior to simple PE or TT because it allows faster scanning of the test part. Using a pair of transducers that transmit and receive normal to the test article surface allows inducing various Lamb wave modes and can provide qualitative information. This method is widely known as the acousto-ultrasonics (see the section "Acousto-Ultrasonics" in this article). Alternatively, one can use immersion coupling and induce Lamb waves to obtain quantitative data about the part; the related NDE technique is known as the leaky Lamb wave (LLW) method.

The LLW phenomenon is induced when a pitch-catch ultrasonic setup insonifies a platelike solid immersed in fluid (Ref 28). The phenomenon is associated with the resonant excitation of plate waves that leak energy into the coupling fluid and interfere with the specular reflection of the incident waves. The destructive interference between the leaky waves and the specularly reflected waves modifies the reflected spectrum, introducing a series of minima in the spectra of the reflected waves. The LLW experiment for composite laminate specimens involves measurement of the reflected field and extraction of the minima in the reflected spectra at various angles of incidence and orientations (polar angles) with respect to the laminate. The data is presented in the form of dispersion curves showing the phase velocity (calculated from Snell's law and the angle of incidence) of the LLWs as a function of frequency. The sensitivity of the dispersion curves to variations in the properties of the composite material, namely its anisotropy, layers thickness, stiffness constants, and the presence of defects, has made this phenomenon an attractive NDE method.

Bar-Cohen and Chimenti (Ref 29) investigated the characteristics of the LLW phenomenon and its application to NDE, focusing on the experimental documentation of observed modes and the effects of various types of defects on the measurements. Their study was followed by numerous theoretical and experimental investigations of the phenomenon (e.g., Ref 30, 31, 32, 33, 34, 35, and 36). A method was also developed to

invert the elastic properties of composite laminates from the LLW dispersion data (Ref 32, 37, and 38), and the study was expanded to the NDE of bonded joints (Ref 39).

The experimental acquisition of dispersion curves for composite materials requires accurate control of the angle of incidence/reception and the polar angle with the fibers. The data acquisition involves the use of sequentially transmitted tone bursts, each of a specific frequency, spanning a selected frequency range. The reflected signals are acquired as a function of the polar and incidence angles and saved in a file for analysis and comparison with theoretical predictions. The minima in the acquired reflection spectra represent the LLW modes and are used to determine the dispersion curves (phase velocity as a function of frequency). The incident angle is changed incrementally within the selected range, and the reflection spectra are acquired. For graphite/epoxy laminates, the modes are identified for each angle of incidence in the range of 12 to 50°, allowing the use of free-plate theoretical calculations. At each given incidence angle, the minima are identified, added to the accumulating dispersion curves, and plotted simultaneously on the computer display.

The capability to invert the elastic properties using LLW data is limited to the matrix-dominated stiffness constants (Ref 39). This limitation can be partially overcome if the incidence angles of 10° or smaller can be used in the experiments, but this is difficult, if not impossible, to achieve in practice with a single scanner. An alternative methodology based on pulsed ultrasonics was developed by Bar-Cohen, Mal, and Lih (Ref 28). Using pulses in pitch-catch and PE experimental setups, it was shown that all five elastic constants of a unidirectional laminate could be determined with a fairly high degree of accuracy.

The behavior of ultrasonic waves propagating through fiber-reinforced composites is determined by the material stiffness and dissipative characteristics. Theoretical modeling of this behavior requires several simplifying assumptions regarding the properties of the material. First, the unidirectional bulk material is treated as homogeneous, because the fiber diameter (e.g., graphite 5 to 10 μm and glass 10 to 15 μm) is significantly smaller than the wavelength. (For frequencies up to 20 MHz, the wavelength is larger than 100 μm.) Each layer of a composite laminate is assumed to be transversely isotropic, bonded to its neighboring layers with a thin layer of an isotropic resin at their interfaces. The mechanical behavior of the material of each lamina is described by an ensemble average of the displacements, the stresses, and the strains over a representative volume element (Ref 40). The average strains are related to the average stresses through the effective elastic moduli.

Calculation of the effective elastic constants of composite materials has been the topic of many studies. Extensive discussions of the bounds for the effective elastic moduli of fiber- reinforced composites can be found in (Ref 40) and other associated literature cited therein. For low frequencies and low fiber concentration, the theoretical prediction of the effective elastic constants is in good agreement with experimental results. On the other hand, for high frequencies the theoretical estimates are not satisfactory, because the effect of wave scattering by the fibers becomes significant. For fiber-reinforced composite materials, dissipation of the waves is caused by the viscoelastic nature of the resin and by multiple scattering from the fibers as well as other inhomogeneities. Both dissipation effects can be modeled by assuming that the stiffness constants, c_{ij}, are complex and frequency-dependent(Ref 41). Because the effects of dissipation on the velocity of the waves are usually quite small, the material is often assumed to be perfectly elastic in the application of the LLW technique.

An experimental system is shown schematically in Fig. 22. The height, rotation angle, and the angle of incidence of the transducer are computer controlled. The control of the angle of incidence allows simultaneous changes in the transmitter and receiver angles while maintaining a pivot point on the part surface and assuring accurate measurement of the reflected ultrasonic signals. The signals are transmitted by a function generator that frequency-modulates the required spectral range. This generator also provides a reference frequency marker for the calibration of data acquisition when converting the signal from time to frequency domain. A digital scope is used to acquire the reflection spectra after being amplified and rectified by an electronic hardware. The signals that are induced by the transmitter are received, processed, and analyzed by a personal computer after being digitized. As discussed earlier, the reflected spectra for each of the desired angles of incidence is displayed on the monitor, and the location of the minima (LLW modes) are marked by the computer on the reflection spectrum. These minima are accumulated on the dispersion curve, which is shown in the lower part of the display in Fig. 23. The use of the frequency-modulation approach introduces a significant increase in the speed of acquiring the dispersion curves. In this approach, 20 different angles of incidence can be acquired in about 45 s in contrast to over 15 min using the former approach. Once the dispersion data is

ready, the inversion option of the software is activated, and the elastic stiffness constants are determined, as shown in Fig. 23.

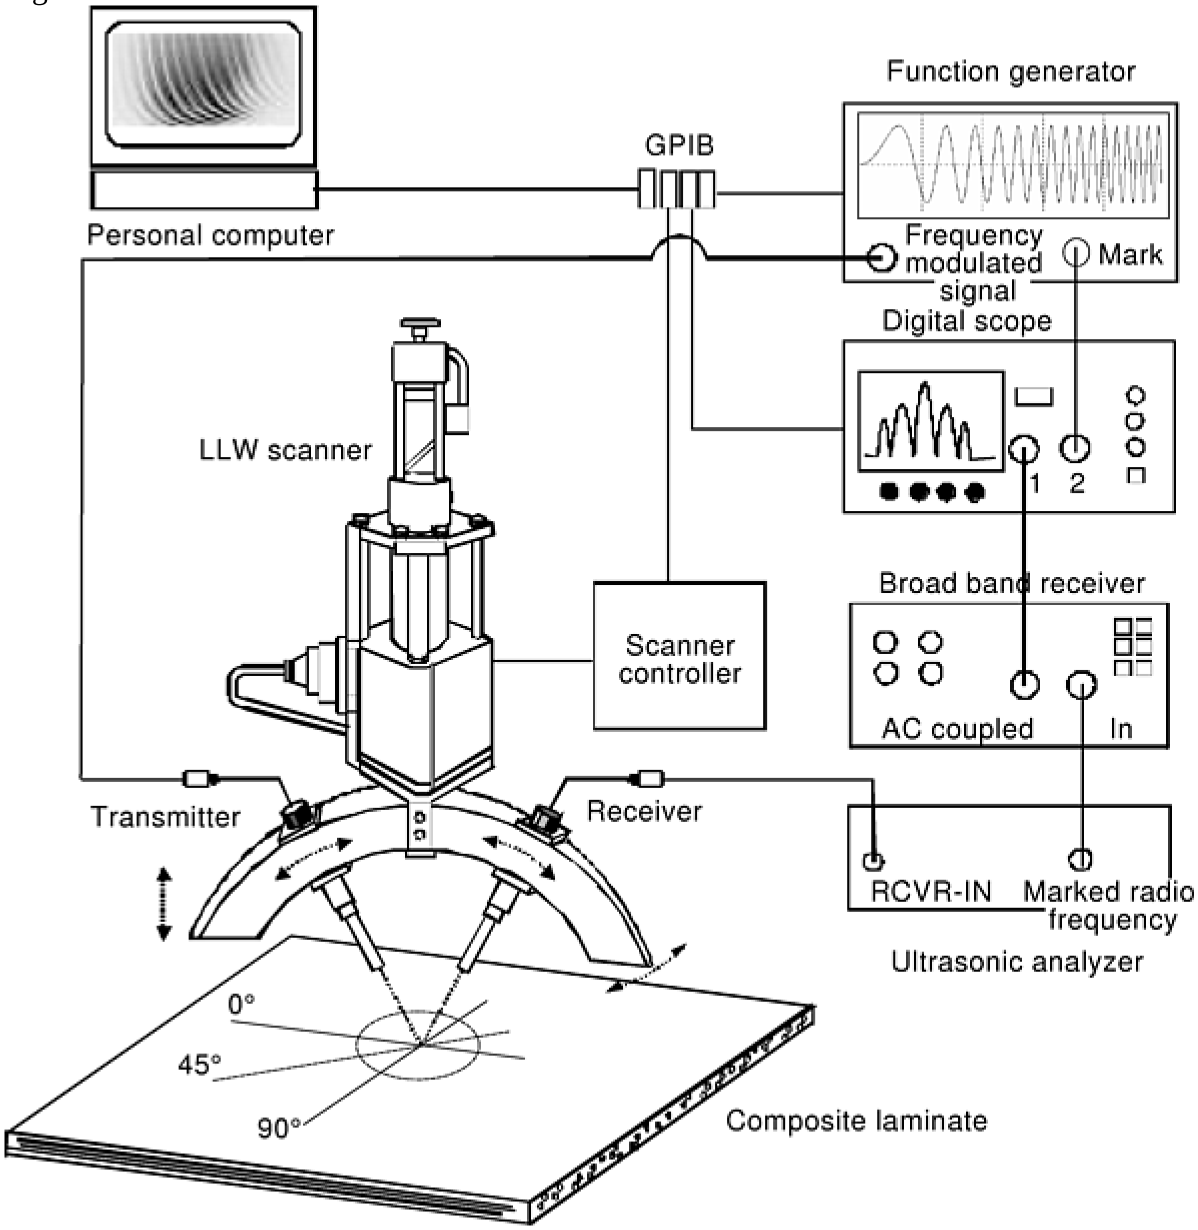

Fig. 22 A schematic view of the rapid LLW test system

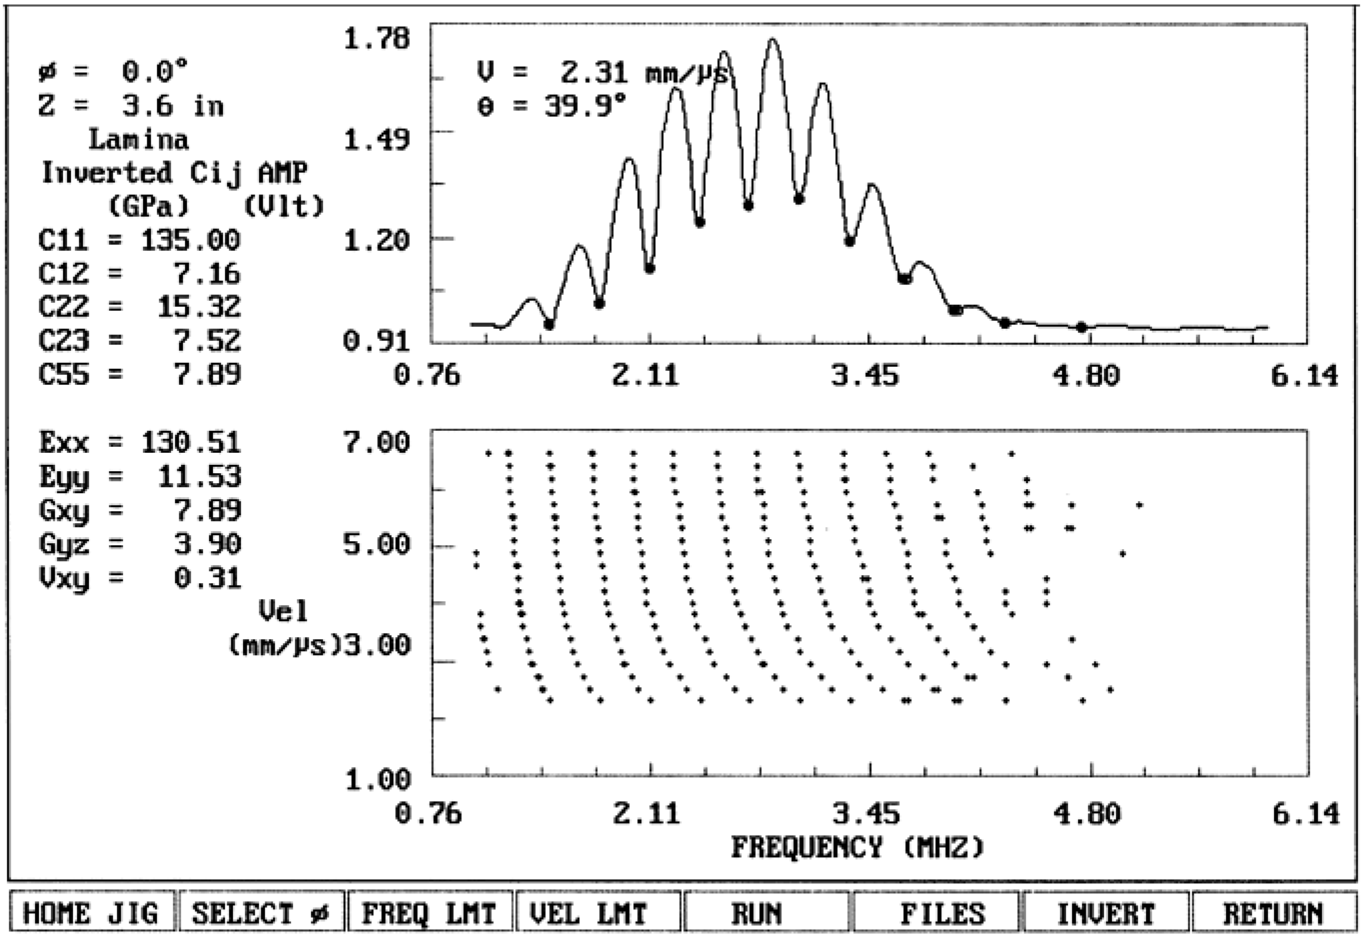

Fig. 23 Computer display after the data acquisition and inversion completion. The elastic stiffness constants are inverted from the dispersion curve and are presented on the left of the screen

Various defects can be detected and characterized based on the quantitative data that is available from the dispersion curves. In Fig. 24(a) the response from a defect-free graphite/ epoxy laminate tested at the 0° polar angle is shown. In Fig. 24(b), the response from an area with a layer of simulated porosity (microballoons) is presented. As expected, at low frequencies the porosity has a relatively small effect, and the dispersion curve appears similar for the two cases. On the other hand, as the frequency increases, the porosity layer emulates a delamination and modifies the dispersion curves to appear as those for a laminate with half the thickness of the undamaged laminate.

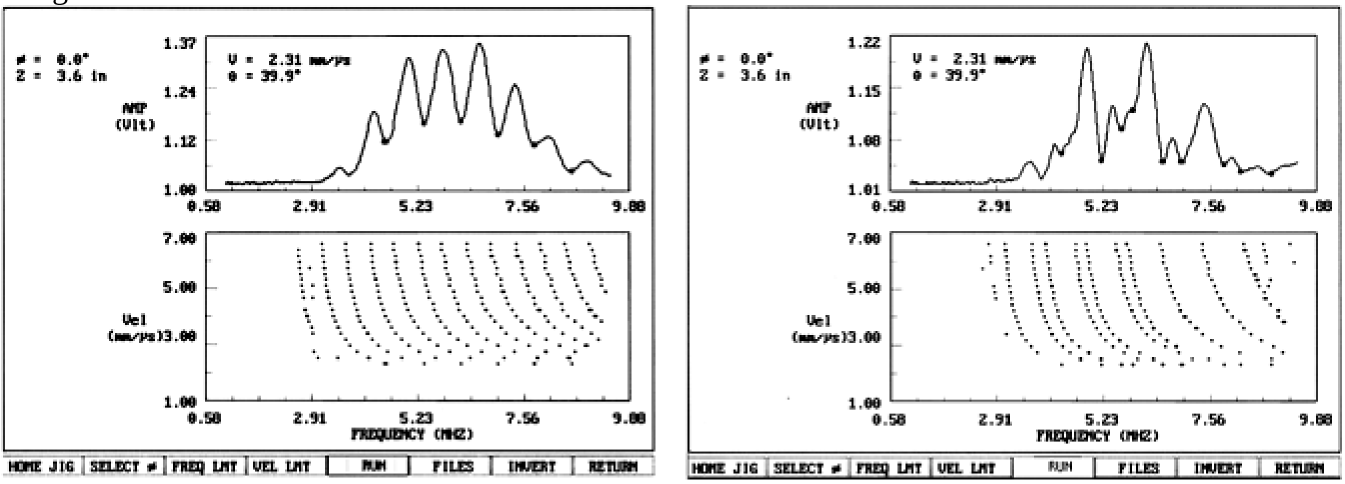

Fig. 24 Leaky Lamb wave characterization. (a) The reflection at 39.5° incidence angle and the dispersion curve for a graphite/epoxy $[0]_{24}$ laminate with no defects. (b) The

response at a defect area where simulated porosity was introduced in the middle layer using microballoons

To further enhance the accuracy of the dispersion data, a method has been developed to acquire and to display them as an image. Examples of such dispersion curves are shown in Fig. 25(a) and (b) for a 3.125 mm (0.12 in.) thick unidirectional laminate tested at 0 and 45° polar angles, respectively. This method has been found to allow viewing modes with amplitude levels that are significantly smaller than what has been observed before. The white curved lines show the modes of the dispersion curve. In the case of propagation at 45° to the fibers (Fig. 25b), it can be seen that the modes that would otherwise be considered noise are clearly identified using this approach.

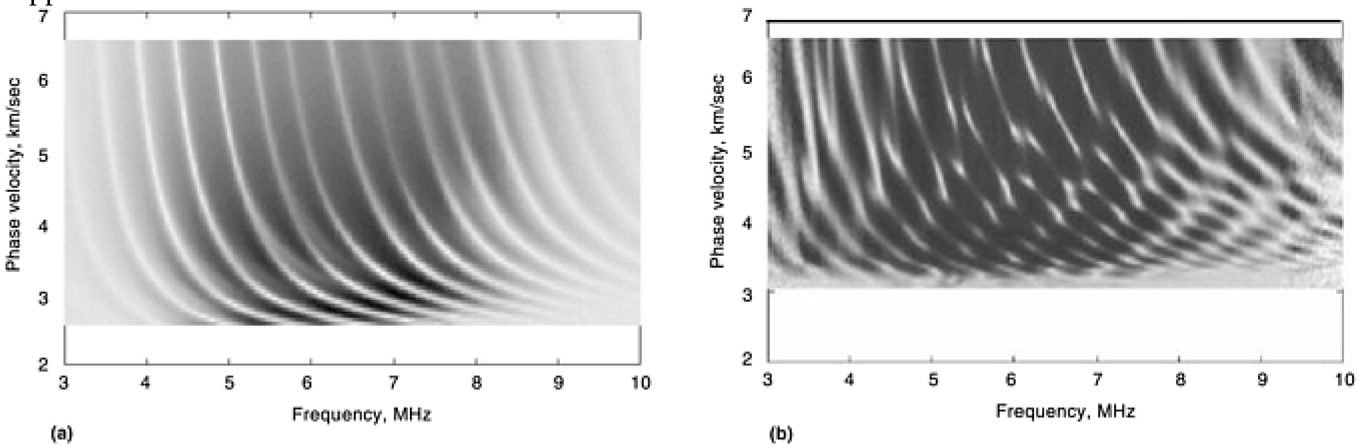

Fig. 25 Leaky Lamb wave dispersion curves for a unidirectional graphite/epoxy composite. (a) Curve showing wave propagation along the fibers generated by an imaging method. (b) Curve showing wave propagation at 90° to the fibers

The LLW method has been studied by numerous investigators since 1990, and this has resulted in a good quantitative understanding of the behavior of the waves in composite materials. However, this knowledge base has yet to be translated into the development of practical NDE methods for production or field applications.

Nonlinear Ultrasonics

Standard ultrasonic inspection is based on linear acoustics. Under this condition, the acoustic waves transmit across an interface with equal intensity during the compression and tension mechanical motions at the interface. However, when the interface is imperfect, the transmission in the tension mode may not be fully supported, perhaps by the opening of microimperfections that change the surface area in contact at the interface. This change in characteristics of the interfaces in a structure between compression and tension results in harmonic signals that are characteristic of the nonlinear acoustic transmission of material (Ref 42). This nonlinear elastic behavior of interfaces provides a method for materials characterization, and in particular, the evaluation of bonded interfaces (Ref 43, 44, and 45).

There are several ways to perform nonlinear ultrasonic inspection. One basic method uses two beams of ultrasonic energy at different tone burst frequencies. When the two acoustic signals interact, harmonics will be created. The presence of a signal at sum and difference of the two input frequencies is an indicator of nonlinear characteristics. Figure 26 shows this measurement configuration. The signal can be used for the detection of nonlinear features in material samples. Another approach is to use a high-amplitude tone burst as a probing signal frequency and a second signal created by vibration of the test article, also at high-amplitude, to stress an interface of interest. When the two signals interact, sidebands are generated. The sidebands to the probing frequency are at plus and minus the vibration frequency value. A Fourier transform display of the detected signal will show the sideband effects when nonlinear processes are present in the test objects. Figure 27 shows this configuration. Cracks, delaminations, and poorly bonded interfaces should serve as sources for the nonlinear effect and be detected.

Acousto-Ultrasonics

Acousto-ultrasonics, a technique originally developed by A. Vary and coworkers, is basically a pitch-catch method that uses two transducers, one to generate a wave and one to receive it after it has progressed along the material (Ref 46, 47, and 48). It differs from the normal pitch-catch ultrasonic technique in that the two transducers are not placed in sight of one another to receive body waves. Rather, the two transducers are placed on the same side of a plate, shown in Fig. 28, and the receiver responds to plate (Lamb) waves that are generated by the transmitter. The transmitter simultaneously generates body waves that are either partially converted into plate waves or reflected back and forth between the front and back faces of the plate under the transmitting transducer until all of their energy is thermally dissipated. The signal received by the second transducer has been found to correlate well with the location of the final catastrophic failure site and with stiffness changes during fatigue (Ref 49, 50). Various signal analysis procedures can be used to obtain more reproducible results from the technique (Ref 51).

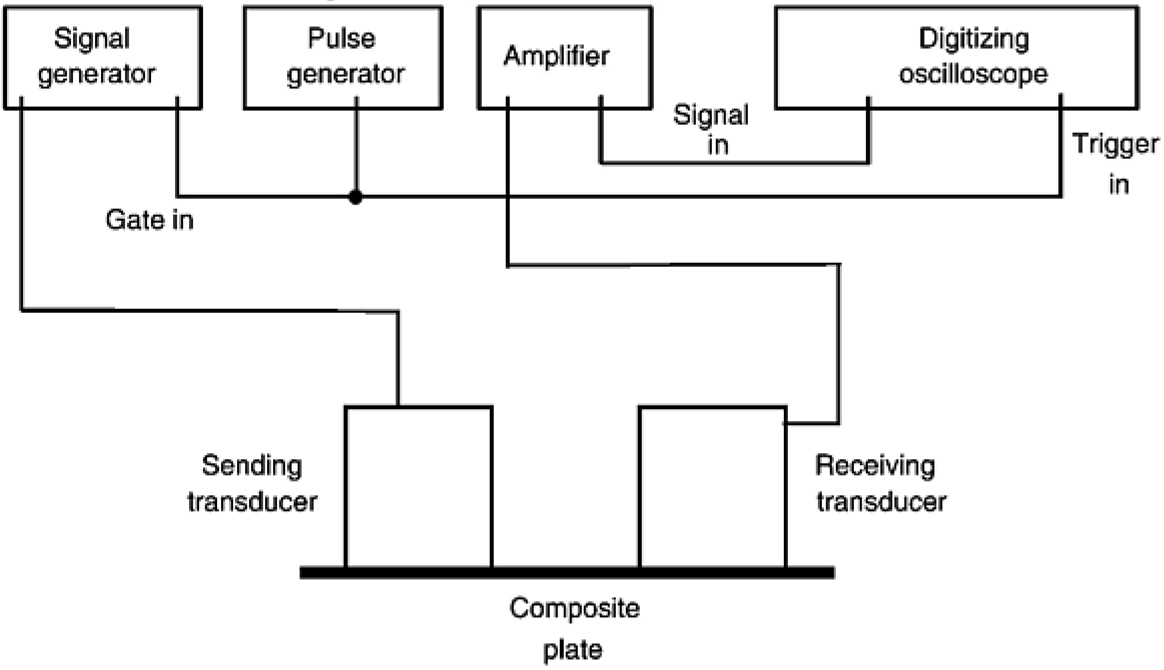

Fig. 28 Acoustic-ultrasonic experimental configuration

Acousto-ultrasonic measurements are made by stimulating stress waves in the material and measuring a stress wave factor (SWF) (Ref 52). The SWF can be measured in several ways, such as the ring-down count, peak voltage, or energy. This is similar to acoustic emission testing. Lower values of SWF indicate higher material attenuation, related to microcracks, porosity, cure state, bond quality, morphology, and microstructure. Figure 29 presents typical results comparing changes in the RMS of the energy of an acousto-ultrasonic signal with stiffness during a fatigue test of a graphite/epoxy specimen. The acousto-ultrasonic technique may find application as a sensitive indicator of degradation of composites due to damage, fatigue, or other forms of material attack. However, this knowledge base has yet to be translated into the development of practical NDE methods for production or field applications.

Radiography

Radiography is a well-established production process with many variables in image formation and interpretation (Ref 53). The equipment performance, personnel qualifications and certification, test criteria, and test procedure scope must be identified and documented, if reliable and repeatable test results are to be achieved. Well-defined test criteria and high-quality reference images are needed to separate unacceptable material from acceptable materials with confidence. Radiography can be used with composite materials. It provides a permanent record of the test specimen in the image, reveals fabrication, assembly, and structural defects, and often suggests a corrective action in the process used. Digital data files can be easily communicated and shared. Digital data can be rescaled to accurately reconstruct engineering values of material density and size.

Radiographic testing involves exposing a media to x-ray radiation that has penetrated the specimen of interest, developing an image from the media, and interpreting the image developed. The general equation for the absorption of x-rays through material is:

$$I = I_0 e^{-\mu(E)x} \quad \text{(Eq 14)}$$

where I is the transmitted intensity, I_0 is the initial intensity, μ is the linear attenuation coefficient as a function of energy (E), and x is the material thickness. The variation in the transmitted radiation field (detected as image features) is the result of variable attenuation, due to changes in the material makeup or construction of the composite structure. Sensitivity to these feature changes are improved with lower x-ray energy and larger feature size. Higher x-ray energy is required to penetrate thicker or denser structures.

Radiographic testing can be applied to assure the maximum reliability of fiber-reinforced composite products and bonded assemblies, both with and without honeycomb. It is complementary to ultrasonic inspection, in that these methods can detect different types of defects, and data from one method can often be used to help interpret results from the other. Existing processes involve tube-type constant potential or rectified radiation sources for production radiography, and many systems are capable of operating at low energy (< 50 kV). Radiographs are normally produced on a high contrast, small-grain- size medium capable of meeting the flaw detection requirements of the applicable product inspection and acceptance specification. Film radiography typically uses the human eye for a detector. Films are interpreted by passing sufficient quantities of light through the film during observation. If the radiograph has sufficient contrast and spatial resolution, it will be possible to detect small variations within the specimen. Contrast variations of 2% and spatial details of 0.50 to 1.25 mm (0.020 to 0.050 in.) are easily detected in most composite materials.

Radiographic contrast is actually a combination of subject contrast and film contrast. Subject contrast is directly affected by the energy of the ionizing radiation used, the density and thickness of the specimen, and the atomic number of the specimen material(s). Always apply the lowest practical energy level to maximize radiographic contrast. Film contrast is a function of the behavior of the film when it is exposed to varying quantities of radiation. Film contrast values are expressed as a relationship between film exposure and the resulting film density. Film radiography normally requires a darkroom to prepare film cassettes for exposure and to stage film in an automatic processor for development. There are many variables to control in this process; for example, exposure to light will compromise the quality of the radiographs, as will unsuitable film-processing chemistry.

Nonfilm methods, such as computed radiography (CR) and digital radiography (DR), can be employed as an alternative to x-ray film (Ref 54, 55, and 56). The CR systems employ a plate coated with phosphor, which consists of barium fluorohalide containing a minute quantity of bivalent europium ions. The phosphor exhibits a phenomenon called photostimulable luminescence. Once the imaging medium is exposed to radiation, it is processed by scanning the image medium by laser in an image plate reader. The photostimulated luminescent light thus emitted is converted to a digital number representing the intensity. Once the stored photon energy has been extracted, the image plate is erased and ready for reuse. Digital radiography systems include charge-coupled device (CCD) arrays, amorphous silicon, and amorphous selenium. The CCD and amorphous silicon systems use an x-ray-to-light conversion layer (phosphor) and then a silicon imaging detector array.

Amorphous selenium array detectors have a direct x-ray-to-light conversion process (Ref 57). The quality of these systems is dependent, among other things, on the combination of the x-ray sensing layer performance, the array pixel size, and, the readout system capability. The digital data from both CR and DR systems can be input to image processors for enhancement, archived, and/or converted to a hard copy image.

The use of an image quality indicator or reference standard is normally required for each inspection. Required image quality levels should be documented in a written inspection procedure, and image quality verification shall demonstrate a radiographic process capable of producing results with the level of quality necessary for detection of anomalies within the test material. Image quality indicators can contain naturally occurring or artificially produced flaws and/ or holes or wires. The image quality indicators, which are sensitive to both contrast and definition factors, should be placed on the test specimen in the area of interest for each radiograph.

Radiographic testing of composites involves two primary processes: static, or stationary, radiography and in-motion radiography. Static radiography involves placing imaging medium under a test specimen and exposing the medium without any specimen or source movement. Figure 30 shows a view of a radiation cell for composites material inspection. Radiation beam orientation and the number of exposures for any part or material are governed by the test object geometry and the size and location of the various types of anomalies to be detected. For most structures, the beam of radiation should be perpendicular to the inspection surface in the area of interest. A static exposure depicting minute voids averaging 0.635 (0.025 in.) in diameter in a composite structure is shown in Fig. 31.

Fig. 30 Radiation cell for composites material inspection

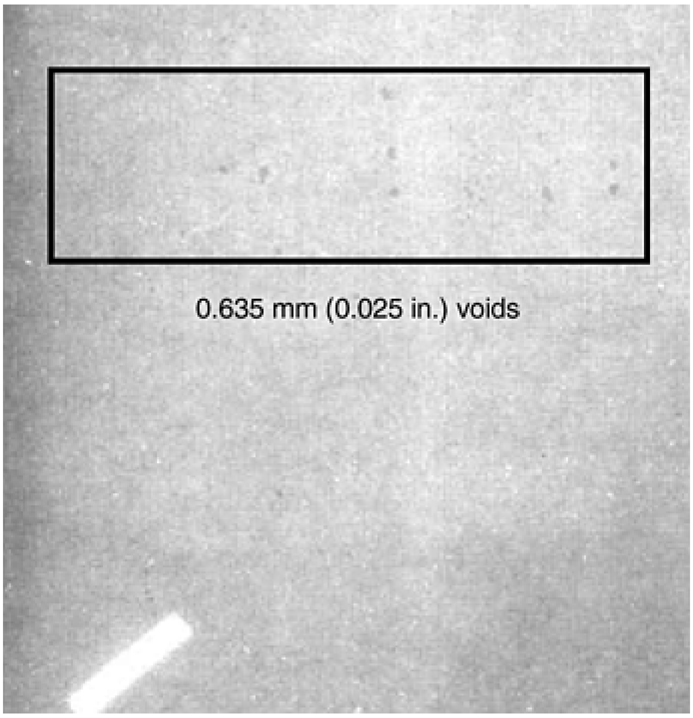

Fig. 31 Example of a radiograph of composite material containing voids

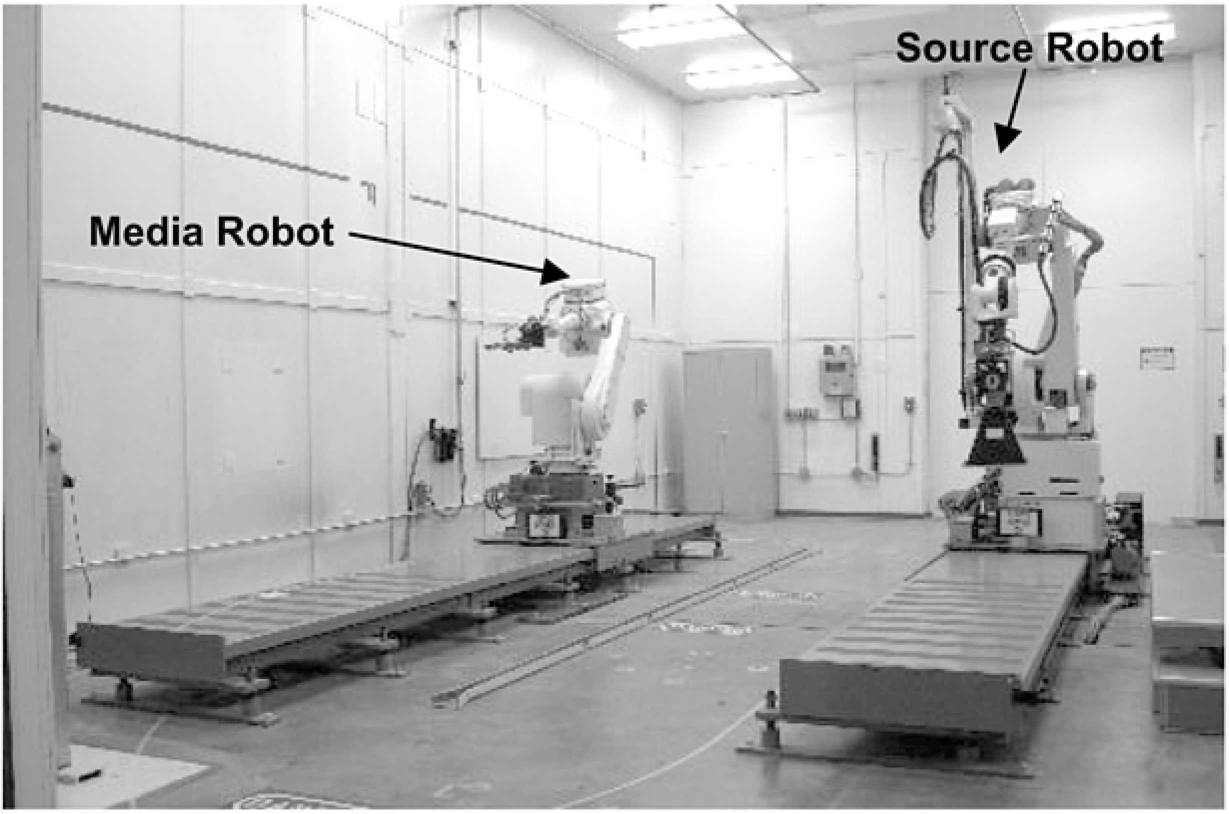
In-motion radiography employs a robotic or electrically driven tube head support system to provide vertical motion as well as longitudinal and transverse motion of the x-ray tube. Typically, in-motion equipment is computer controlled, which provides a programmable means of varying the x-ray parameters in addition to velocity of the tube head motion. The motion system shall provide a smooth contiguous transition at all speeds, and the radiation energy system shall provide a degree of stability that will not cause radiation intensity banding within the radiograph. Figure 32 shows an example of an in-motion radiography facility.



(a)

(b)

(c)

Fig. 32 Example of an in-motion radiography facility showing (a) the facility, (b) a close-up of the source robot, and (c) the collimator and slits

For bonded honeycomb assemblies, the assembly should be oriented with the honeycomb cells (depth) parallel to the central ray of the x- ray beam. The long axis of the slit in the collimator should be aligned perpendicular to the direction of motion and the longitudinal axis of the x-ray tube. When radiographing metallic or composite close-out or web structures for adhesive or core tie-in, the x-ray beam shall be oriented parallel to the close-out or web structure. The long axis of the slit in the collimator shall be aligned perpendicular to the direction of motion and the longitudinal axis of the x-ray tube. Measuring the imaged web or close-out thickness on the radiograph and comparing it to the nominal web thickness, per the part drawing, shall verify critical beam alignment. Typically, if the imaged structure is 0.75mm (0.030 in.) over the blueprint nominal thickness, beam realignment should be preformed. Off-angle shots can obscure defects, such as lack of tie-in, voids, short core, and so on, due to geometric image enlargement on the medium. This being the case, accurate defect measurements cannot be performed. When parts are radiographed to detect cracks, only the area of the part within a cone of radiation with a maximum plane angle of 10° should be considered valid for interpretation. An

in-motion exposure optimally aligned on a bonded honeycomb assembly depicting three areas of adhesive tie-in defects is shown in Fig. 33.

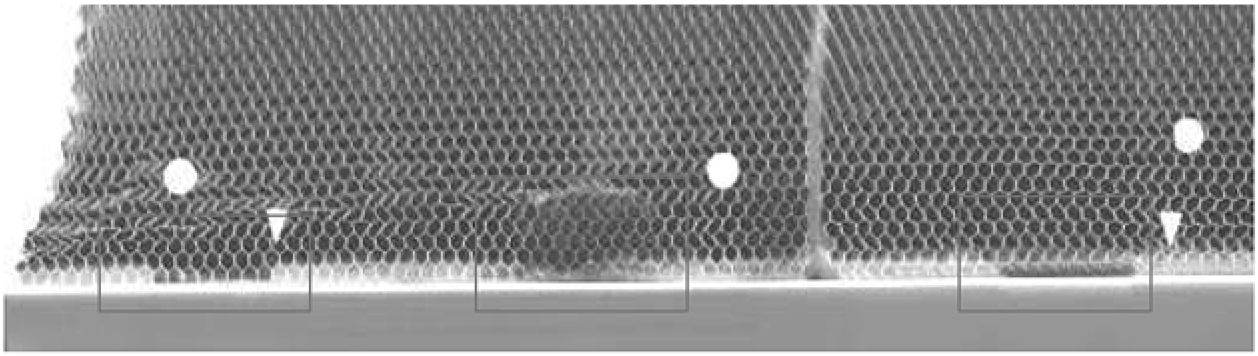


Fig. 33 Example of an in-motion radiograph depicting three areas of adhesive tie-in defects

Geometric unsharpness is the foundation for establishing the quality needed to read and interpret radiographic images. Geometric unsharpness, as applied to in-motion and static radiography, is a derived numerical value from a specifically defined equation. In stationary radiography, the geometric unsharpness shall satisfy the following:

$$U_g = Ft/d \quad \text{(Eq 15)}$$

where U_g is the geometric unsharpness, F is the maximum dimension of radiation source size, t is the thickness of the part (assuming that the film is against the part, otherwise it is the sum of the thickness of the part and the distance between the film and the part), and d is the distance from the source to the source side of the object.

For in-motion radiography, the unsharpness must meet the Eq 15 requirement, but an additional unsharpness criterion in the direction of motion must be satisfied. Geometric unsharpness for the in-motion method in the direction of motion is calculated as follows:

$$U_m = [T(F + S)]/C \quad \text{(Eq 16)}$$

where C is the minimum focal spot to collimator slit distance (collimator length), T is the distance between the imaging medium and the surface to the part farthest from the imaging medium to be interpreted, F is the effective focal spot size, and S is the collimating opening slit width in the direction of travel. The slit width is the opening at the distal end of the radiation collimator responsible for the focusing of the image.

Radiation energy levels should be selected in accordance with the standard x-ray potential curve based on equivalent material thickness. Figure 34 shows energy selection curves for x- ray inspection as a function of material and thickness. When radiographing a test specimen containing multiple materials, determine the predominate material and calculate the radiographic equivalence factor of the secondary materials to the predominate material equivalent thickness. Now the x-ray potential curve can be used for a single equivalent material thickness.

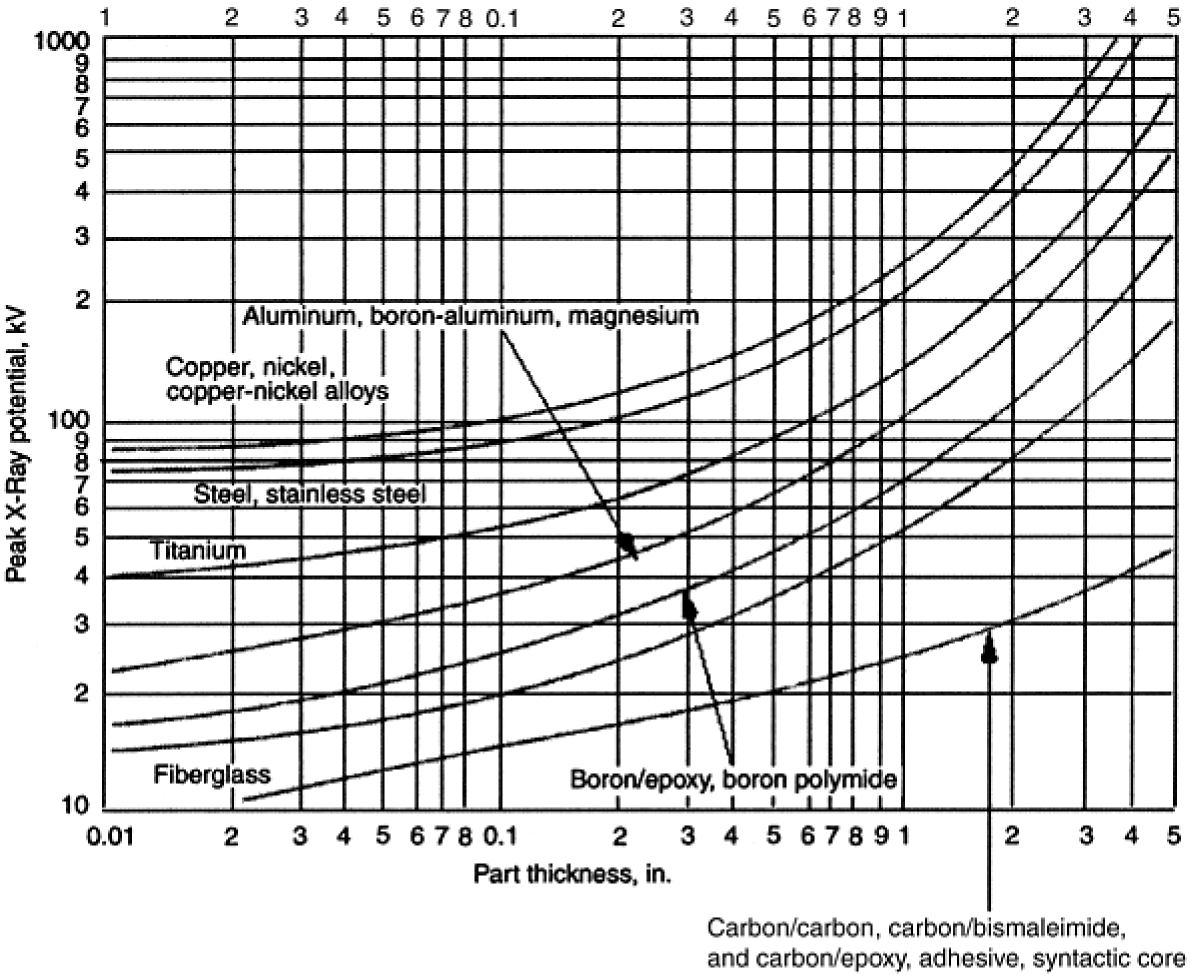

Fig. 34 Chart for the selection of x-ray energy as a function of material and thickness

Computed Tomography

X-ray computed tomography (CT) can play an important role in the evaluation of composite materials and structures. Thick graphite- or plastic-fiber composites, multilayer bonded structure, honeycomb, and ceramic and metallic composites can exhibit difficult-to-interpret indications from standard NDE methods. Computed tomography can be used to detect and measure features, such as delaminations, porosity/voiding, resin-rich/resin-poor, bondline fill, cracking, dimensions, and so on, providing useful information during the composite structure development or the evaluation of nonconforming articles.

X-ray CT was invented in the 1960s and developed for medical applications in the 1970s and 1980s (Ref 58, 59, 60, 61, 62, and 63). Industrial application of CT has followed the medical developments, perfecting the technology for the evaluation of objects as small as an optical fiber to objects as large as an intercontinental ballistic missile. Medical CT systems are designed for high throughput and low dosages specifically for humans and human-sized objects. These systems can be applied to industrial objects, such as composite structure, that have low atomic number and are less than one-half meter (20 in.) in diameter (Ref 64). In the late 1970s and 1980s, industrial CT systems were specifically developed and applied to a variety of hardware items (Ref 65, 66, and 67). Both medical and industrial CT systems are applicable to composites object inspection, depending on the object size, constituents, and features of interest (Ref 68, 69, 70, and 71).

While conventional radiography, as shown in Fig. 35(a), creates a shadowgraph containing superposition of information, x-ray CT uses measurements of x-ray transmission from many angles around a component to compute the attenuation coefficient of small volume elements. This data, as shown in Fig. 35(b), is presented as a cross-sectional image map of the object. The clear images of interior planes of an object are achieved without the confusion of superposition of features. Computed tomography results are easy to interpret for feature detection and placement. Computed tomography can provide quantitative information about the density/ constituents and dimensions of the features imaged. Figure 36 demonstrates the application of CT to a composite tail cone. The image on the left is a radiograph. The CT slice on the right, taken near the top of the cone, shows the internal configuration, dimensions, and material variation without the confusion of superposition of information in the radiograph. Multiple CT slices at sequential locations along the vertical axis are required to image the entire cone with CT.

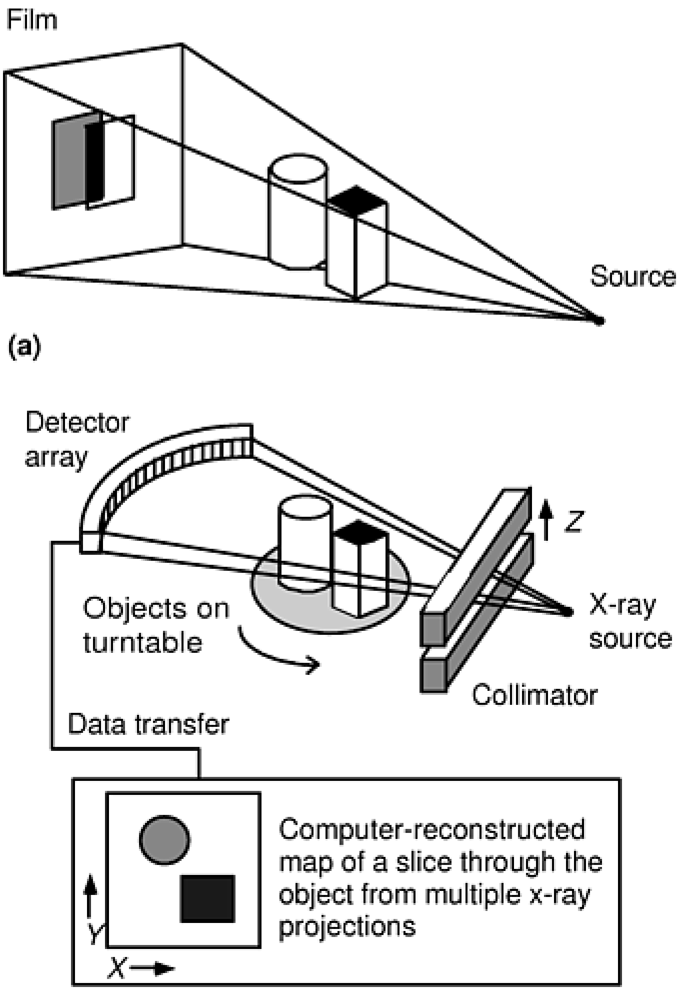

Fig. 35 Comparison of radiography and computed tomography (a) Conventional projection radiography. (b) CT using slit collimation

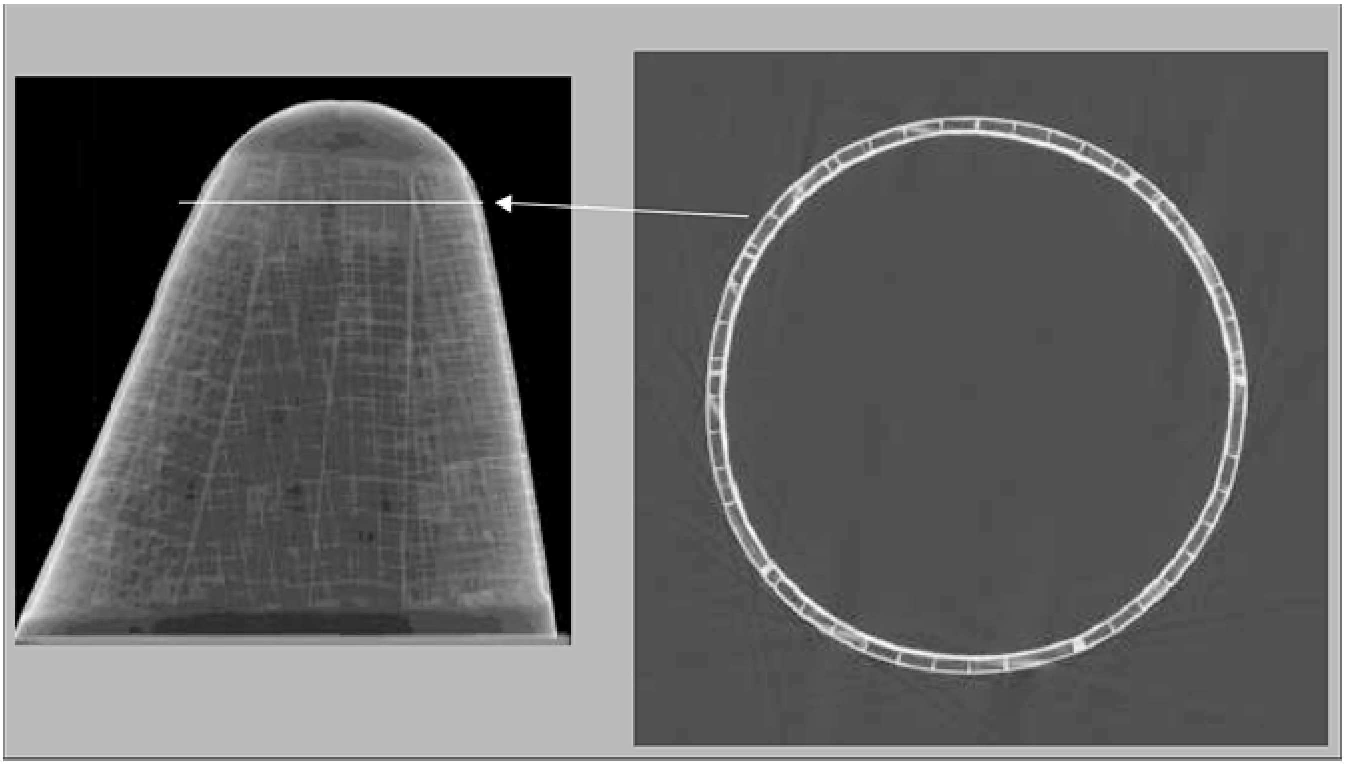

(a) (b)

Fig. 36 Example of a composite tail cone approximately 800 mm (31.5 in.) tall and 50 mm (2 in.) in diameter at the midplane. (a) Radiograph of the sample. (b) CT slice near the top

X-ray CT can be considered the high-end application of radiation measurements, because the data obtained are quantitative measures (directly related to the x-ray linear attenuation coefficient) for each volume element throughout an object. The sensitivity can be high, because each reconstructed volume element is composed of back- projected rays from many orientations about the object. Equation 17 shows an estimate of the SNR in a voxel element (a unit of graphic information that defines a point in a three-dimensional space) as a function of various CT system characteristics for a reconstruction of cylindrical object (Ref 70):

$$SNR = 0.665\ \mu d^{3/2}[(vnt/\Delta p)e^{-2\mu R}]^{1/2} \qquad \text{(Eq 17)}$$

where μ is the linear attenuation coefficient, *d* is the x-ray beam width, *v* is the number of views, *n* is the photon intensity rate at the detector, *t* is the integration time of the detectors, Δ*p* is the ray spacing, and *R* is the radius of the object. Equation 17 shows that the SNR improves with larger beam width, number of views, x-ray beam intensity, and integration time. The SNR will also be improved by decreasing the ray spacing and object diameter. These CT system characteristics reflect the trade-offs in optimizing a CT system. Fast scan times, fine resolution, high contrast sensitivity, and large object size are mutually exclusive, requiring compromise in system design.

Because of the high signal-to-noise in any voxel, CT can detect features below the resolution limit of the image (voxel size). For features that are larger than a single voxel, the contrast sensitivity improves by the square root of the number of pixels making up the feature. For a feature smaller than a pixel, the apparent density is averaged over the image voxel, and therefore, the signal for that image voxel is reduced. This is called a partial volume effect. Although the signal is reduced by the partial volume effect, the feature may still be detected. This is a significant point about the application of CT, because very often relatively large image voxels (compared to very fine defects) may be used, but small features are still detected, although they are not necessarily resolved. The contrast sensitivity typically provided by CT is in the range of 0.1 to 1%.

Computed tomography requires more sophisticated equipment for data acquisition and reconstruction than conventional radiography. The total time required to inspect an object volumetrically is relatively long, making CT a significantly more expensive inspection. Computed tomography has several variations from its basic concept of Fig. 35. The most useful forms for composite structure are second-generation and third-generation CT. The second-generation, rotate/translate scheme is commonly used for industrial objects, because objects larger than the x-ray beam fan angle can be accommodated. The third-generation, or rotate-only, scanning approach is used on small industrial objects, because it is faster than second-generation. Both the second- and third-generation methods use a one-dimensional detector array and only image one slice location through the part in a single CT scan. That slice inspection volume is the size of the fan beam height collimation. Another method, "volume CT" or "cone beam CT," uses a two-dimensional area detector and an uncollimated cone of radiation, such that the entire object may be inspected in one scan. This technique sacrifices some detail in the image quality for a higher throughput when the entire object must be inspected with CT and has limitations on the applicable part size (Ref 72, 73). It also generally works well only for relatively small objects. Limited-angle, tangential, and annular reconstruction CT are also methods that can be beneficial to large composite structure. Limited-angle CT does not require that the CT data be taken from all angles completely about the part. This can be particularly advantageous for large planar composite structure (Ref 74). Tangential and annular reconstruction offer advantages for large cylindrical structures where information is only needed along annular rings, particularly near the outside of the structure (Ref 75, 76).

Computed tomography data allows accurate evaluation of dimensions and locations in three- dimensional object space or material density (as related to x-ray linear attenuation coefficient) to be performed in any orientation throughout the volume of an object that has been scanned with the CT system. Tables 5 and 6 list the benefits and limitations of CT for composite materials and structures that result from the capability and complexity of the CT measurements (Ref 77). Figure 37 demonstrates the sensitivity of CT to features in composite structure. The CT image of the composite "J"-stiffener shows how the variations in the consolidation and the ply lay- ups can be evaluated, particularly at T-junctions.

Table 5 Capabilities of computed tomography for NDE of composites

Evaluation parameter	CT capability
Material consolidation uniformity (mixture distribution), voiding, porosity, dry ply, resin/fiber distribution, flow characteristics	**Quantitative measurement of density and variation over a three-dimensional volume**
Foreign material	**Detection, location, and quantification**
Bonds (inaccessible to other NDE methods)	**Location, extent, variations (limited to bond separation)**
Internal structures/reinforcements	**Detection and measurement of placement, interface quality, shape, and condition**
Damage and testing (impacts, environment, loading, etc.)	**Volumetric feature detection measurement**
Coatings	**Thickness, variation, interface quality**
Anisotropic fiber structure	**Fiber direction, tow alignment, wrinkles, waviness**
Dimensional measurements	**Noncontact, internal, external measurement**
Repairs (honeycomb)	**Adhesive location and amount**

Table 6 Limitations of computed tomography for NDE of composites

Attribute	Technical limitations
Volumetric measurement	**Disbond must have separation**
Detail sensitivity	
Resolution	**Large structures: typically 0.5 mm (0.02 in.) features are resolved, smaller high-contrast features can be detectedSmall structures: (<250 mm, or 10 in.) typically resolves 1 to 2 parts in 500**
Density measurement	**Multiple materials must differ in x-ray linear attenuation coefficients (density and atomic number) for detection (0.01% to 0.1% for large, > 1 mm, areas)**
Artifacts	**Large aspect ratios cause streak artifacts (>15:1 is difficult). Detail sensitivity in low-density material near high-density features is compromised.**
Part handling	
Penetration	**X-ray transmission is limited by size, density, and atomic number of the part and by the available x-ray energy.**
Size/shape	**Access to 360° around the part**

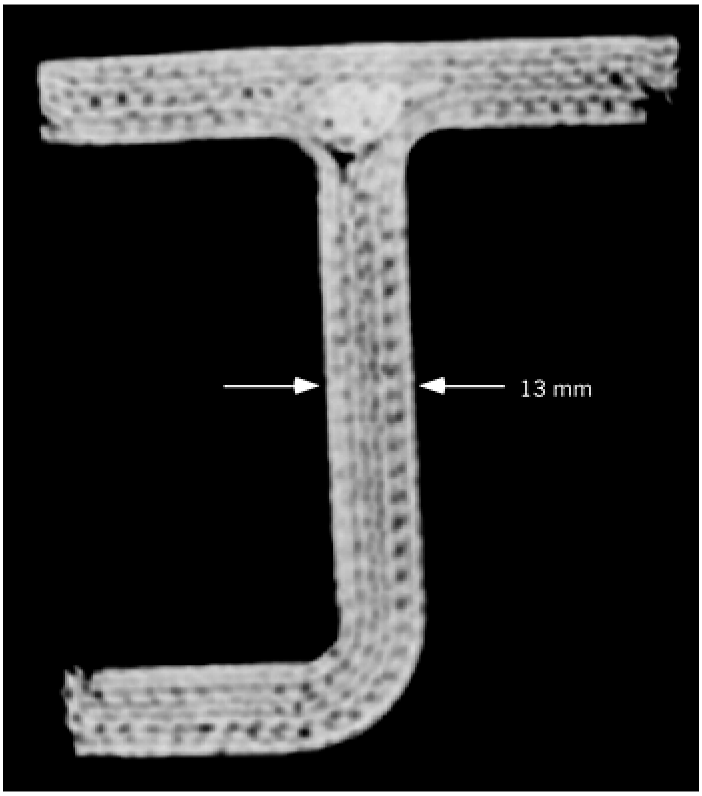

Fig. 37 Computed tomography image of a graphite/epoxy woven "J"-stiffener, showing ply condition and consolidation

Thermography

Infrared thermography offers an ideal, cost- effective NDE solution for a wide range of in- service and manufacturing composites applications (Ref 78, 79, 80, 81, and 82). It is fast, noncontact, can be single-sided, and offers wide area coverage of flat or curved parts. It is used for composite NDE applications, including detection of delaminations, impact damage, water entrapment, inclusions, density variations, and evaluation of adhesive bonds. Thermographic NDE systems range from a simple heat gun-infrared (IR) camera combination to fully automated inspections systems capable of thickness or defect measurement and advanced materials characterization.

In thermographic NDE (TNDE), a surface of the component under test is actively heated, and the subsequent surface temperature response of the part to the stimulation is monitored with an IR camera. Although there are

many possible configurations for TNDE (e.g. TT, cooling stimulation, and step or modulated heating, to name a few), the same basic principles apply. The physical process can be reduced to three steps in which energy is converted to various forms:

- The surface of the component is uniformly heated. Typically this is accomplished using light, although forced air, steam, hot water, electrical current, electromagnetic induction, and acoustic energy have been demonstrated for particular applications.
- As thermal energy from the heated front surface diffuses toward the cooler interior and back surface of the component, the front surface temperature of the component falls. However, areas of the front surface that are located above subsurface defects (discontinuities in the material density, thermal conductivity, or heat capacity) will cool at a different rate than defect-free areas. Figure 38 graphically depicts this scenario for regions with and without subsurface defects.
- An image of the surface temperature of the heated component is monitored using an IR camera, which collects IR radiation from the surface of the sample. Defect areas will exhibit anomalous cooling behavior, which will appear in the infrared IR of the surface.

It is important to understand the energy conversion processes described previously, because ineffective conversion in any of these steps will adversely affect the result. For example, a component with an optically reflective surface will not absorb light efficiently, and may have to be treated with a removable paint or heated using a nonoptical source. A material that is a poor thermal conductor will respond to the heat stimulus very slowly, while the image of a sample with poor IR emissivity will be relatively weak.

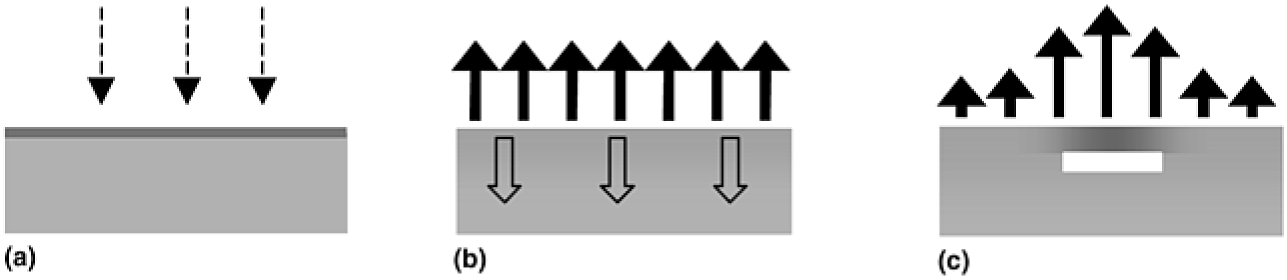

Fig. 38 Energy conversion in pulsed thermography. (a) A brief light pulse uniformly heats the sample surface. (b) Infrared radiation is emitted uniformly from the surface as thermal energy from the surface diffuses toward the interior of the sample. (c) Increased infrared radiation at the surface above a buried defect is due to interruption of the flow of heat into the sample by the defect

Although it is possible to find large or shallow subsurface defects using a heat gun and an IR camera, pulsed IR thermography is the most widely used approach for industrial applications, because it offers the best combination of speed, sensitivity, repeatability, depth and spatial resolution, and quantification. In pulsed thermography, the surface is typically heated using flashlamps that provide a spatially uniform light pulse with a duration of a few milliseconds. A continuous image data sequence is acquired from the IR camera, beginning just before flash heating occurs and continuing until the sample reaches a steady-state temperature. (The duration depends on the thermal properties of the sample.) In most cases, digital data from the camera is acquired and stored on a personal computer for subsequent processing and analysis. Commercial pulsed thermography software analyzes each pixel individually to identify defects and measure physical properties. Figure 39 shows an example of a pulsed thermograph image of a honeycomb composite compared to x-ray and ultrasonic images.

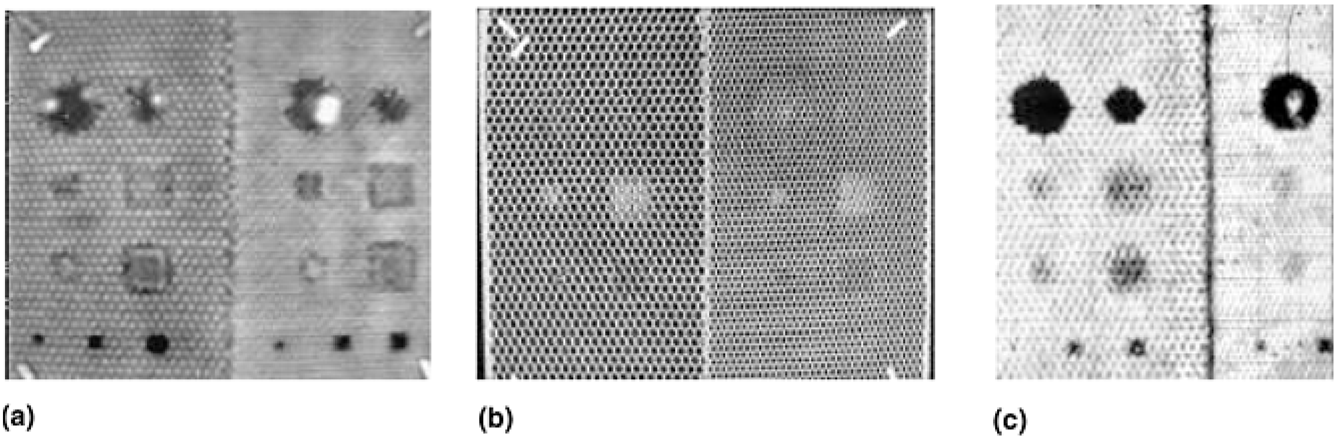

Fig. 39 Comparison of pulsed thermography. (a) X-ray. (b) Through-transmission ultrasound. (c) Images of a carbon/ epoxy 5-ply laminate with aluminum core. Intentional defects include (top to bottom) synthetic fluorine- containing resin inserts in the laminate, synthetic fluorine-containing resin inserts at the skin-core interface, and potted core and simulated disbonds in the laminate

Unlike imaging systems where resolution and sensitivity can be defined in absolute terms based on detector characteristics, characterization of resolution capabilities of TNDE requires consideration of sample material and defect depth, diameter, and composition, as well as the IR camera. Although a particular IR camera may be capable of extremely high spatial resolution of the sample surface, the true critical defect size is limited by the aspect ratio (minimum width-to- depth ratio) of the defect. The minimum detectable defect size is proportional to the aspect ratio. Although it is possible to image weaker defect responses using various signal processing methods, defects with aspect ratio greater than 2 are readily detectable with modern TNDE systems.

In many respects, composites are ideal materials for TNDE. Their optical reflectivity, IR emissivity, and thermal diffusivity generally fall within a range that allows evaluation without surface preparation or high-speed IR cameras. (This is often not the case for metals, where these measures are routinely applied.) Common composites applications for TNDE include detection of voids, delaminations, inclusions, density variations, impact damage, bonding irregularities, and trapped moisture. Since IR radiation is emitted most strongly in the direction perpendicular to the surface, pulsed thermography is well suited to large planar structures or curved components with large radii of curvature. It can be applied to lay-ups or randomly oriented fiber materials. Defect contrast varies in proportion to the contrast between the thermal diffusivity of the defect and surrounding material. As a result, applications where the defect presents a composite- to-air, -vacuum, -metal or -water interface offer better performance than situations where materials such as a material inclusion are to be detected. For most composite applications, pulsed thermography systems are capable of evaluating an area of 0.1 m^2 (1 ft^2) in 5 to 20 seconds, depending on the thickness and thermal diffusivity of the material. (Low diffusivity materials require longer inspection times.) As thicker samples are inspected, it may be necessary to provide more input energy. In general, samples thicker than approximately 13 mm (0.5 in.) are not considered practical for thermographic inspection.

ASM International Committee on Nondestructive Testing of Composites

Low-Frequency Vibration Methods

Techniques that use frequencies lower than ultrasonic methods can be used to inspect composite structures (Ref 83). The adhesive bond between the skin and core of a composite sandwich structure can be inspected with one of a variety of low-frequency vibration techniques. In certain instances, solid laminate structure can also be inspected for impact damage or internal delaminations. The advantage of these vibration-based techniques over the higher-frequency methods is that a couplant between the probe and the testpiece is not required. They also generally require access to only one side of the structure and can be used when the material is too attenuative for PE or TT ultrasonic testing. Some of the most common vibration techniques are discussed subsequently.

The tap test uses the human ear as a sensor (which can pick up vibration in the 15 Hz to 20 kHz range), and is perhaps the oldest of all low- frequency vibration inspection methods. This method uses a coin or small hammer to “tap” the surface of a laminate or bonded composite while listening to the sound it makes (Ref 83). This method works because of the difference in the sound produced when a “good” versus “bad” region is tapped. A “good” region tends to “ring,” while a “bad” region will sound “dead.” The sound difference is due to the difference in the nature of the tap impact response. Damage, such as a disbond, results in a local decrease in the mechanical impedance of the structure, which changes the force-time curve caused by the tap near the flaw. The tap test is, in essence, related to the local stiffness. Tap testing is routinely used to detect disbonds, delaminations, and water in honeycomb core cells (Ref 84). However, it cannot detect small voids or disbonds smaller than about 13 mm (0.5 in.), and its sensitivity decreases with thickness to a depth of about 6 mm (0.25 in.) under a stiff material, after which it is totally unreliable. Tap testing is also very susceptible to changes within the structure of the part under test. Ply-thickness changes, core details, core fillers, bonded substructure, and edges are some of the features that can cause false calls. Knowledge of the design of the internal structure is essential to determining if tap testing will be effective and for effectively interpreting the inspection.

In recent years, instruments such as the Mitsui Woodpecker and the WichiTech RD^3 (digital) Tap Hammer have been developed to improve upon traditional tap inspection by providing quantitative data that are independent of inspector experience and ear sensitivity. These instruments make use of the amplitude, duration, or frequency response of the impact curve, because all are affected by the local stiffness. One or more of these features can be flagged as indicators of defects or damage.

Mechanical Impedance Analysis. Another method that senses the changes in the local stiffness due to flaws is called mechanical impedance analysis (MIA), which has been shown to be very effective at finding delaminations in composites (Ref 85). With MIA, a transducer contains a piezo-electric element subjected to an alternating current. The element causes the probe to physically vibrate at a low—and often audible—frequency. When the probe is placed on a structure, it vibrates the local area in a characteristic fashion, depending on the local mechanical impedance. The presence of a disbond below the probe will change the impedance of the structure, which will be measured by a second piezo- electric element in the probe. A popular instrument incorporating the MIA technique is the Staveley BondMaster (Staveley Instruments).

Velocimetric Methods. A family of test instruments exists that takes advantage of the flexure wave generated when an oscillating force is applied to a platelike structure. The speed of propagation and amplitude of these waves will depend upon the thickness and materials properties of the structure. Changes in the speed and

amplitude can be monitored over a short distance by the use of low-frequency transducers. A typical probe will have a sending and receiving transducer set at a fixed distance (approximately 13 to 19 mm, or 0.5 to 0.75 in.) apart. Several examples of velocimetric instruments are the Zetec Sondicator (Zetec Inc.) and the Staveley BondMaster, when operated in its pitch-catch mode.

Higher-Frequency Bond Testers. A variety of bond testers operate in the range of 100 kHz to about 1 MHz. These operating frequencies are below typical ultrasonics, but above the low-frequency methods. They have a vibrating transducer that operates at one frequency or over a small range of frequencies near the natural resonance of the part. When the transducer is touching the part, its vibration characteristics are determined by the local impedance of the part. Local flaws or changes in the structure will change the resonance of the transducer. The Fokker Bond Testers, which have been used for bond inspection for many years, operate on these principles (Ref 86). They work by forcing the bonded structure to resonate. Disbonds within a joint or delaminations in a laminate will cause a shift in the resonant frequency and/or amplitude, which can then be detected and displayed.

The Bondascope is another well-known bond tester. Manufactured by NDT Instruments, it measures the amplitude and phase of the local mechanical impedance and displays the result on an oscilloscope (Ref 87).

Acoustic Emission

Acoustic emission is the transient release of elastic waves when materials undergo deformation. In composite materials, the sources of these emissions include matrix cracking, delamination, and fiber breakage. Acoustic emission can be a very sensitive measure, responding to microstructural variations, and has received significant attention as a technique for monitoring damage development in composites (Ref 88, 89). Acoustic emission is most often applied during structural testing, but can be used in process control and in-service monitoring.

The stress waves, created by the acoustic emission of a sample under a load, travel along a sample and can be detected by piezo-electric crystals placed on the sample. The signals must be of short duration and sufficient energy. Acoustic emission from fiber breakage in composites is actually quite loud and is often heard audibly. Research indicates that there are three distinct energy-level groupings that indicate the different amounts of energy emitted from fiber breakage, matrix cracking, and delamination (Ref 90). By using multiple sensors and time- based triangulation methods, the location of the emission in the sample can be determined. An important

phenomenon in acoustic emission in the Kaiser effect. When a sample is loaded, it will generate acoustic emission signals as internal breakage occurs. If the loading is stopped and released, the acoustic emission signal will go to zero. As the sample is reloaded, acoustic emission signals will not occur until the level of load exceeds the previous highest loading level.

As the signals are detected from acoustic emission tests, the amplitude data may be recorded as counts above a threshold energy, level in the detector. Measurements of interest include the count rate, the total counts, the total energy, and the ring-down of the counts from a loading step. The data are most often plotted against the load level on the test sample. Acoustic emission has been shown to be useful to predict failure loads for composite pressure vessels (Ref 91).

Eddy Current

Although eddy current testing (ET) is a common means of flaw inspection in metals, it can also be used in composites to find flaws or damage (Ref 92, 93, and 94), as long as the composite contains electrically conductive materials, such as graphite fibers. Eddy current testing can also be used to determine the thickness of nonconductive coatings and the local conductivity of conductive coatings, both of which are often applied to composites.

The physics of ET are based upon well-known electromagnetic theory, as defined by Maxwell's equations (Ref 95). A wire containing a time- varying electrical current (i.e., alternating or pulsed current) produces a corresponding magnetic field variation that will induce electrical currents in any conductive material in close proximity to it. These currents, called "eddy" currents, are sensitive to the local electrical conductivity of the material in which they are generated. Perturbation of these eddy current paths due to flaws can be detected by an impedance change in the coil (the exciting coil, or a separate nearby pick-up coil) and measured by standard electrical bridge circuit in line with the coil.

The ET skin-depth equation describes the depth of penetration of eddy currents in an isotropic material:

$$\delta = 1/(\pi f \mu \sigma)^{1/2} \quad \text{(Eq 18)}$$

where δ is skin-depth, f is frequency of inducing current in the ET probe, μ is magnetic permeability, and σ is electrical conductivity of the material being measured.

This equation shows that lower frequencies penetrate further. However, lower frequencies lose sensitivity to flaws, because the signal is essentially being averaged over a larger volume. It also shows that eddy currents will penetrate composites well, because polymer composites are much lower in conductivity than metals.

However, this equation is an approximation, because composites are not isotropically conductive. The fibers (rather than the matrix) are generally the conductors within composites. Often these fibers are continuous with the composite layers (plies) as the elements of unidirectional tape laid up in various orientations or as bundles of fibers woven together into a fabric form. In either case, the fibers are generally parallel to the surface of the structure to be inspected. Therefore, the composite will have a relatively high conductivity in the planes parallel to the surface, and low conductivity normal to the plies. This produces a tight, deep region of eddy current penetration in composites, which can sometimes be advantageous. However, it also means that the eddy currents will tend to run parallel to the plies (and surface) regardless of the ET coil orientation. This means that ET will be relatively insensitive to planar flaws, because the eddy current paths are altered little. Eddy current testing does not work well for identifying small delaminations or common composite foreign objects (such as composite bagging materials, tape, or misplaced adhesive), unless they produce significant local alteration of the ply orientations. It is also insensitive to porosity and matrix cracking, because both occur in the (ordinarily) nonconductive matrix. However, ET is very effective in finding cracks produced by fiber breakage and ply wrinkles (Ref 96) in composites. It has been shown to be particularly effective at detecting composite damage caused by low-energy impacts (Ref 97). Because cracks and wrinkles can be very difficult to find using other common nondestructive inspection methods, such as ultrasonic or radiographic techniques, ET of composites enjoys a small, but growing composites inspection market.

Eddy current systems are portable, easy to operate, and relatively inexpensive. Most provide an alternating, continuous current to the excitation coil, but some produce a pulsed signal that can produce greater penetration (which is not generally needed in most composite structures). The probe that is used to interrogate the part can contain the excitation coil that also senses the impedance changes. A separate pick-up coil is also common and can be located within the probe head, adjacent to the first probe, or on the opposite surface. Coils come in various shapes and size, and are manufactured to function at various frequencies. Generally, composite flaw inspection is done at frequencies between 100 kHz and about 30 MHz. The lower frequencies work best for carbon-carbon composites, which are highly conductive (but still orders of magnitude less conductive than metals), while the less-conductive graphite/epoxy composites are generally best suited to the mid-to-high end of the range. The electrical impedance changes sensed by the coil and accompanying bridge circuit are generally displayed on an oscilloscope as amplitude and phase or electrical resistance and reactance components. If the probe is attached to an x-y bridge, maps of the inspected area can be developed, which facilitate interpretation (Ref 98). Experimentation with the probes, drive frequencies, and standards with known flaws is necessary to determine the effects on the received signal.

Like other inspection methodologies, flaw identification must be based on calibration standards, and care must be taken to eliminate or account for other sources of signal change. Eddy currents are sensitive to nonrelevant parameters, such as minor dimensional changes, surface roughness, lift-off (probe-to-part distance), and proximity to real part features (edges, flanges, fastener holes, etc.). Signal changes due to flaws can often be separated from those produced by these features using phase or frequency adjustments provided by the ET hardware.

A special application for ET in composites is the measurement of conductive coatings thickness or conductivity. If the thickness can be determined using another method (such as pulse- echo UT), the conductivity can be measured. If the conductivity is constant within the coating, the thickness can be measured with a calibration block. Eddy current testing coating inspection requires sufficient conductivity difference between the coating and composite substrate. When a laminate is covered with a conductive coating, the composite itself will have to be evaluated with another method.

Nondestructive Testing

ASM International Committee on Nondestructive Testing of Composites

---

Optical Holography and Shearography

Optical holography is a technique that uses coherent light to generate interference patterns of the surface that change under small amounts of stress (Ref 99). By using a laser light, dual- exposure holograms are acquired before and after stressing the part. The interference patterns recorded can measure very small surface displacements, due to internal flaws. The stress is applied through heating, acoustic vibration, or service-type loads. With composites, this method is used to detect disbonds and delaminations. Its disadvantages are that it is less sensitive than ultrasonics, and the holographic apparatus must be isolated from vibration.

Laser shearography is a more recent variation of optical holography that monitors differential motion (Ref 100). As with optical holography, the part must be placed under stress. The constructive and destructive optical interference of the incident laser forms a speckle pattern on the stressed surface. The image is viewed by a video camera through an optical shearing device. When two sets of sheared images are compared electronically, surface changes are detected based upon the change in the speckle patterns. The output takes the form of an image-processed video display of the contour of the derivative of the displacement—a fringe pattern. This technique can be used to locate and size defects, such as disbonds or delaminations. Shearography is much less sensitive to vibrations than optical holography, making it much more portable and useful for field applications. Shearography can be used in the field with a vacuum chamber that has an open end, which seals to the skin of the structure under inspection. As a vacuum is pulled in the chamber, a measurable strain is produced that can be imaged.

Because they are mechanical-strain based, these methods work best with thinner composites, where internal flaws are close enough to the surface to be detected. Detectability and resolution decrease with defect depth, and a critical aspect ratio (flaw size-to-flaw depth) determines detectability. They are also blind to defects open to the surface when the surrounding-vacuum stressing method is used, and they have trouble finding bonded foreign material and contaminated bonds, because insufficient surface displacement occurs. On the other hand, these methods can be used to evaluate very large areas very quickly and are much faster than other inspection methods. In addition, they can be used to detect defects in large honeycomb structures that ultrasonic methods are incapable of penetrating. Shearography is regularly used to find impact damage in sandwich structures (Ref 101) and delaminations between plies in laminated composites (Ref 102).

Data Fusion

Data fusion can be applied to composite materials to improve data reduction and analysis for NDE. (Ref 103, 104, 105, 106, 107, 108, and 109). The term "data fusion" in the NDE context refers to the process of integrating data from diverse process measurements and nondestructive observations of an object into a consistent description of the condition of the object (Ref 104). The objective of data-fusion methods is to coregister, colocate, and combine multiple data sets into useful forms. Combining carefully selected "modes" or alternative views of process and NDE data leads to reduced ambiguity by overcoming limitations of some inspection methods through the visualization of complementary information. Combining data from different process steps and NDE tests requires systematic engineering methodologies that are often outside the norms of conventional (i.e., single-mode) data analysis. In particular, precise cross-registration techniques and techniques for normalizing, cross-calibrating, and resampling are necessary. Of these, systematic registration of data with respect to the evaluated part is the fundamental requirement.

Data-fusion processing draws on technology in signal processing often used in target recognition or other processes. Statistical and probabilistic algorithms are used to reduce multimodal data for prediction of the material condition. Bayesian methods and Dempster-Shafer evidence theory are examples of methods that are being used for data fusion (Ref 105, 106). Figure 40 shows the levels of data fusion. Once registration of data is obtained, various mathematical algorithms can be applied to the data.

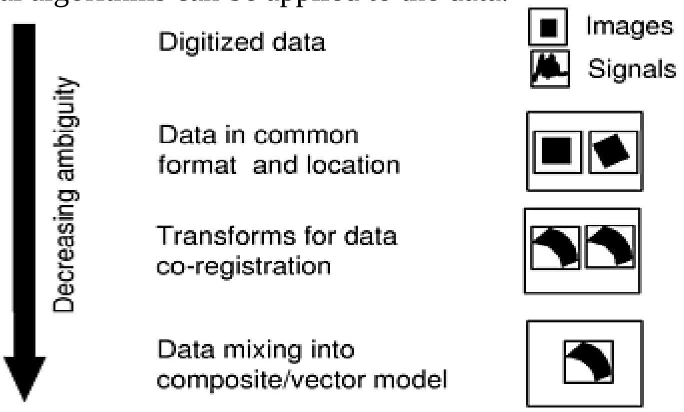

Fig. 40 Levels of data fusion

Managing the data from diverse measurements that may use differing frames of reference can be a formidable problem. An approach for the data handling that has been very successful replaces the familiar "image" data model with an "object" or finite-element data model (Ref 105). In the object model, not only the value of data is described, but also its geometry. Essentially, the data acquired from process monitoring or NDE operations are expressed in a part-fixed coordinate system, using techniques commonly used in finite-element analysis. Features of interest can be calculated by appropriate combinations of inputs from the various sources, which are transformable in a common coordinate system. The results can be mapped back onto any of the original test system representations or presented in standard computer graphics, visualization, or database representations.

Figure 41 demonstrates the registration of NDE data on a solid rocket motor nozzle. This figure shows that the visualization of ultrasonic, computed tomography, and eddy current test data can be presented together in part-fixed coordinates. The rocket nozzle exit cone shape is shown as a surface with features from each methodology displayed over the critical (i.e., highly stressed) forward region of the nozzle exit cone. The quantitative parameters evaluated here are eddy current impedance, minimum CT density through the wall, CT density averaged through the wall, and ultrasonic amplitude.

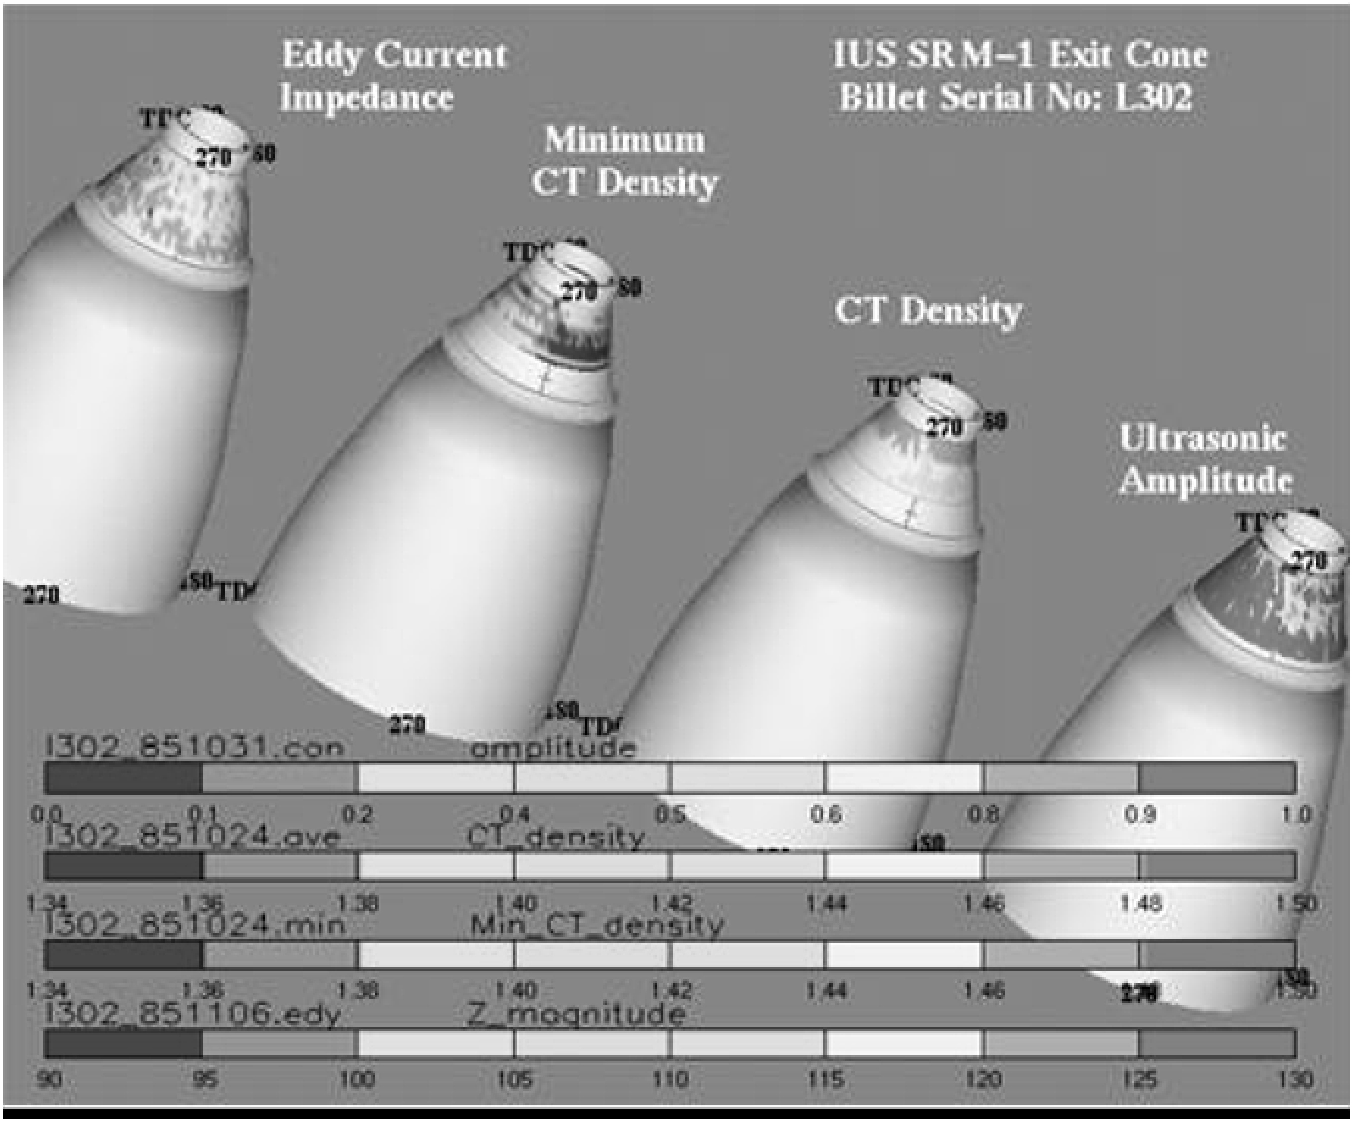

Fig. 41 Nondestructive evaluation multimode data fusion for a carbon-carbon rocket nozzle exit cone

The importance of the multimodal data in the evaluation of a carbon-carbon composite rocket nozzle is shown in Fig. 42. Each inspection modality (e.g., CT or UT) can indicate the presence of an anomaly without necessarily distinguishing the material defect. For example, CT images of a dry ply and a delamination on two different parts are essentially indistinguishable. Conversely, different NDE modalities may respond to an anomaly in differing degrees. Low-density CT indications can be due to wrinkling, dry-ply conditions, or delaminations. The dry ply condition can have sufficient across-ply tensile and interlaminar shear strengths to

support the mission loading. A delamination, however, could result in mission failure if misdiagnosed as a dry ply. Only by considering complementary features of the ultrasonic data and the CT data can the two conditions be distinguished. In Fig. 41, the eddy current scan allows a correct interpretation of an otherwise benign low-density indication in the CT scan as a wrinkle whose presence would almost certainly lead to flight failure.

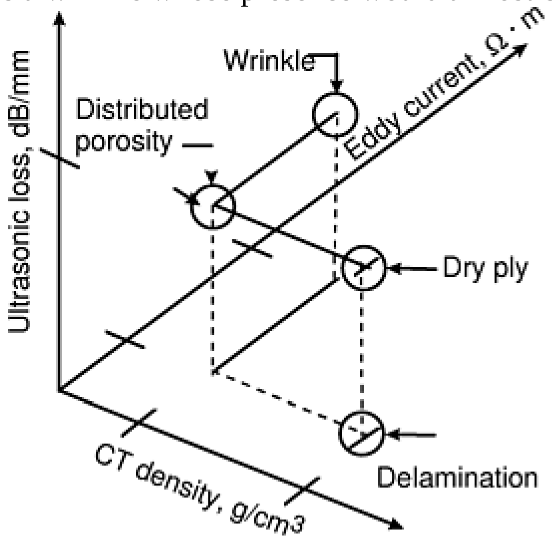

Fig. 42 Nondestructive evaluation parameter representations of anomalies

Another example of data fusion for a complex process is the integration of process monitor data and NDE measurements for thermoplastic induction welding. Time, temperature, and pressure are the critical parameters that must be sufficient for welding but not overprocessed enough to cause voiding. During welding, thermocouples are used to monitor the time and temperature at specific locations in the weld zone and may be adjusted by the induction coil controls. The time at temperature for the weld interfaces has been determined to be the most important measurement for the process control. The pressure to the tooling is a fixed value assigned for specific welding conditions. The temperature data is obtained from thermocouples placed at various locations along the weld. The equivalent time (in minutes) to a process target temperature is calculated for each thermocouple and is plotted as a function of position along the weld.

Ultrasonic inspection of the weldline is performed using PE ultrasonics with a full waveform digitizing scanning system. This full waveform data is processed to compare signal strengths from the weldline and the back of the spar cap to similar data taken from the skin surface. Figure 43 is an illustration of combining test data from both the final ultrasonic inspection and the processing time at temperature, as described subsequently. This data-fusion workstation display shows the geometric configuration of a welded skin to a T-spar. The geometry data includes chalkmarks for position information. The data-fusion workstation display in this case shows a three-dimensional view of the weld. The time at temperature data are shown at the top of the Fig. 43 image display by colored squares at the position of thermocouples in the test object. The depth locations in the object are very close, but can be shown by manipulation of the image display and also by the use of increasing square size with depth. The ultrasonic models shown in the lower portion of Fig. 43 are processed image data that are overlaid onto the geometry model of the weld. The bottom model is the ratio of the weldline echo to the front-face surface echo. Low intensity (dark) level is the most desirable. The middle model is a “weld factor” calculation, which is a point-by-point calculation of the ratio of the difference of the back of the spar cap signal and the weldline signal to the sum of the back of the spar cap signal and the weldline signal. This value is positive for a good weld and negative for a poor weld, although, because there is no back of the spar cap signal over the web of the T-spar, the weld factor along this longitudinal region is not a valid representation. This weld factor model is processed data, which essentially fuses ultrasonic amplitude data information from different depths in the part.

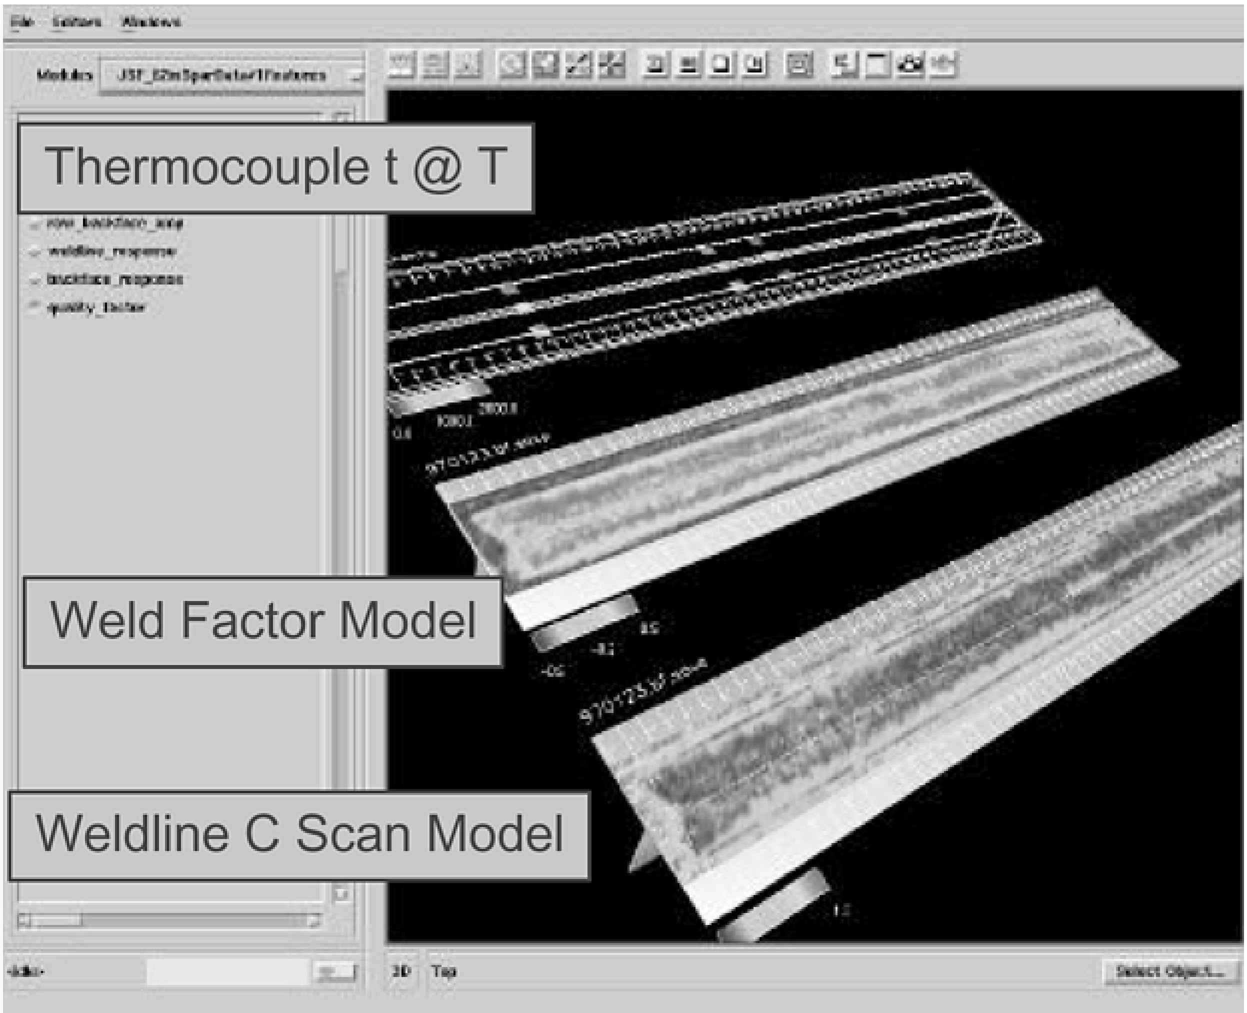

Fig. 43 Induction welding data fusion models of process data and NDE measurements

The data-fusion approach can be used to provide visualization of multimode NDE data and process information. The fundamental requirement for NDE data fusion is the coregistration of data obtained from various techniques or at different times and locations in part-fixed coordinates. This allows mapping the data to a geometry model of the part and allowing that data to be reviewed in a single workspace. Mathematical processes can then be performed to combine data types for evaluation purposes, such as estimation of feature size and criticality.

Nondestructive Testing

ASM International Committee on Nondestructive Testing of Composites

Standards

The internal structural quality of every composite detail, subassembly, and assembly must meet baseline quality criteria that design engineering establishes to ensure that the fabricated composite configuration meets the performance requirements. Internal quality that does not meet design performance requirements may result in failures at various stages of manufacture and life cycle. Nondestructive evaluation, inspection, and testing are used to determine the internal quality of composite configurations. Ultrasonic and radiographic methods are most commonly used to make this determination in composite materials. Technicians are certified to the specific customer requirements and most likely to the requirements of the American Society for Nondestructive Testing level II certification. The technician, using validated reference standards that contain known representative induced anomalies, calibrates equipment. Calibration ensures that the equipment is capable of detecting unacceptable conditions defined by the customer requirements. The technician then reviews and evaluates the results provided by the nondestructive method used to inspect/test the composite configuration and assesses the internal quality of the composite configuration. Ultrasonic and radiographic reference standards are critical quality tools of the composite manufacturing process. Without these tools the inspector would be unable to accurately evaluate the internal quality of the part. Composite configuration and engineering acceptance requirements are used to develop reference standards.

Reference standards can be fabricated in the environmental-controlled areas where normal composite lamination and bonding processes are performed. However, specific methods of inducing or creating known anomalies may require special areas to perform the required operation. Examples would be grinding of metallic and nonmetallic materials, milling of notches, or spraying of specific release agents. No special equipment is normally required to support the fabrication of composite ultrasonic or radiographic reference standards.

Ultrasonic Standards. The basic purpose of the ultrasonic reference standard is to provide the nondestructive inspection/test technician the capability to calibrate ultrasonic detection equipment to known anomalies. Once the selected system has been calibrated, the composite component can be evaluated to determine the internal quality. This determination is made by comparing the values obtained from the component being evaluated with those obtained from the "validated" reference standard. Customer requirements provide the amount of deviation allowed from the reference standard to the actual part values. The reference standard provides the operator with the capability to characterize the detected anomaly by the location, depth, size, and type. This information is then used to evaluate the component for acceptance and rejection.

Ultrasonic reference standards must be designed with as much versatility as possible. The reason is that composite configurations sometimes vary during the manufacturing process. If this occurs, the material thickness may change, bond lines become thicker or thinner, or the void content (porosity) may increase. Therefore, when designing an ultrasonic reference standard, one must ensure that the critical verification points are included in the basic design. Once standards are fabricated, they can sometimes be modified to represent missed or new conditions. Reference standard design, manufacture, and verification information should be accurately documented using written and graphic medium.

Typical methods of fabrication for cured composite laminate reference standards include, but are not limited to, milling flat-bottom holes or notches from the opposite side of the laminate and side-drilled holes into the side of

a cure laminate. A typical laminate reference standard configuration containing typical induced defects is shown in Fig. 44. Precure methods of inducing laminate-type defects present a risk factor and should be created by personnel with extensive fabrication experience to ensure success. Duplicate standards are recommended when building precured laminate or adhesive bondline-type standards so that one can be destructively evaluated after verification to ensure that the defect is as intended. The process of inducing material to create between-ply laminate or bondline anomalies requires placing a "foreign" material between two plies or at adhesive bondline. The following materials have been used effectively for this purpose: synthetic fluorine-containing resin-coated fiberglass (0.075 mm, or 0.003 in.), synthetic fluorine-containing resin film, metallic shim stock (copper or stainless steel, 0.25 mm, or 0.010 in.), or precured, single-ply, extremely high-fiber content composite material. When using inserts, the adjacent ply should be cut out to minimize the bump due to inclusion of the induced defect. Metal shim stock works well, if the shim surface is prepared with a release agent.

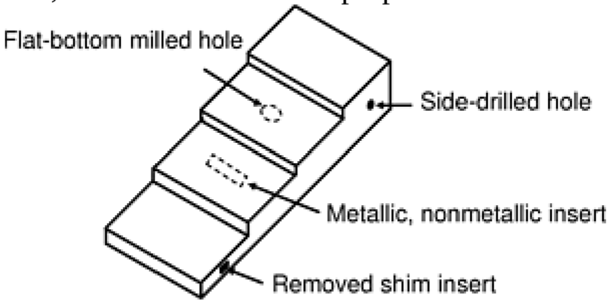

Fig. 44 Typical laminate reference standard configuration containing typical induced defects. Standard configuration should represent the configuration being evaluated and induced defects positioned in accordance with the NDT engineer's direction

The design of the reference standard must consider the ultrasonic evaluation method. The primary methods used in industry are PE and TT. Pulse-echo standards are used to perform defect characterizations, such as depth, size, and defect type (i.e., delamination, porosity, unbonds, etc.). Through-transmission standards are not normally designed to determine location. They are designed to identify areas that are later reevaluated using contact PE methods to characterize the defect in accordance with accept/reject criterion. Pulse-echo standards can be fabricated using several of the defect-induction methods mentioned previously. Care needs to be taken when developing PE induced defects. The induced defect must be representative of the defect induced during the manufacturing process. If induced defects are not representative of manufacturing defects, the chance of defects being accepted or good parts being rejected increases. Design and fabrication processes need to take into consideration the need to remove metallic and nonmetallic inserts used to create voids. This choice is normally made by the NDT engineer who has the ultimate responsibility of determining the reference standard design to meet evaluation requirements. Nondestructive testing standard design should be a part of the initial design phase process to ensure inspectability during fabrication and at completion of the product.

Validation of reference standards is a choice normally made by the customer and contractor. The standards should be scanned and the results documented. Signal response and location of each induced and noninduced anomaly must be documented for production inspection/test use of the standard. Confirmation of defect size and location by other methods, such as radiography, should also be considered. Customer specifications or government specifications provide the minimum requirements for signal response. Photographs are an excellent mode of documentation for both initial and destructive evaluations.

Radiographic reference standards are used to evaluate the internal quality of composite components that contain typical anomalies (porosity, cracks, adhesive voids, etc.) and "other" materials, such as honeycomb, metallic components, foam details, foreign material, and water inclusion. Typically, standards are not developed for foreign material, such as Exacto blades, washers, nuts, bolts, and other common items in the fabrication area that are readily recognizable when mistakenly included in a part. Radiographic reference standards are typically designed for various levels of porosity, cracks, nonmetallic inclusions, and honeycomb core defects (crushed, condensed, blown, cut, etc.). The radiographic standard is not used to calibrate the x-ray system. These reference standards are used as a post-process comparison to evaluate radiographic images from the composite component and to determine the internal quality. These standards provide the evaluator with a traceable record by which quality decisions can be made and supported. Reference standards are required to provide a uniform evaluation guideline from technician to technician.

Normally, radiographic reference standards are provided by specific sources and customers. Composite laminates typically exhibit porous conditions that are evaluated by comparison- type radiographs. The production radiograph is compared to the reference radiograph to determine the internal quality of the laminate and to determine acceptance. Radiographic standards are also used to evaluate the internal quality of adhesive (film and paste) bondlines for voids, porosity, and inclusions. Foreign material standards containing materials common to the composites fabrication process are normally developed by the manufacturer.

Porosity reference standards are difficult to fabricate repetitively. The major problem is controlling the amount of porosity. These standards can be used for radiographic as well as ultrasonic evaluation.

Composite radiographic reference standards are used to evaluate the internal quality of laminates, encapsulated metallic and nonmetallic details (honeycomb core, phenolic core, machine details, and others), adhesive bondlines, and co- cured composite details. Typical honeycomb core defects include condensed core, blown core, node separation, cut core, and crushed core. Other defects characterized by radiographic reference standards include various types of foreign material, bond-line porosity, and laminate porosity. These defects are positioned in accordance with the NDT engineer's direction. Figure 45 shows typical radiographic reference standard configurations.

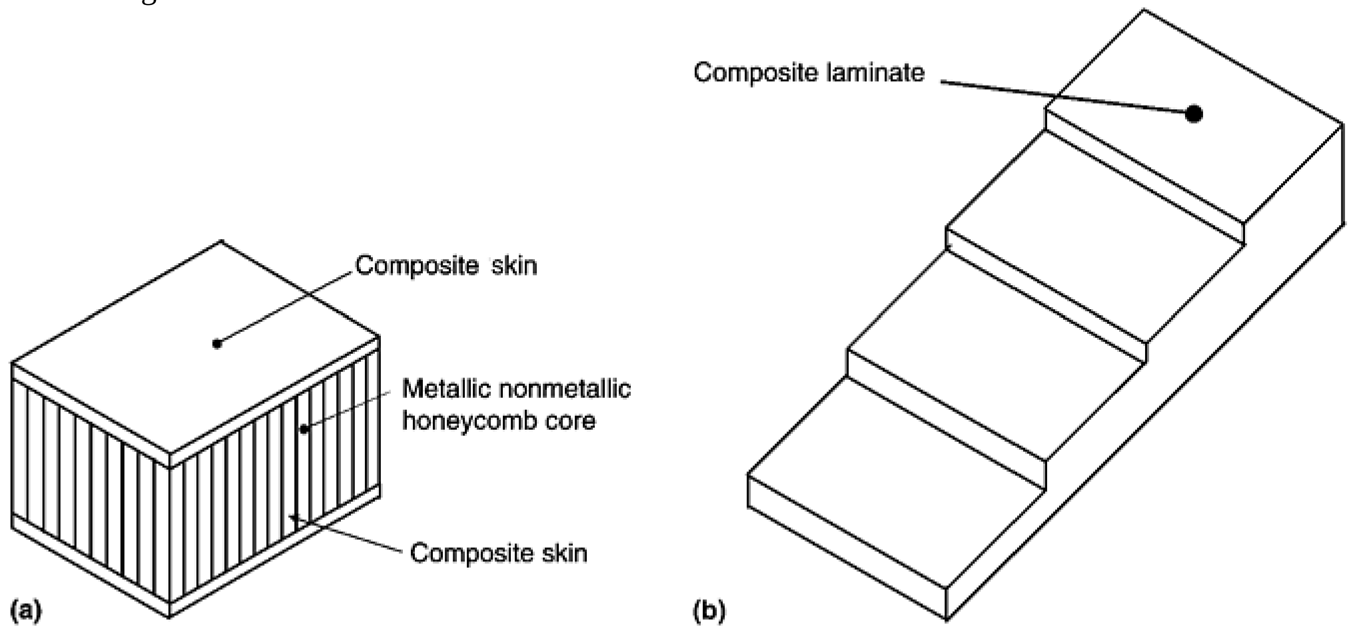

Fig. 45 Typical radiographic reference standard configurations. (a) Laminate skin honeycomb core sandwich configuration. This configuration also may be used in ultrasonic evaluation. (b) Laminate stepped wedge configuration

Nondestructive testing reference standards are fabricated in many configurations to support the verification needs of the customer. The aforementioned examples provide a basic look at those configurations. The NDT and design engineers must coordinate as early as possible in the design phase to ensure that the design is inspectable using identified NDE methods. The documentation of reference standards is critical to the inspection process. Begin this process during the design phase and continue updating as the standard is periodically reevaluated. All NDT standards should be reevaluated periodically to ensure that they continue to provide the correlation established when the standard was approved for use. Standards that do not maintain this correlation must be documented and the area(s) of failure controlled to prevent use. This information should be part of the quality plan.

Quality Assurance of Metal-Matrix Composites

William C. Harrigan, Jr., MMC Engineering, Inc.

Introduction

QUALITY ASSURANCE of metal-matrix composites (MMCs) is similar to that of polymer-matrix composites (PMCs) in that the matrix and reinforcements need to be inspected and characterized prior to the manufacture of the composite, and the completed composite must also be inspected and characterized (see preceding articles in this Section for detailed information on quality assurance methods used for PMCs). Also, many of the techniques (and the exisiting infrastructure) used to assure the quality of monolithic-matrix alloys (e.g., aluminum alloys) can be used for particle-reinforced MMCs. This article describes characterization techniques, mechanical tests, and nondestructive evaluation methods commonly used for MMCs.

William C. Harrigan, Jr., MMC Engineering, Inc.

Characterization Techniques

For particle-reinforced aluminum composites, the reinforcements are characterized for chemical composition and particle size distribution. The matrix alloys are analyzed to ensure they are appropriate for the alloy and incoming form. Casting alloys are analyzed as ingots by spectrochemical techniques (Ref 1). Powder metallurgy alloys are characterized for particle size distribution and chemically analyzed by spectrographic methods for the melt or by inductively coupled plasma (ICP) methods (Ref 2) for the powder.

Composites manufactured from these components must also be chemically analyzed by appropriate methods. Composites containing silicon carbide cannot be analyzed by spectrographic methods due to the silicon signal coming from the reinforcement. The most reliable method is the ICP method. Since the ICP method involves dissolving the sample, a volume fraction analysis can be conducted on the same sample (Ref 3). The chemistry of the alloys and the microstructure of the resulting part control, to a large extent, the mechanical and physical properties of these alloys. The addition of the fine ceramic particles to the matrix alloy results in the maintenance of a fine microstructure. The ceramic particles act as grain nucleation sites for castings and as grain boundary pins in wrought alloys.

Ceramic particle reinforcements are single- crystal or polycrystalline particles that have well-defined physical and mechanical properties. The performance of the particles in the matrix is dictated by the particle shape and size distribution. Several methods are used for measuring the size distributions for particles in the 1 to 100 μm size range. Several of the common methods for particle size analysis are listed in Table 1 (Ref 4).

Table 1 Typical methods of particle size and size distribution measurement

Measuring principle	**Method**	Approximate useful size range, μm
Mechanical or ultrasonic agitation	Sieving	**5–125 mm**
Microscopy	Optical	**0.5–100**
	Electron	**0.001–50**
Electrical	Coulter counter	**0.5–800**
resistivity	Electrozone	**0.1–2000**
Sedimentation	Sedigraph	**0.1–100**
	Roller air analyzer	**5–40**
	Micromerograph	**2–300**
Light scattering	Microtrac	**2–100**
Light obscuration	HIAC particle counter (Pacific Scientific Instruments)	**1–9000**
Permeability	Fisher subsieve sizer	**0.2–50**
Surface area	**Gas adsorption (BET)**	**0.01–20**

BET, Brunauer-Emmett-Teller.

Source: Ref 4

One method uses a laser to pass a light beam through a suspension of particles. Dispersing the particles in a liquid, such as water, produces a suspension. The analysis is conducted by passing the light beam through the suspension. An alternate method is to disperse the particles in air and pass the suspension through the laser beam. The diffraction pattern that is produced by the interaction of the laser beam with the suspension is analyzed to determine the size distribution of the particles in the suspension. This analysis method produces a measure of the actual size of the particles. Other methods, such as the Coulter counter, using electrical resistivity, present data for a calculated diameter for a spherical particle with the same volume that was detected by the instrument. For spherical or near-spherical particles, these two analysis methods result in similar particle

size distributions. However, for irregular particles, these two methods differ in the size that they present. For an irregular particle with dimensions 2.5 by 1 by 2 μm, the laser scattering device will report a particle size of 2.5 μm while an electrical resistivity device will report a particle size of 2.12 μm. A plot of the spherical equivalent diameter for particles with fixed dimensional relationships of 2.5 to 2 to 1 is shown in Fig. 1. In applications where an absolute maximum size, such as 30 μm, is needed, a laser measurement will result in a particle size of 30 μm while a spherical equivalent device will measure only 25.5 μm. For some applications, these differences are very important, and one must understand the values presented by a given analysis technique.

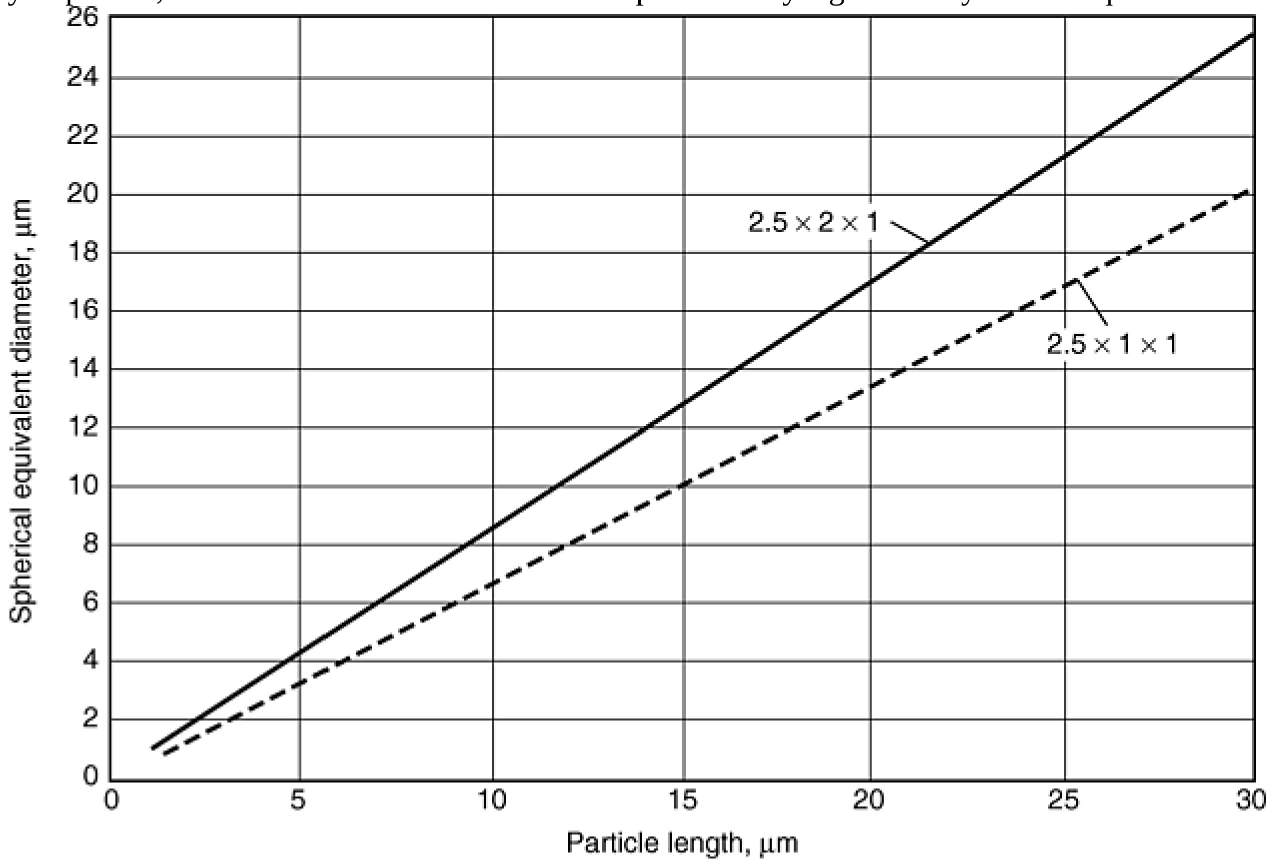

Fig. 1 Plot of spherical equivalent diameter as a function of maximum particle dimension for an irregular particle with relative dimensions of 2.5 to 2 to 1

Commercially available silicon carbide, alumina, and boron carbide powders are measured by techniques defined in the British Abrasive Federation standard FEPA 42-GB-1984 (Ref 5). Typical particle size distributions for silicon carbide powders classified as F400, F600, and F800 are shown in Fig. 2. These powders will be blended with aluminum alloy powders to create a metal-matrix composite. The size of the ceramic reinforcement must be compatible with that of the matrix in order for mixing to occur. The particle size distribution for a commercially available 6061 aluminum powder is also shown in Fig. 2. These powders have compatible size distributions and are typically used for production of aluminum-matrix composites. Submicron-sized ceramic particles have presented problems in blending with commercial matrix powders.

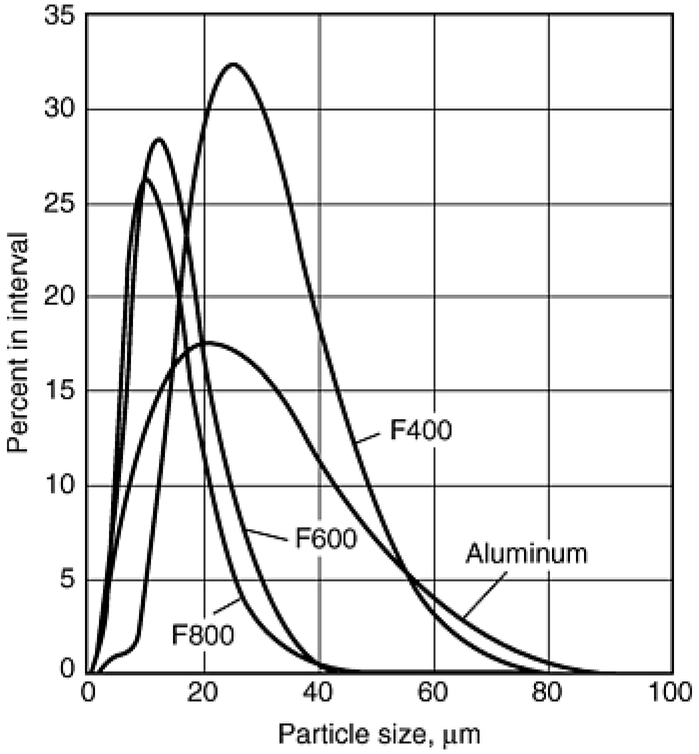

Fig. 2 Particle size distribution for F400-, F600-, and F800-grit silicon carbide particles and commercial 6061 aluminum powder

The appropriate size of ceramic particles for composites made by molten processing is influenced by several factors. Silicon carbide can react with molten aluminum to form aluminum carbide and free silicon. Aluminum carbide is a very brittle phase that renders the composite unusable. In order to reduce the chances for the formation of this undesirable phase, particles with a minimum surface area are desirable. This leads to the use of larger particles. The strain-to- failure and strength of the composite has been found to be a function of the particle size. Each reinforcement has a critical particle size above which the probability of having a critical flaw increases markedly. For commercial silicon carbide and alumina particles, this size is approximately 20 μm. Composites made with reinforcements above the critical size tend to have low strain-to-failure and low strength. This limits the maximum size for the manufacture of structural aluminum-matrix composites. For cast composites it is important to know the relationships between strength, strain-at-failure, and reactivity as a function of particle size. It is also important to monitor the microstructure of these composites during processing in order to avoid or control reactions. The metallographic practices for these composites require standard practice (Ref 6), with care taken to polish the mount in a manner appropriate for a soft metal with hard particles in it.

Additional information about particle characterization techniques can be found in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook.* More information about characterization techniques, in general, for a broad range of materials is available in *Materials Characterization,* Volume 10 of *ASM Handbook.*

Quality Assurance of Metal-Matrix Composites

William C. Harrigan, Jr., MMC Engineering, Inc.

Mechanical Testing

Mechanical testing of wrought or cast composites can be done using appropriate metallic material test procedures. A list of relevant tests and associated standards is given in Table 2. Tensile testing is done with reduced-section specimens as defined in ASTM B 557 (Ref 8). The machining of samples should be done with diamond tools. The use of carbide or coated steel tools has been unsuccessful since these tools are dulled by the ceramic particles in the composite. Dull or worn tools result in torn surfaces or surfaces with highly disturbed metal. These surfaces result in widely variable mechanical properties. The same comments are appropriate for fatigue samples. A good example of consistent fatigue test results is the R = -1 tests (where R is the ratio of minimum stress to maximum stress) done on a 6090/SiC/25p composite by DWA Aluminum Composites Inc. in an Air Force Title III test program. Samples for this study were not hourglass shape, but had a constant gage section diameter of 5.1 mm (0.20 in.) diameter and were 25 mm (1 in.) long. The samples were accurately machined with diamond tools and tested at two laboratories, Northrop Aviation and Lockheed Aeronautical Systems. The data from this study are presented in Fig. 3. The uniformity of these data from two laboratories demonstrates the value of careful machining to ensure reproducible data.

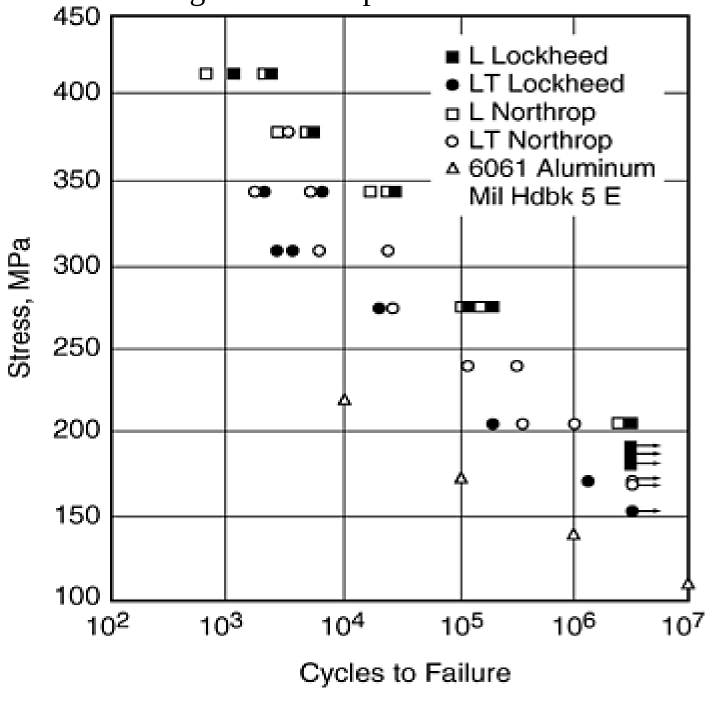

Fig. 3 Fully reversed (*R*=-1) fatigue test data for 6090/ SiC/25p-T6P composite

Table 2 Mechanical test specifications for aluminum-matrix composites

Property	**Specification**	**Sample**	Special considerations
Tensile strength	ASTM E 8 (Ref 7), ASTM B 557 (Ref 8)	Reduced section, round or rectangle	**Similar to aluminum**
Elastic modulus	ASTM E 111 (Ref 9)	Reduced section, round or rectangle	**Similar to aluminum**
	Ultrasonic velocity	Round or rectangular section	**Similar to aluminum**
Compression strength	ASTM E 9 (Ref 10)	Rectangle or cylindrical, constant section	**Similar to aluminum**
Fracture toughness	ASTM E 399 (Ref 11)	Compact tension	**Precrack difficult due to non-straight crack front**
	ASTM E 1304 (Ref 12)	Subsize samples	**Valid due to low ratio of plane-strain fracture toughness to yield strength**
Fatigue	ASTM E 466 (Ref 13)	Hourglass, reduced section	**Polish test section with scratches in test direction**
Shear	ASTM B 769 (Ref 14)	Rectangular sheet samples	**Similar to aluminum**
Pin bearing	**ASTM E 238 (Ref 15)**	**Sheet with high-quality drilled holes**	**Hole quality must meet specification, pin strength must be high enough for composite**

The elastic modulus is an important attribute of these composites. The measurement of the modulus can be achieved by methods described in ASTM E 111 (Ref 9). Ultrasonic velocity measurements and resonant frequency measurements have also been used to determine the elastic modulus. By using appropriate ultrasonic transducers, the longitudinal and shear sound velocities can be measured. The Young's modulus and shear modulus can be calculated from the relationship:

$$E = 4\rho V_S^2 \left[\frac{3/4 - (V_S / V_L)^2}{1 - (V_S / V_L)^2} \right]$$

$$\gamma = \rho V_S^2$$

where E is Young's modulus, γ is shear modulus, V_L is longitudinal sound velocity, V_S is shear wave sound velocity, and ρ is density.

Quality Assurance of Metal-Matrix Composites

William C. Harrigan, Jr., MMC Engineering, Inc.

Nondestructive Evaluation

Nondestructive assessment methods that have been successfully applied to particulate-reinforced aluminum composites are listed in Table 3. Ultrasonic techniques have been very successful in assessing the blending quality present in these composites. A paper by Shannon et al. (Ref 22) describes the ultrasonic inspection of large (349 mm, or 13.7 in. diam) billets containing 25 vol% silicon carbide in a 6000 series aluminum alloy. A through-diameter edge scan is shown in Fig. 4, and a through-thickness axial scan is shown in Fig. 5. The billet volume containing several of the indications found in this inspection were removed from the billet for microstructural examination. A small indication located at point “G” in Fig. 5 was one of the cut sections. A low-magnification optical micrograph from this area, Fig. 6, shows a localized high volume fraction of silicon carbide. A higher-magnification scanning electron micrograph, Fig. 7, demonstrates that this region contains silicon carbide particles with little or no matrix aluminum. The size of this matrix-starved region is on the order of 30 μm. This demonstrates that the ultrasonic test method is capable of detecting very small regions of poor blending.

Fig. 7 Scanning electron micrograph of section "A" of Fig. 6 showing a small area of matrix-free silicon carbide particles

Table 3 Quality assurance techniques for aluminum-matrix composites

Type	**Test methods**	Comments
Ultrasonic	C-scan and velocity, ASTM E 1001 (Ref 16), ASTM E 127 (Ref 17)	**Similar to aluminum; C-scan very sensitive to mixing**
Eddy current	ASTM E 215 (Ref 18)	**Similar to aluminum; sensitive to matrix alloy and volume percent**
Optical methods	Holography	**Appears to be effective for some shapes**
Electrical conductivity	…	**Similar to aluminum**
Hardness	ASTM E 18 (Ref 19)	**Similar to aluminum**
X-ray	ASTM E 1030 (Ref 20)	**Similar to aluminum**
Liquid penetrant	**ASTM E 165 (Ref 21)**	**Similar to aluminum**

Source: Ref 22

Other test techniques that are appropriate for aluminum alloys have also been shown to be appropriate for particulate-reinforced aluminum composites. These methods and the appropriate test standards are listed in Table 3. Eddy currents measure electrical conductivity and can be calibrated to assess matrix alloy as well as volume fraction of the reinforcement. Holography techniques that employ stressing the component and calibrating a response appear to be useful in some shapes made with composites. The change in electrical conductivity during the age process of the matrix alloy can be used to track the age condition of these composites. Similarly, the change in hardness with heat treatment can be useful in assessing the heat treatment of these composites. X-ray inspection of these composites will yield results similar to that found in the unreinforced aluminum-matrix alloy. The x-ray cross section of silicon carbide is similar to aluminum and no contrast will be expected for localized areas of high volume fraction. The x-ray cross section for boron carbide may be sufficient for detection of mixing anomalies, however, appropriate standards must be provided for

correct interpretation. Liquid penetrant inspection has been successfully applied to these composites. The addition of the ceramics to the aluminum matrix does not alter the performance of standard penetrants.

Introduction to Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Introduction

ENGINEERS commonly want to predict the *future* performance of a material (or structure) using a property determined by measuring the test response of a current *or* pastsample of the material (or structure), but it can be difficult to understand how to obtain reliable test data. The definitive resource for testing and certification of advanced composites is the multivolume U.S. Department of Defense (DoD) *Composite Materials Handbook,* Military Handbook 17 (MIL- HDBK-17). The Handbook is constantly being updated. Print copies of released versions are available through the DoD Single Stock Point (Philadelphia, PA) or from Technomic Publishing Company (Lancaster, PA). Released and working versions are publicly available on the Internet at http://www.mil17.org.

MIL-HDBK-17 was initiated in the 1950s to provide design data for plastics and glass-reinforced plastics. In 1988 the scope was updated to focus only on polymeric composites, and then in the mid-1990s was extended to metal matrix and ceramic matrix composites. MIL-HDBK-17 is now a multivolume set that describes in rigorous detail the aerospace industry consensus approaches for the testing and use of composite material data in structural applications. While MIL-HDBK-17 continues to be reviewed and distributed by the U.S. DoD, support has recently increased to include civil authorities such as the U.S. Federal Aviation Administration, other regions of the world such as Europe, Canada, South America, and Japan, and even nonaerospace industries and applications.

While MIL-HDBK-17 was developed with a focus on aerospace primary structure, its philosophies can be adapted to less critical aerospace structures as well as nonaerospace applications in other industries such as marine, ground transportation, and civil infrastructure.

The mammoth size of MIL-HDBK-17 illustrates the complexity of the subject. Further, the size and complexity are barriers to many that would benefit from MIL-HDBK-17. Despite on- going efforts to improve the readability of MIL- HDBK-17, a competent engineer can still have trouble understanding enough content to follow its intent.

Introduction to Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Section on Testing and Certification

In this Section, the content of the testing and certification philosophies of MIL-HDBK-17 Volume 1 are distilled down to the most important concepts, written by a number of the contributors to MIL-HDBK-17. In a condensed and hopefully more readable format this Section covers the basics of whatto test, howto test, and how manyto test to obtain specific properties of common advanced composite materials. MIL- HDBK-17 prefers the full-consensus standard test methods developed by ASTM Committee D- 30 on Composite Materials, and so the discussions on test methods focus on ASTM standards, where they are available.

This Section begins by reviewing some important general concepts, then addresses more specific concerns and provides coverage of testing concepts for each major topical area. The Section includes the following articles:

Article	Topics addressed
Overview of Testing and Certification	The significance of certification The MIL-HDBK-17 “building-block” approach to testing Test result correlation, basic statistics, property normalization, and basic design allowables

Test Program Planning	Potential testing problem areas Test method selection Common and developing testing standards Test matrix planning and population sampling Factors that affect test results and design values Factors that affect schedule and cost of testing programs
Constituent Materials Testing	Standard test methods and testing issues for common properties of composite prepreg, fibers, and matrices
Lamina and Laminate Nonmechanical Testing	Standard test methods and testing issues for physical, thermal, and moisture properties of advanced composites
Lamina and Laminate Mechanical Testing	Standard test methods and testing issues for strength and modulus testing of lamina/laminate forms, including tests for tension, compression, shear, fracture, and fatigue
Element and Subcomponent Testing	Why element and subcomponent tests are performed Standard test methods and testing issues
Full-Scale Structural Testing	Why full-scale tests are performed Test methods and testing issuesResults correlation

For additional details and more direct guidance on the application of these concepts in practice, the reader can refer to the relevant sections of MIL-HDBK-17.

Overview of Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Introduction

COMPOSITES are complex engineered materials that often behave differently than common isotropic materials. As a result, the testing of composites remains something of an art rather than a science. Before testing a composite material, or before ordering or supervising such testing, the responsible party should first review the following considerations, each of which is covered in more detail in the following sections of this article:

- The differences between testing of composites and testing of isotropic materials
- The role of certification agencies and the importance of their early involvement
- The building-block approach to composites testing
- Determining the purpose of testing
- The need to normalize results, where feasible
- The use and application of basic statistics
- Other factors that influence design allowables

Related subjects are discussed in the next article in this Section, "Test Program Planning," which is followed by additional articles on specific types of tests.

Differences Between Testing of Composites and Testing of Isotropic Materials

The physics of composites testing may appear to be similar to the physics of testing isotropic materials, but the differences are significant (Ref 1). Laboratories that are expert and experienced at testing other materials are *not* automatically qualified to achieve good results when testing composites. Why is the testing of advanced composites so different, and often so difficult? The reasons include the following.

Material Anisotropy. The properties of a test sample made of composite materials are often significantly different in different directions; consequently, special testing methods may be required. For example, uniaxial mechanical tests never produce a pure uniaxial stress state throughout an entire test specimen; three-dimensional stresses always exist at discontinuities and loading points. The combination of multiaxial stresses and low strengths in directions other than the test direction can result in premature or erratic failure, which lowers the mean and increases scatter in the data. Careful attention to both test specimen design and testing practices are often required to overcome this problem. While the example mentioned previously is a mechanical test, similar difficulties can be experienced when testing other properties, such as in thermal or electrical testing.

Complicated and Nonintuitive Failure Modes. A correctly executed test for a strength- or fracture-based property should produce an expected failure mode, but multiple failure modes are possible in some tests, and some failure modes are not unique to correctly executed tests. Some failure modes can be so explosive (such as uniaxial tension strength) that they disguise potential testing or specimen preparation problems and provide few clues to test acceptability. Other failure modes (compression) are often ambiguous, with physical appearance of the failure being similar for both correctly and incorrectly run tests.

Unintentional Inhomogeneity. Many (though not all) isotropic materials are created as bulk material and then later formed into the end product. However, most composites are consolidated into the final materials form at the same time that the end product is produced. This can introduce additional process variation into the basic material. For example, local fiber volume changes are common, especially at part edges and in radii. Fiber orientation changes are another example of unintentional inhomogeneity— for example, the nominal 90° angle between warp and fill yarns of an orthogonal fabric can change drastically as the fabric is spread over a complex contoured surface.

Environmental Sensitivity of a Constituent. Many of the constituents of composite materials are sensitive to environmental conditions that do not affect many competing materials, such as metals. This is especially true of moisture in the case of polymer-matrix composites and organic- fiber composites, such as those that use aramid fiber.

Developing Nature of Composites Testing. While there have been a number of testing advancements and considerable progress toward consensus standards, the field of composites testing and certification is still maturing. Test methods are being developed that are less sensitive to some of the issues presented here, but more development is required to perfect the existing test methods. New materials systems, analysis methods, and structural applications continue to require new developments in test methods, test configurations, testing matrices, and data reduction approaches. If the reader is new to composites testing, he or she should seek help from or the advice of someone who has previous experience in composites testing.

Overview of Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Involvement of Certification Agencies

If a property is used to verify system capabilities, *especially* when human safety is involved, testing usually becomes an integral part of a process that is commonly called certification. The engineering of certain critical

structures typically follows a specific approval process under the authority of an organization other than the designer. The approving organization can be the end user (especially in the case of a military application, where the process might be called *qualification*) or a government regulatory agency, in the case of publicly regulated structures. (An example of very stringent requirements for certification is seen in the U. S. Federal Aviation Administration requirements for design or modification of passenger-carrying aircraft.) Since both *certification* and *qualification* are also used with other specific meanings, MIL-HDBK- 17 (Ref 2) has recently begun using the term “structural substantiation” to mean the generic process of validating the integrity of a structure, regardless of the agency in charge.

Certification requirements exist in many other industries, although often under a different name and certainly with different rules. In the United States, railroad equipment must meet Federal Railway Administration requirements, automotive equipment must meet Department of Transportation/National Highway Transportation Safety Administration requirements, pressure vessels must meet the codes of the American Society of Mechanical Engineers, civil engineering structures must meet their respective codes, and so on. However, in industries where design with composites is not yet common, composites applications are not always specifically addressed in certification requirements.

When a structure is developed that requires certification, the preapproval of the certification agency should be sought for the design database (or the plan for creating it, if design data does not exist) and the analysis and testing process. Even so, before committing to a specific process, the entire process should be understood. For example, there are parts of the MIL-HDBK-17 statistical flowchart that remain, at this writing, at least partially open-ended. This means that if the test results fail certain statistical tests and if it was agreed upon to literally follow MIL-HDBK- 17 statistics to the letter, substantially more testing than was originally planned may ultimately be required in order to satisfy the flowchart. This can be disastrous to both cost and schedule, so it is advisable to both clearly understand the full process as well as to fully define—perhaps with sampling limits or alternative statistical methods—how to deal with statistical decision points.

Overview of Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Understanding the Building-Block Approach

The same factors that often make composites difficult to test, combined with the lack of validated and widely applicable standard analytical methods, result in distrust of structural substantiation by analysis alone. A specific combination of analysis and testing is most often used, with test results providing input to the analyses as well as confirming the analyses. This is called the *building-block approach* to design development testing, so named because it starts with large numbers of simple, focused tests and, in each succeeding level, builds on the level below with fewer, but more-complicated tests. The building-block approach is discussed in detail in Chapter 2 of MIL-HDBK-17 Volume 1.

The pyramid of Fig. 1 illustrates the building- block concept. At the lowest levels, the basic materials properties are determined using large quantities of test specimens, and multibatch population scatter is estimated. At each succeeding level, progressively more-complicated structures are built and tested, and the failure mode and load are predicted by analysis based on the lower-level data. When more data are obtained, the structural analysis models are refined as needed to agree with the test results. As the test structures become more complex, the number of replicates (repeated specimens of the same type and environment) and the number of environments

are reduced. The culmination of the building-block pyramid is often a single confirming test of a full-scale component or a full-scale structural assembly.

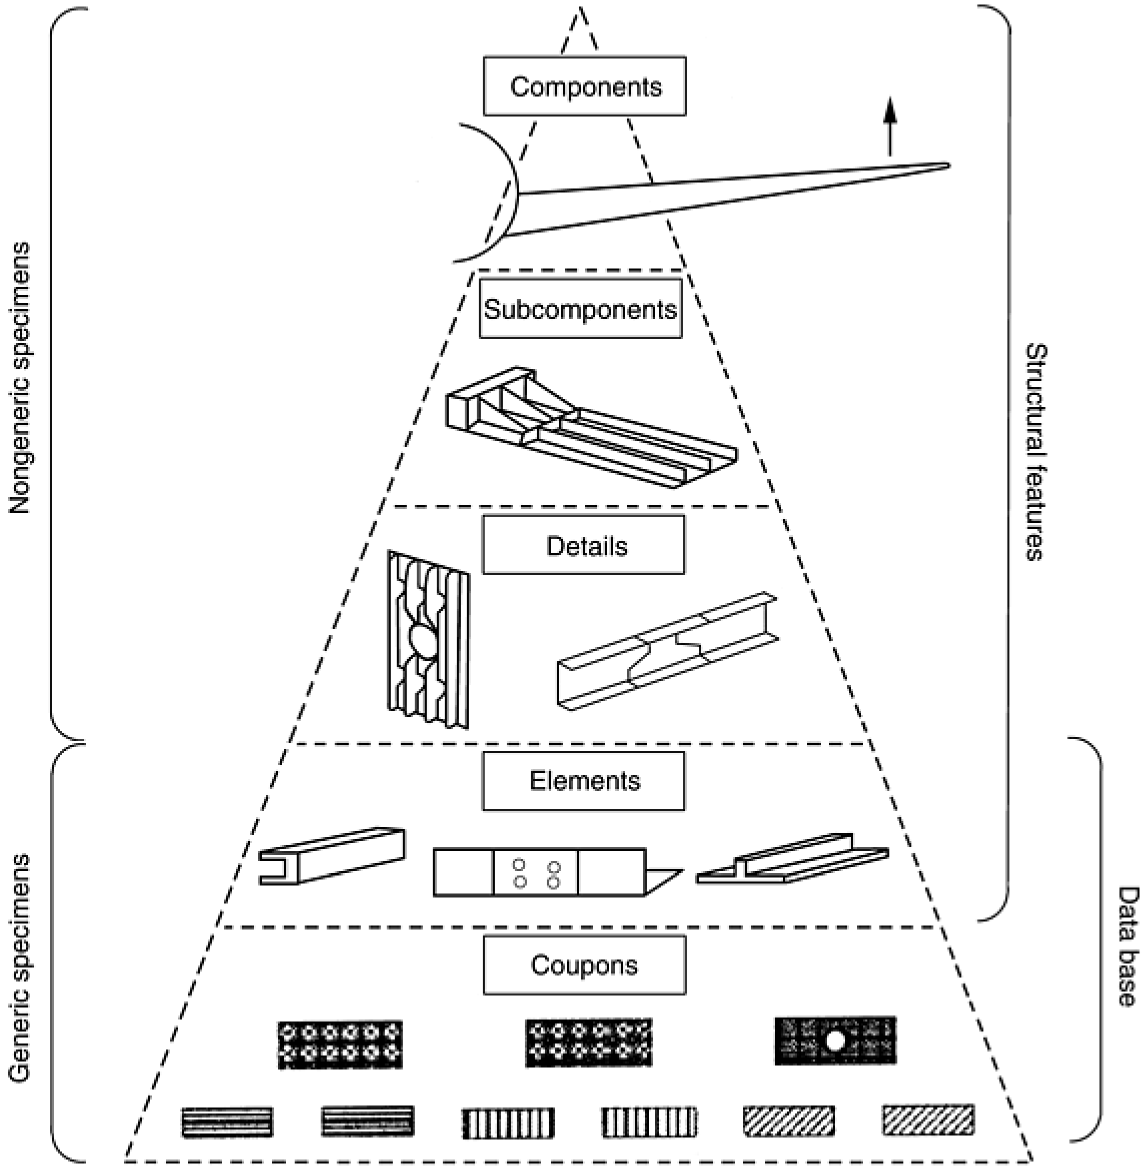

Fig. 1 The building-block pyramid for testing of composites

Upper-level (especially full-scale) tests are not always performed at the worst-case design environment. Data from the lower levels of the building-block approach can be used to establish environmental compensation values to be applied to the loads of higher-level room-temperature tests. Similarly, other lower-level building-block tests determine truncation approaches for fatigue spectra and compensation for fatigue scatter at the full-scale level. The building-block approach can be summarized in the following steps:

- Procure and process materials to a specification that includes controls on constituent, prepreg, and lamina/laminate physical properties.
- Determine multibatch materials properties at the lamina and/or laminate level, and calculate the statistical basis values and preliminary design allowables.
- Based on the design/analysis of the structure, select critical areas and design features for subsequent test verification.
- For each design feature, determine the load/ environment combination that is expected to produce a given failure mode with the lowest margin. Special attention should be given to matrix-sensitive failure modes (such as compression, out-of-plane shear, and bond lines) and potential "hot spots" caused by out-of- plane loads or stiffness-tailored designs.

- Design and test a series of test specimens, each of which simulates a single selected failure mode and load/environment condition. Compare test results to previous analytical predictions and adjust analysis models or design properties as necessary.
- Conduct increasingly more-complicated tests that evaluate more-complicated loading situations with the possibility of failure from several potential failure modes. Compare to analytical predictions and adjust analysis models as necessary.
- Conduct, as required, full-scale component (or assembly) static and fatigue testing for final validation of internal loads and structural integrity. Compare to analysis.

Overview of Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Building-Block Levels

Early in the test-planning process, decisions must be made about which building-block levels to test and the relative importance of each level in comparison to the other levels. Factors in these decisions include: manufacturing process, structural application, corporate/organizational practices, and/or the procurement or certification agency. While testing a single level of the building-block may suffice in rare instances (e.g., some noncritical, filament-wound applications subjected only to tensile loading), most applications will require at least two building-block levels, and it is very common to use three or more levels.

Coupon Tests. This class of testing can be further subdivided into the levels of constituent, lamina, and laminate testing.

Constituent testing evaluates the individual properties of fibers, fiber forms, matrix materials, and fiber-matrix preforms. Key properties of both matrix and reinforcement include density, tensile strength, and tensile modulus. Most constituent tests are conducted using ASTM standardized test methods.

Lamina testing determines the properties of the fiber and matrix together in the composite materials form. Prepreg properties are included in this level, although they are sometimes included in the constituent level or even broken out into a separate level. Key properties include fiber areal weight, matrix content, void content, cured ply thickness, lamina tensile strengths and moduli, lamina compression strengths and moduli, and lamina shear strengths and moduli. Interlaminar fracture toughness is often tested at this level, but may also be tested at the laminate level. Depending on the design/analysis philosophy, the lamina level may be the primary source of structural design data, or the data may mostly be used for analysis confirmation and correlation and specification support. Most lamina tests are conducted using ASTM standardized test methods.

Laminate testing characterizes the response of the composite material in a given laminate orientation design. It is sometimes combined with lamina testing due to test method similarities. Key properties include laminate tensile strengths and moduli, laminate compression strengths and moduli, laminate shear strengths and moduli, interlaminar fracture toughness, and fatigue resistance. Depending on the design/analysis philosophy, this level may focus on confirming the ability of analysis methods to predict response from the lamina properties, or it may be the primary source of the design data. Most laminate tests are conducted using ASTM standardized test methods.

Structural Feature Tests. This class of testing can be further subdivided into the levels of structural element, detail, subcomponent, and component/full-scale testing.

Structural Element Testing. This level evaluates the abilities of the material to tolerate common laminate discontinuities and of analysis tools to predict the response(s). Key properties include open- and filled-hole tensile strength, open- and filled-hole compression strength, compression-after-impact strength, and joint-bearing and bearing-bypass strengths. Some of these properties may have full statistical test samples at all major environments; other properties may use truncated samples and/or environments. ASTM has standardized the simplest of these tests (with others being considered for standardization at the time of this writing), while some of the more-complicated tests may be application specific.

Detail Level Testing. More-complicated generic discontinuities are evaluated in special *structural detail* specimens that are designed to mimic many of the behaviors of complicated structural configurations that produce three-dimensional stress states. None of these tests are standardized as of 2001, but within an industry or within the engineering organization of a particular manufacturer, some quasi-standard test configurations may be common.

Subcomponent Level Testing. At the next level, the emphasis begins to shift from focusing on single failure modes to evaluation of the general structural response. A subcomponent test article may be an actual production hardware piece, or it may be a special design piece that includes a number of generic features of the typical subcomponents of concern. These test configurations are strictly application dependent.

Component/Full-Scale Level Testing. The highest level looks at the behavior and failure mode of increasingly more-complex structural assemblies. It typically uses the data from the lower levels of the building-block pyramid to simplify testing loads and/or environments. The details of these tests are application specific and are not specifically covered by MIL-HDBK-17.

Overview of Testing and Certification

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Determining the Purposes of Testing

In addition to grouping material property tests by building-block level, collections of material property test data can be grouped by purpose into the five categories of screening, qualification, acceptance, equivalence, and structural substantiation. MIL-HDBK-17 calls these “data application categories.”

Screening Data. The purpose of screening testing is initial evaluation of new material systems under worst-case environmental and loading test conditions. The MIL-HDBK-17 Volume 1, Chapter 2 screening test matrix results in small-sample mean values for various strengths, moduli, and physical properties and includes key properties at both lamina and laminate levels. It is designed to both eliminate deficient material systems from the material selection process and to reveal promising new material systems before planning subsequent, more in-depth evaluations.

Material Qualification Data. This collection of tests defines the requirements necessary for a material to meet a procurement specification. Ideally, material qualification testing is a subset of, or directly related to, the design allowables testing performed to satisfy structural substantiation requirements. The objective is quantitative statistics for key material properties. The resulting statistics are used in establishing material acceptance, equivalence, quality control, and design basis values. At the time of this writing, MIL-HDBK-17 does not yet fully define this testing, however, there are recommended guidelines that should be considered and requirements on those portions of the data that will be used for design allowables.

Acceptance Data. These tests are normally a subset of material qualification. They serve to verify material consistency by periodic sampling of material product and evaluation of key material properties. Test results from small sample sizes are statistically compared with control values established from prior testing to determine whether or not the material production process has changed significantly.

Equivalence Data. This testing category assesses the equivalence of an alternate material to a previously characterized material, usually for the purpose of using an existing design property database. In general, the alternate material is substantially the same as the known material, but may have minor process changes to the raw material or minor changes in the final end-object process due to processing at a different site by different equipment and operators. Key properties are tested in quantities large enough to provide an engineering conclusion, but small enough for significant cost savings (if equivalence is shown) as compared to generating an entirely new, self-sufficient database.

Structural Substantiation Data. These are all data used in the engineering assessment of the ability of a given structure to meet the requirements of a specific application. The development of design allowables, ideally derived or related to statistical data obtained during a material qualification task, is a subset of this category.

Richard E. Fields, Lockheed Martin Missiles and Fire Control

Data Normalization

Most composite material properties are dependent on the relative proportion of reinforcement and matrix that make up the composite material. If the specimens in a test sample have somewhat different proportions of the composite constituents, statistical conclusions about test results for some properties may not be entirely valid. *Normalization* is a post-test data adjustment process that seeks to eliminate unrealistic artificial variation in certain measured properties caused by local changes in constituent content. The details of the process of adjusting fiber-dominated results to a reference fiber volume (or, via a related procedure, a reference ply thickness) are summarized here and described in more detail in MIL-HDBK-17 Volume 1, Chapter 2.

In an oriented-fiber composite, a portion of the variation of a property value is simply due to locally changing fiber volume rather than variation in fiber, matrix, or fiber-matrix interface properties. For many processes, the fiber content is relatively fixed and the variation in fiber volume is due to locally greater or lesser amounts of matrix. Fiber volume can change enough to affect test results—even for the same nominal material—certainly between batches, commonly between panels of the same batch, and even between specimens within the same panel.

For many composites properties measured in the direction parallel to reinforcing fiber ("fiber- dominated properties"), the relation between property and fiber volume is essentially linear. This makes possible a procedure for adjusting raw test values so that the normalized values appear to have resulted from specimens at the same fiber volume content (or, via a related procedure, at the same ply thickness). The following sections discuss the theory, methodology, and practical application of this type of normalization. (The properties of other types of composites, such as randomly oriented, discontinuously reinforced composites, are also dependent on constituent content, but their property-constituent relationships are more complicated, and normalization procedures for these have not been widely adopted as of 2001.)

Normalization Theory. Composites properties that are dominated by the properties of the reinforcing fiber are dependent on the volumetric proportion (expressed either as a fraction or as a percentage) of fiber in the laminate. In the common "rule of mixtures" model, 0° tensile strength of a unidirectional laminate, for example, is assumed equal to the matrix tensile strength at 0% fiber volume and equal to the fiber tow tensile strength at 100% fiber volume:

$$F = V_f F_f + (1 - V_f) F_m \quad \text{(Eq 1)}$$

where F is strength of the composite, F_f is strength of the fiber tow, F_m is strength of the matrix, and V_f is the fiber volume fraction.

The fiber volume fraction fiber is the same as the area fraction of fiber in the specimen cross section. Neglecting the effects of matrix starvation at high-fiber contents, the relationship between fiber volume and laminate ultimate tensile strength is therefore assumed to be linear for all proportions of fiber and matrix between 0 and 100% in this model. Given that the typical fiber properties are more than an order of magnitude higher than the matrix properties (less true for MMCs and CMCs), a common assumption is that the matrix properties are negligible compared to the fiber properties. With this assumption, the model relationship simplifies further to:

$$F = V_f F_f \quad \text{(Eq 2)}$$

The model for elastic modulus follows the same behavior.

To apply this to laminate normalization, consider two laminates made from the same amount of the same fiber, but with slightly different fiber volumes (due to a slight difference in matrix content, which is manifested by a slight difference in thickness). Therefore $F_1 \neq F_2$, and a relationship exists that can adjust fiber-dominated properties between two different fiber volumes:

$$F_f = \frac{F_1}{V_{f_1}} = \frac{F_2}{V_{f_2}} \quad \text{(Eq 3)}$$

Normalization Methodologies. Given the basic simplified theory above, a number of variants can be developed for practical application.

Direct Approach. One obvious method of application is to determine, post-test, the actual fiber volume of each test specimen by an appropriate test method and to adjust the raw data values by the ratio of the common fiber volume fraction to the measured values, as shown:

$$F_n = F \times \frac{V_{fn}}{V_f} \qquad \text{(Eq 4)}$$

where F_n is strength of composite, normalized; F is strength of composite, actual/measured; V_{fn} is fiber volume fraction, normalization value; and V_f is fiber volume fraction, actual.

This direct approach has a significant limitation. For large sample sizes, it is very expensive and generally impractical to accurately and directly measure fiber volume for each individual test specimen. Normally, only representative pieces from each test panel are used to estimate the typical panel fiber volume, and the within-panel matrix content (and fiber volume) variation is not directly assessed.

Cured Ply Thickness (CPT) Approach. Another method of data normalization employs the relationship between fiber volume and laminate CPT and requires some further derivation. Composites are commonly composed of three constituents: fiber, matrix, and (usually unintentionally) void. For such a composite with a given void and fiber content, laminate fiber volume is entirely dependent upon matrix content. This means that panel thickness (and hence CPT) is also dependent only upon matrix content. From this it can be shown that, for constant fiber areal weight, CPT is solely dependent upon fiber volume fraction. This dependency permits normalization of each individual test specimen by its ply thickness (total thickness divided by number of plies).

To create a useful working equation, start by defining the theoretical equivalent thickness of fiber that would result if the fiber could be shaped into a solid sheet of uniform thickness with no matrix or voids:

$$h_f = \frac{\text{FAW}}{\rho_f} \qquad \text{(Eq 5)}$$

where (when using consistent units) h_f is the equivalent thickness of solid fiber material in one ply, FAW is the fiber areal weight of one ply, and ρ_f is the density of fiber.

The fiber volume fraction for the ply (and the laminate, because it is assumed here that all plies are the same type) is this theoretical fiber thickness divided by the overall ply thickness (and this relationship applies to both the actual laminate and the normalizing laminate):

$$V_f = \frac{h_f}{\text{CPT}} \qquad \text{(Eq 6)}$$

and

$$V_{fn} = \frac{h_{fn}}{\text{CPT}_n} \qquad \text{(Eq 7)}$$

Substituting Eq 5 for h_f, yields:

$$V_f = \frac{\text{FAW}}{\text{CPT} \times \rho_f} \qquad \text{(Eq 8)}$$

and

$$V_{fn} = \frac{\text{FAW}_n}{\text{CPT}_n \times \rho_f} \qquad \text{(Eq 9)}$$

And then inserting these into the direct approach, Eq 4, results in a useful normalization equation in terms of FAW and CPT:

$$F_n = F \times \frac{\text{FAW}_n}{\text{FAW}} \times \frac{\text{CPT}}{\text{CPT}_n} \qquad \text{(Eq 10)}$$

To express Eq 10 in terms of normalized fiber volume rather than CPT, substituting Eq 8(b) back into Eq 10 (or, alternately, not inserting it in the first place) results in:

$$F_n = F \times \frac{FAW_n}{FAW} \times \frac{CPT}{FAW_n} \times V_{fn} \times \rho_f \quad \text{(Eq 11)}$$

or

$$F_n = F \times \frac{CPT \times \rho_f}{FAW} \times V_{fn} \quad \text{(Eq 12)}$$

One common view is that FAW variation should not be included in statistical variation, because FAW variation is commonly limited in the materials specification by physical tolerances. This view holds that if FAW variation is to be included in the data results, then it is best done as a uniform adjustment after data analysis, rather than additional variation. However, others may require that FAW variation be included in the data scatter, with the view that this variation is "real" and therefore should be considered in the data. (The author will not attempt to harmonize these two different views.) To include FAW variation in the data scatter, eliminate the first ratio of Eq 10 from the normalization, resulting in the simplest form of CPT normalization:

$$F_n = F \times \frac{CPT}{CPT_n} \quad \text{(Eq 13)}$$

Compare Eq 13 to Eq 4 and note that CPT and fiber volume are inversely related, as confirmed by Eq 8(a) and (b).

Other normalization forms based on these same physics can be derived for special purposes.

Practical Application Notes. The FAW is assumed to be the actual fiber areal weight for each individual specimen, but, like fiber volume, this measurement is not made on a specimen basis. However, since FAW does not usually vary greatly within a batch of material, the batch average (or roll average, if available) FAW is generally sufficient for normalization. In the case of laminates made by resin transfer molding or other nonprepreg processes, lot or roll average areal weights for the fabric or preform would be used.

The derivations mentioned previously assume a consistent set of units. In actual practice, FAW is commonly reported in grams per square meter (g/m^2) and fiber density in grams per cubic centimeters (g/cm^3) or megagrams per cubic meter (Mg/m^3), while ply thickness is commonly reported in millimeters or inches. To use common, but inconsistent units, the appropriate conversion factors must be added to the equations.

As stated earlier, void content affects fiber volume. If porosity is "added" to a laminate without changing the absolute amounts of fiber or matrix, the thickness will increase and the fiber volume will decrease. However, for a given FAW, the change in fiber volume will be the same regardless of the source of a thickness change (matrix content change or void content change). Thus, when normalizing with these equations, there is no need to make any adjustment for void volume. (This assumes, of course, that the void content is not so large or localized that basic load- carrying capability is reduced.)

Common practice is to normalize fiber-dominated lamina and laminate strengths (both unnotched and notched) and moduli for laminates fabricated from tapes, fabrics, and rovings. Although fiber volume does affect, to a lesser extent, various matrix-dominated properties (in- plane and interlaminar shear, for example), as of 2001 there is no widely accepted normalization model for these effects, and such properties are not normalized by MIL-HDBK-17. In MIL- HDBK-17, normalized values for all mechanical strength and stiffness properties are presented except: 90° (transverse) tension and compression properties of unidirectional laminates, interlaminar tension and shear properties, in-plane shear properties, short beam strength, bearing and bearing-bypass properties, strain energy release rate, and Poisson's ratio.

Laminates fabricated from rovings and similar forms using a winding process present a unique situation relative to normalization. Such constructions do not have plies in the usual sense: the wound "ply" thickness depends upon tow band width, wind spacing, and tow spread during winding. Since nominal ply thickness and FAW are not directly applicable, normalization by ply thickness and FAW is not possible. Test data for these materials must be normalized using the direct approach based on the panel average fiber volume.

When fiber-dominated properties are normalized, data scatter should decrease compared to the un-normalized values, because variability due to fiber volume fraction differences is being reduced. Thus, coefficients of variation should be lower after normalization. However, this is not always observed, and there are a number of reasons why the reduction in scatter expected from normalization is not invariably realized:

- If measured CPT is close to the normalizing thickness and FAW is close to nominal, correction factors will be small and may be nearly the same magnitude as errors in measuring these quantities.

- Compression strength generally increases as fiber volume increases (over a practical range of fiber volume), but compression failure does not result in a “strength” in the same sense as tensile strength—compression failure is a form of buckling. The linear normalization model is sometimes inconsistent for compression strength, though it tracks well with compression modulus.
- Poor testing practices or badly prepared test specimens will cause premature failures. Inconsistent failures will result in erratic normalization results. (But such testing problems should be corrected anyway.)
- If the coefficient of variation is already small (less than 3%, for example), further reduction in variation as a result of normalization should not be expected, because this level of variability is about the minimum usually observed for most composites properties.

Lack of change in data scatter after normalization is usually not a cause for concern. However, if data scatter increases significantly after normalization, the reason should be investigated, because a testing problem may be the cause.

Overview of Testing and Certification

Statistical Data Reduction

Virtually all engineers have had at least some exposure to basic statistics, so this article does not concentrate on the science (any decent statistics textbook will take care of those details) but on specific engineering application of statistics to composite materials (and structure) properties. This article goes into depth on this topic, because understanding the basics of what will be done with the data is critical to understanding issues in planning and execution of testing.

A series of property tests of a given type, evaluated on what is nominally the same material, will normally yield slightly different results from each test. This isn't a surprise, because materials properties are expected to have some inherent variation that is manifested by a range of test results. The greater the number of tests, the greater the confidence that the test data reasonably represents the larger population of all possible outcomes.

One test result gives a minimum indication. Two or three test results confirm (hopefully) that the first test result was not an anomaly and begin to qualitatively indicate the variation in the data. However, it takes a far larger amount of data to give any reasonably accurate quantitative estimate of the variation. Exactly how much data are required is an engineering trade-off between the number of assumptions, the level of confidence required for a given need, and the cost associated with obtaining large amounts of data. Some issues of sampling versus statistics are briefly discussed subsequently and in more detail in MIL-HDBK-17.

One would like statistical data reduction to be straightforward and easy, but in actual practice, of course, this is often not the case. Some of the more significant problems include:

- Variation in data can come from a number of other sources (Ref 2). This added variation in the data distorts our view of the property. The actual property may best fit one statistical distribution, but with added external variation, the test data may best fit a different (incorrect) distribution. It is hard to tell from the data itself if this is a problem; one must look at the physical test evidence and monitor the testing closely to discern indications of problems that create external variation. In some cases this requires extensive training, experience, and direct observation of the testing in question.
- The test sample may not reflect the broader current/future population that is being characterized. This may be due to a defect in sampling; for example, material may have been sampled that has a different distribution from the nominal material, or it may be due to future changes in the properties of the broader material resulting from some change or loss of control in the process that creates the material. The MIL-HDBK-17 attempts to address the first issue by requiring multibatch sampling. The second issue is one of materials specification control; while the details of it are beyond the scope of this article,

the message is that the specification must properly control the material via key characteristics of the process, materials result, or both.

Given a set of results from valid testing, one can make some statistical assumptions, apply some basic (or advanced) math, and arrive at common quantities that describe the properties of the test data variation, such as (for the normal distribution) the *sample mean*, $\overline{x}$, and *sample standard deviation*, *s*. These are called point estimates of the exact, but unknown, values of mean and standard deviation of the total population. Other important statistics are the *basis values*, which are interval estimates of a given percentile of the total population. The first two terms are well defined in any basic statistics book, but basis value requires further explanation, given subsequently.

Basis Value. A basis value is an estimate of a given percentile value of a materials property. There are two commonly used basis values, *A*- basis and *B*-basis, illustrated in the example shown in Fig. 2. Figure 2 shows a normal (Gaussian) probability density curve, which is familiar as the “bell-shaped” curve. (Other probability curves, such as the Weibull distribution, can and are used to improve fit to test data, but this article focuses on the common normal distribution for these examples.) The normal probability density curve is an exponential function:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}$$

The example shows a normal probability density curve for a sample of unspecified test data with sample mean, $\overline{x}$, of 100, and sample standard deviation, *s*, of 8 (coefficient of variation of 8%). The sample mean of this distribution is the *x*-axis value at the center of the distribution. Dashed vertical lines drawn on either side of the mean show ±1 sample standard deviation. The area under the curve between any two *x*-axis values is the probability that a test result will fall between those two values.

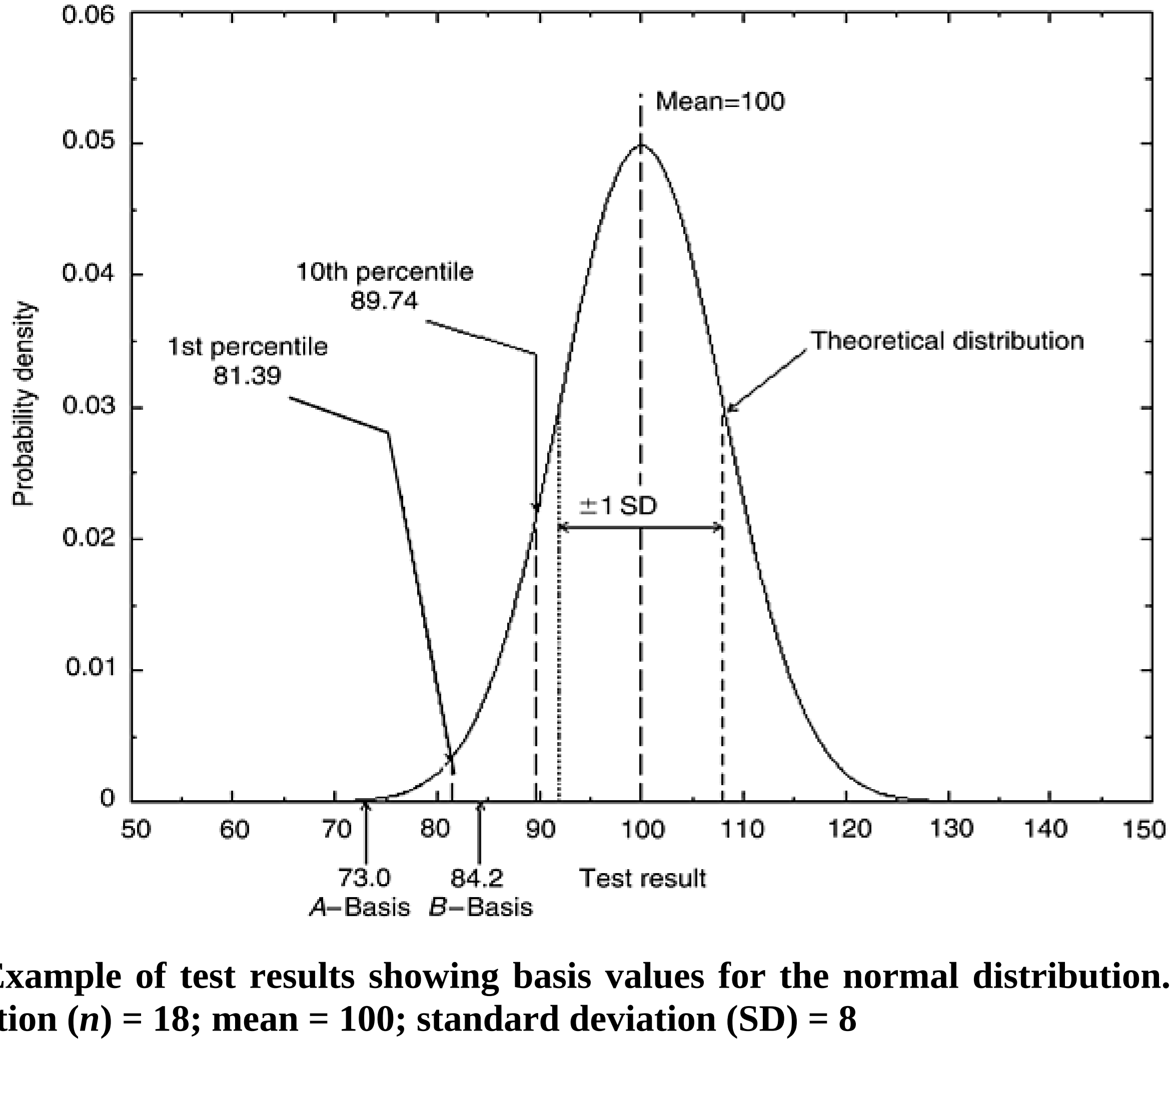

Fig. 2 Example of test results showing basis values for the normal distribution. Normal distribution (*n*) = 18; mean = 100; standard deviation (SD) = 8

Despite agreement on the general definitions, *as of 2001, there is not universal agreement* on the specific details of the sampling methods or data reduction procedures for calculating basis values. A number of different sampling and statistical data reduction methods are in use by different organizations. In particular, the approach selected for composites by the MIL-HDBK-17 (Ref 2) committee is distinctly different from that selected for metals by the MIL-HDBK-5 (Ref 3) committee.

10th/1st Percentile Values. Those points where 90 and 99%, respectively, of the total population have a greater value than the percentile value are defined as 10th/1st percentile values. Looking at the example, if the sample accurately reflected the total population, the dark vertical dashed line at the *x*-axis value of 89.74 shows the 10th percentile value, and the similar line at a value of 81.39 shows the 1st percentile value. The areas under the curve to the right of each line equal 0.90 and 0.99, respectively. Correspondingly, 10 and 1%, respectively, of the total population have lower values, and the areas under the curve to the left of each line equal 0.10 and 0.01, respectively. With a 10th percentile value, it is expected that 10% of the total population will be below it. Likewise, with a 1st percentile value, it is expected that 1% of the population will be below it.

B-Basis Value. This is a type of 10th percentile value, but it is not *the* 10th percentile value. The *B*-basis is a conservative estimate of the 10th percentile value, given that it cannot be trusted that the limited test data are completely representative of the broader population. The B- basis value in the example, for a small sample size of 18, is 84.2 and considerably lower than the theoretical 10th percentile value of 89.74.

The 10th percentile value for the sample equals the *B*-basis value only when the sample exactly mirrors the broad population; but this would be a poor assumption, especially with a small number of replicates. With limited data, one can't be sure of the true 10th percentile value, so a conservative estimate of the 10th percentile value is used instead.

The *B*-basis value is a *lower bound estimate* of the 10th percentile value, and thus the *B-basis value is almost always lower than the actual 10th percentile value*. Common aerospace design practice for *B*-basis is a 95% confidence estimate of the 10th percentile, which means 95 times out of 100 the *B*-basis will be at or below the true 10th percentile. Put another way, in only 5 times out of 100 will the *B*-basis estimate be above the true 10th percentile.

B-basis strengths are commonly used in design allowables for structures where it is tolerable that 10% of the material might have lower strengths. These structures might include those with any one of, or combination of, the following: conservative design factors, high margins, structural redundancy, and noncritical structure.

A-Basis Value. Similarly to the *B*-basis value, the *A*-basis value is a type of 1st percentile value, but it is not *the* 1st percentile value. The *A*-basis value is a conservative estimate of the 1st percentile value, given that it cannot be trusted that limited test data completely represent the broader population, and is commonly given as a 95% confidence estimate. The *A*-basis value in the example, for a small sample size of 18, is 73.0 and considerably lower than the theoretical 10th percentile value of 81.39.

A-basis strengths are commonly used when deriving design allowables for critical structures, such as aerospace primary or flight-critical nonredundant structure, where there must be little chance of the materials strength being lower than the basis value. The possibility that 1% of the material might have a lower value is tolerable, given other conservatisms in engineering calculations.

S-Basis Value. In addition to the previous two basis values, there is a third “basis” value that, as of 2001, isn't guaranteed to be a statistical value at all. The *S-basis* value is a specification minimum value that, in general, has no statistical basis. Note that recent changes to MIL-HDBK- 5 are attempting to apply some rigor to this definition by steering users toward a small sample, normal distribution, 99-percentile estimate, which is normally lower than an *A*-basis from the larger sample that MIL-HDBK-5 requires. However, this is not yet an industry-wide practice, has not yet been adopted by MIL-HDBK- 17 for composites, and historical *S*-basis values in existing specifications may have been determined by a different method.

Effect of Sample Size on Basis Values. As has been repeated several times, the more test data one has, the greater the confidence that the test data reflect the total population. The result of this greater confidence is that the basis value comes closer to the percentile value for the population, meaning that the basis value increases. A larger basis value is desirable in strength-critical designs, but there is a trade-off between the costs of the additional testing needed to increase the sample size and the increase in usable design strength. Figure 3 illustrates how the *B*-basis value increases as a function of sample size for three different coefficients of variation (CV). Very small samples (<10) take a huge “hit” in basis value, compared to the sample mean, with basis values for 9% CV at less than one-half of the mean for a sample size of 3. (Meaningful assessment of test scatter doesn't exist at this sample size.) However, at sample sizes of 18 or more, basis values level off and

there is little increase in the basis value for larger sample sizes (although the sample may better reflect the total population).

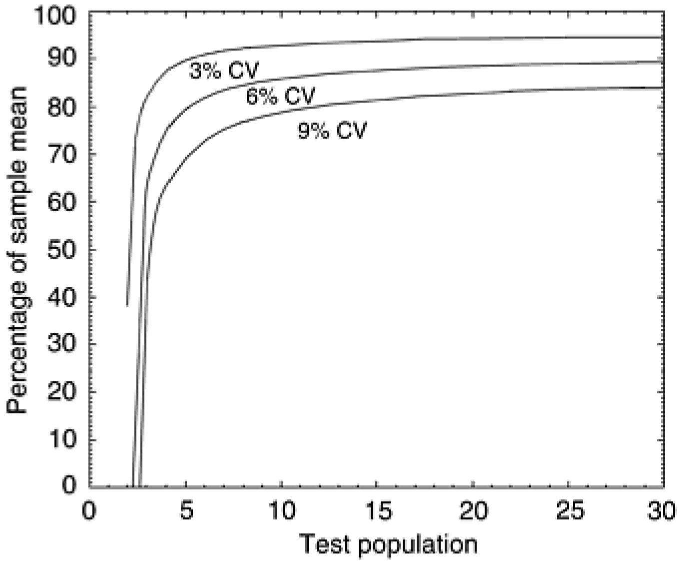

Fig. 3 Example showing how sample size influences *B*- basis values for the normal distribution. CV, coefficient of variation

While testing matrices and related topics on statistics are discussed further in the next major Section, additional details on sampling requirements and calculation methods for *A*-basis and *B*-basis values for composites can be found in Volume 1 of MIL-HDBK-17, Chapter 8 on statistical methods.

Test Program Planning

Carl Rousseau, Bell Helicopter

Introduction

ALL SIGNIFICANT TESTING PROGRAMS should begin with preparation of a detailed test plan document. A test plan specifies material properties to be evaluated, selects test methods, eliminates options offered by standard test methods by selecting specific specimen and test configurations, and defines success criteria. It is prepared by the contractor, approved by the certifying agency, and is the focal point for understanding between the contractor and certifying agency. A clearly written, well-prepared test plan is also a primary management tool used to define the scope of the work, degree of success, and progress toward completion.

Regulatory requirements/guidance and past experience provide starting points for test plan preparation. At minimum, data are required to provide quality control of the material being procured. These data serve as a statistical basis for procurement specification minima and/or acceptance testing conformity. Subsequent levels of the building block process (see Fig. 1 in the article "Overview of Testing and Certification" in this Section) are required for design allowable data, programmatic risk reduction, and analytical model validation. Specific requirements for these intermediate-to-high level building blocks vary widely with application and industry, but once the need for a specific level of testing is identified, a test matrix for those tests must be developed and included in the test plan. Typical types of composite test matrices are shown in Table 1.

Full-scale fatigue test article

This article discusses a number of testing objectives that affect the execution of testing programs. Topics covered include development of test matrices, testing standards, specimen preparation, environmental conditioning, instrumentation and data acquisition, failure modes, and data interpretation and recording.

Test Program Planning

Carl Rousseau, Bell Helicopter

Development of Test Matrices

The test plan primarily consists of the required test matrices. A separate matrix of tests is usually required for each material or structural form at each level of the building block process. This section focuses on general issues that must be considered in developing these test matrices. Subsequent sections cover the specifics of standard test methods, specimen preparation, and so on.

Property Needs. First, identify the material or structural properties requiring measurement. Complete characterization of all possible material properties at a given level or scale is rarely necessary. However, good engineering judgement should be used to balance the critical/minimum design needs with potential unforeseen downstream data needs. For example, the need for a full set of elastic properties may not be obvious in the test planning stage but may become necessary as detailed analytical models are developed in the later stages of design.

Environmental Conditions. Determine the environmental conditions under which the required material properties need to be developed. Room temperature and ambient moisture conditions are almost always required. Other temperature, moisture, and/or atmospheric conditions may be required in order to provide critical design properties or isolate key aspects of material behavior. Environmental conditioning approaches and requirements are discussed in more detail in a subsequent section.

Test Methods. The type of test method must be indicated for each property in the test matrix. A detailed description of how to execute each method should be provided elsewhere in the test plan document. Test method requirements are discussed in more detail in subsequent paragraphs.

Statistics. Perhaps the most contentious and difficult-to-understand aspect of test matrix development is defining the number of test specimens per condition (and per batch of material, if multibatch data are being developed) in order to assure an appropriate level of statistical significance. Much of the detailed test planning guidance found in MIL-HDBK-17, Volume 1 focuses on guidelines for establishing basis values for strength and strain-to-failure properties (see the article “Overview of Testing and Certification” in this Volume for a definition of basis values). Sampling schemes for this and other types of data usage, such as material screening, equivalency testing, and so on are detailed in MIL- HDBK-17, Volume 1. A specific statistical methodology for calculating basis values from test results, illustrated in Fig. 1, is recommended for general use in reducing data and is required for evaluation of data published in MIL-HDBK-17, Volume 2.

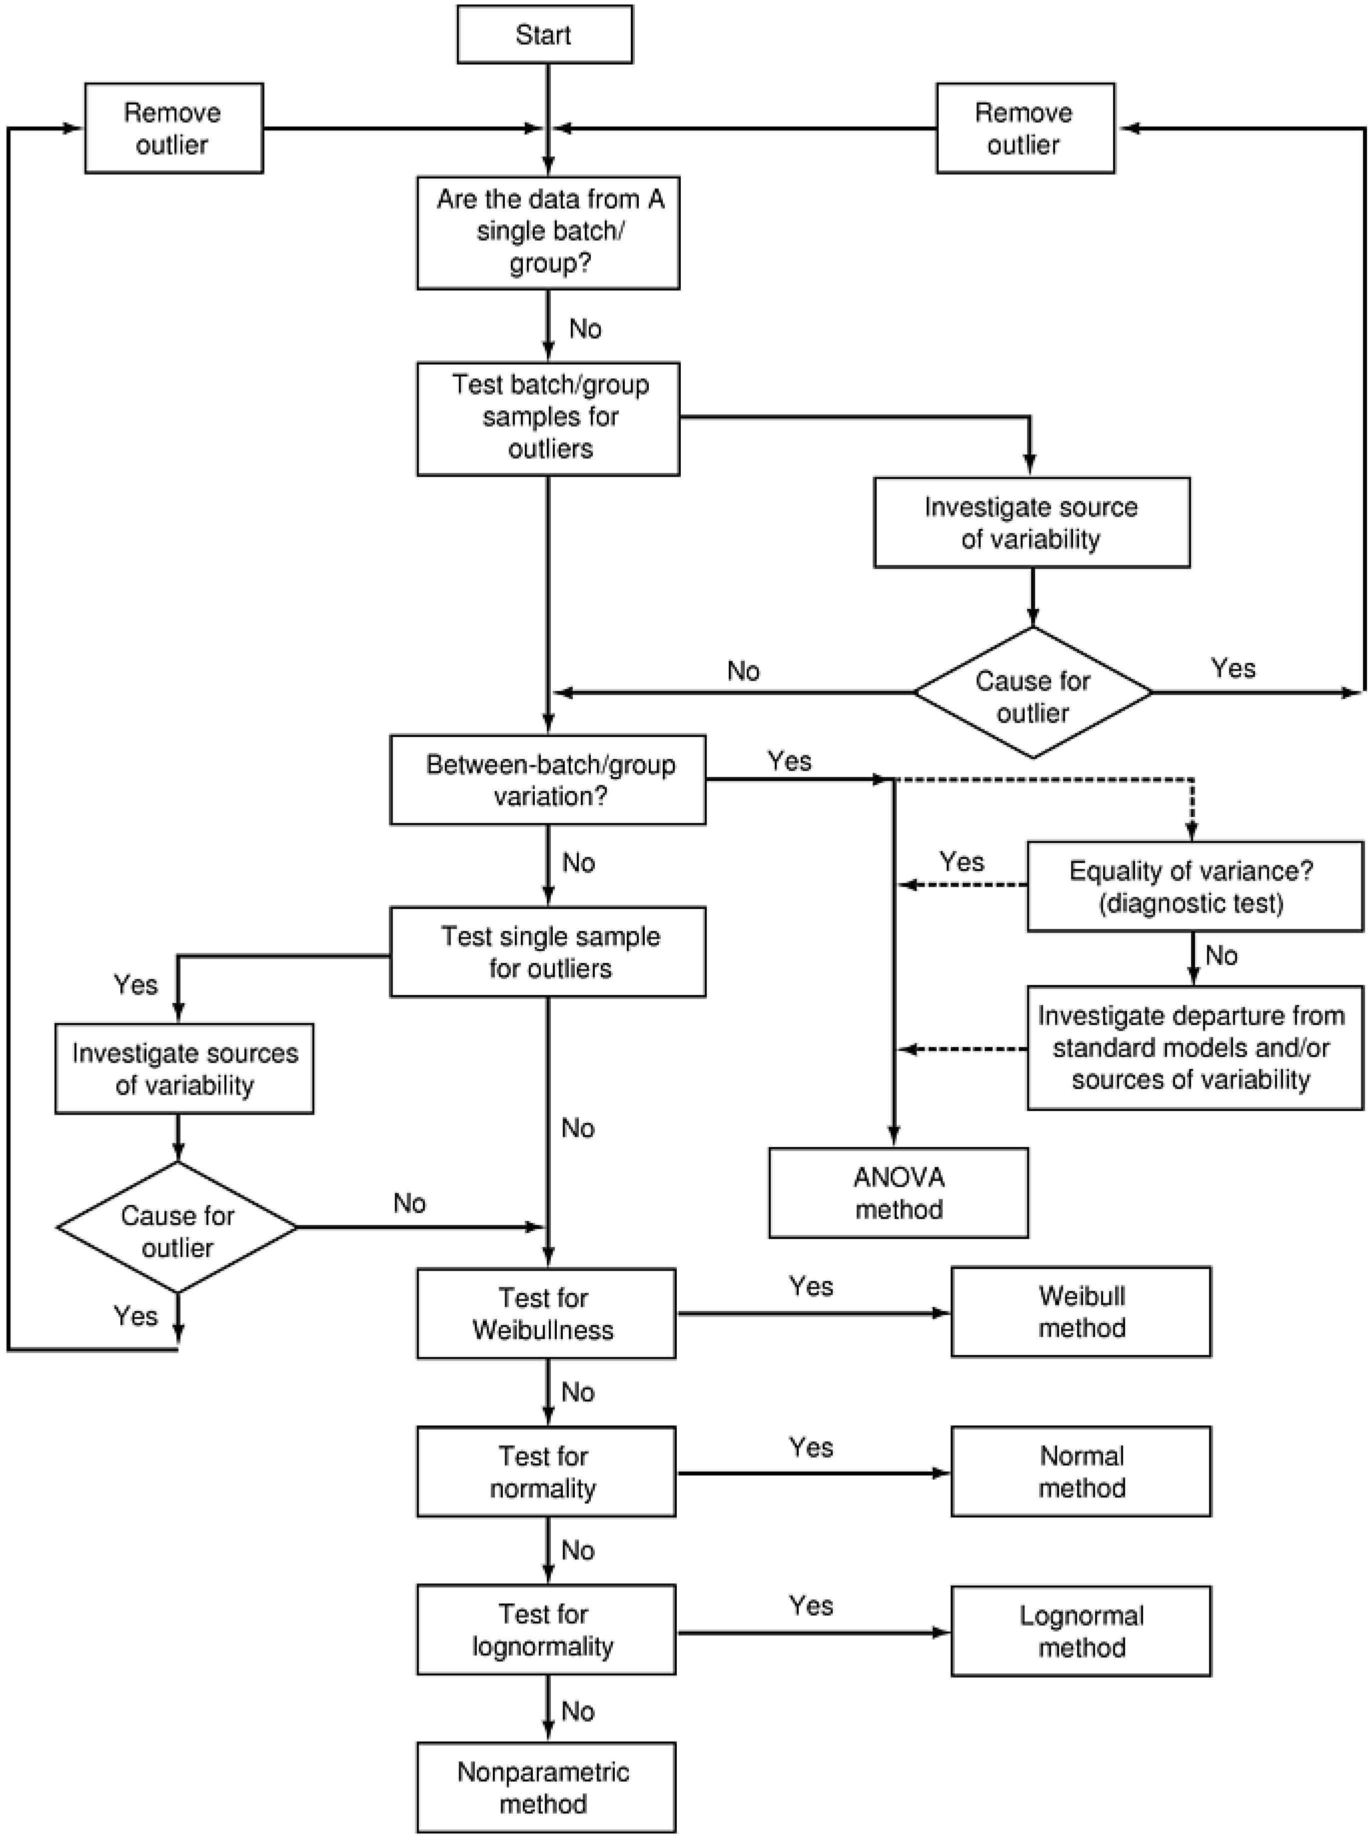

Fig. 1 Statistical methodology for calculating basis values from test results. ANOVA, analysis of variance. Source: MIL-HDBK-17

Depending on both the application and the procuring or certifying agency, modifications to the baseline MIL-HDBK-17 approach may be justified when developing new material data. In such cases, the handbook guidelines remain useful for support and reference. Alternate sampling and statistical approaches to development of basis values may be justified in certain instances, though they are less commonly used. These alternate approaches directly affect test matrix development and generally require a relatively sophisticated knowledge of both statistics and the material behavior of the specific material system. When using such alternate approaches, advance approval of the procurement or certification agency is strongly recommended.

Regardless of the sampling scheme, for small sample populations, the result of any basis value calculation is strongly dependent on the sample size. Smaller sample populations are obviously less costly to test, but there is a price of a different kind to pay since, as the population size decreases, so does the calculated basis value. Figure 2 shows, for example, the effect of sample size on the calculated B-basis value for samples of various sizes drawn from a given infinite population that is normally distributed. In the limit, for very large sample sizes the B-basis (ten percentile) value for this example would be 87.2. The dotted line in the figure is the mean of all possible B-basis values for each sample size; this line can also be interpreted as the estimated B- basis value as a function of population size for a fixed sample coefficient of variation (CV) of 10%. The dashed lines represent the one-sigma limits for any given sample size (a two-sigma limit would approximately bound the 95% confidence interval). Not only does the estimated B- basis value increase with larger sample sizes, but, as the one-sigma limits illustrate, the expected variation in the estimated B-basis value significantly decreases. The lower one-sigma limit is farther from the mean B-basis value than the upper one-sigma limit, illustrating a skew in the calculated B-basis value that is particularly strong for small sample sizes. As a result of this skew, for small populations the calculated B-basis value is substantially more likely to be overly conservative than under conservative, increasing the significant penalty in B-basis value paid by use of small populations. While similar examples for nonnormal distributions would have different quantitative results, the trends with sample size can be expected to be similar.

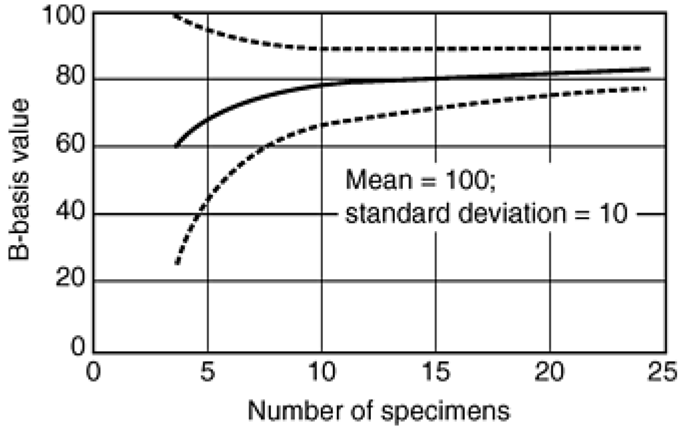

Fig. 2 Normal B-basis values with one-sigma limits. SD, standard deviation. Source: MIL-HDBK-17

Table 2 is an example of a typical test matrix.

Table 2 Typical composite material test matrix

Mechanical property	Suggested test procedure[(a)]	Test condition and number of tests per batch[(b)]			No. of tests
		Min temp dry	**RT dry**	**Max temp wet**	
0° tension	ASTM D 3039	6	6	6	**90**
90° tension	ASTM D 5450	6	6	6	**90**
0° compression	ASTM D 3410 (Method B)	6	6	6	**90**
90° compression	ASTM D 5449	6	6	6	**90**
In-plane shear	ASTM D 5448	6	6	6	**90**
Interlaminar shear	ASTM D 5379	6	6	6	**90**
Total					540

min, minimum; max, maximum.

(a) Refer to the article "Lamina and Laminate Mechanical Testing" in this Volume and MIL-HDBK-17, Volume 1, Section 6.7, Mechanical Property Tests, for more information on these ASTM test methods.
(b) Tests shall be performed on each of the five batches. Minimum and maximum temperature tests shall be performed within ±2.8 °C (±5 °F) of the nominal test temperature. Nominal test temperatures will be as agreed to by contractor and certifying agency. Dry specimens are "as-fabricated" specimens that have been maintained at ambient conditions in an environmentally-controlled test laboratory. Wet specimens are environmentally-conditioned by exposing them in a humidity chamber until they attain an equilibrium moisture content agreed to by the contractor and certifying agency, and then packaging them in a heat-sealed aluminized polyethylene bag until required for test. Tests shall be performed in a manner which maintains the moisture content in specimens at the levels agreed to by the contractor and certifying agency.

Test Program Planning

Carl Rousseau, Bell Helicopter

Testing Standards

In addition to the test matrices, a detailed test plan will also include guidance on what standard test methods to use and specifics on how to use them (e.g., specifying which of the various options in the method to use in practice). The test plan also provides reference to appropriate documentation for nonstandard test methods.
At the coupon testing level, the results are either an intrinsic material property (like material compression modulus or tensile strength) or a generic structural response (like quasi-isotropic laminate open hole tension strength) from a small and relatively simple specimen. This result is often used as input to a simulation of the response of a larger and more complicated specific structure. At and above the subelement test level in the building block process, the testing is usually design-specific, thus no standard test methods are available. In most cases, structural test descriptions are either included in the test plan document or prepared separately and referenced by the test plan.
Coupon test methods, historically developed for metals or plastics, in most cases cannot be directly applied to advanced composite materials. While the basic physics of test methods for composites may be similar to their unreinforced counterparts, the heterogeneity, orthotropy, moisture sensitivity, and low ductility of typical composites often lead to significant differences in testing requirements, particularly with the mechanical tests. The significant differences include the following:

- The strong influence of constituent content on material response, creating a need to measure the material response of every coupon
- A need to evaluate properties in multiple directions
- A need to condition specimens to quantify and control moisture absorption and desorption
- Increased importance of specimen alignment and load introduction method

Other distinguishing characteristics of many composite materials also contribute to testing differences. These characteristics include the following:

- Compression strength that is often lower than tensile strength (though specific material systems like boron/epoxy may behave counter to this)
- Operating temperatures that are closer to material property transition temperatures (compared to metals)
- Shear stress response that is uncoupled from normal stress response
- Heightened sensitivity to specimen preparation practices

A good overview of the mechanics of testing laminated Composites is given in Ref 1.

One measure of a test method is the theoretical ability of a perfect test to produce a desired result, such as a uniform uniaxial stress state throughout the conduct of the test. However, the above factors tend to increase the sensitivity of composites to a wider variety of testing parameters than is seen with conventional materials. Therefore, test method robustness, or relative insensitivity to minor variations in specimen and test procedure, is just as important as theoretical perfection. Robustness, or lack thereof, is assessed by interlaboratory testing and is measured by *precision* (variation in the sample population) and *bias* (variation of the sample mean from the true average). The term *accuracy* is often used as a generic combination of aspects of both precision and bias. The terms *precision* and *bias,* being more specific, are preferred for use where appropriate. The precision and bias of test methods are evaluated by comparison testing, often called "round-robin" testing, both within laboratory and between laboratories. The obvious ideal is high precision (low variation) and low bias (sample mean close to true average) for test results both within laboratory and between laboratories. Such a test method would repeatedly produce reproducible results without regard to material, operator, or test laboratory. However, quantification of bias requires a material standard for each test, none of which is currently available for composites. As a result, bias of composite test methods can currently only be qualitatively assessed.

The effect on precision and bias of variation in test specimen size and geometry is somewhat separate from the precision and bias of a test method (for a given specimen) but more relevant to subelement and component-level testing. For heterogeneous materials, physically larger specimens can be expected to contain within the coupon a more representative sample of the material microstructure. While this effect is desirable, a larger specimen is more apt to contain a greater number of microstructural or macrostructural defects than a smaller specimen and, thus, can be expected to produce somewhat lower strengths (though possibly with lower variation, as well). Variations in specimen geometry can also create differing results. Size and geometry effects can produce statistical differences in results independent of the degree of perfection of the remaining aspects of a test method or its conduct; such effects should be expected. Therefore, even though the specimen response may not (and probably will not) be identical to that of the structure, the ideal test method will incorporate a specimen geometry that can be consistently correlated with structural response.

As the criticality of various test parameters is still being researched and understood (even for relatively common tests) and as "standard laboratory practices," on close examination, are actually found to vary from laboratory to laboratory, it is critical to control or document as many of these practices and parameters as possible. ASTM Committee D-30, responsible for standardization of advanced composite material test methods, tries to consider all of these factors when improving existing standard test methods and developing new ones (Ref 2). Due to both their completeness and their status as full-consensus standards, ASTM D-30 test methods are emphasized in this Volume, where applicable.

Failure to minimize test method sensitivities, whatever their cause, can cause the statistical methods used to develop the necessary design basis values to break down, as all variation in data is implicitly assumed by the statistical methods to be due to material or process variation. Any additional variation due to specimen preparation or testing procedure is added to the material/process variation, which can result in extraordinarily conservative basis-value results.

Test methods, with emphasis on ASTM standards for advanced composites, are discussed in subsequent articles in this Section. The advantages and disadvantages of the various test methods for composites are discussed, including, for completeness, nonstandard but often referenced methods that have appeared in the literature. Test methods for which MIL-HDBK-17 currently accepts data are summarized in Table 3.

Table 3 Standard test methods from which MIL-HDBK-17 currently accepts data

Test category, lamina/laminate	Source of test method[(a)]	
mechanical tests	**ASTM**	SACMA
0° Warp tension	D 3039	**RM 4, RM 9**
90°/Fill tension	D 3039, D 5450	**RM 4, RM 9**
0°/Warp compression	D 3410, D 5467, D 6641	**RM 1, RM 6**
90°/Fill compression	D 3410, D 5449, D 6641	**RM 1, RM 6**
In-plane shear [(b)]	D 3518, D 5448, D 5379	**RM 7**
Interlaminar shear	D 5379	**…**
Short beam strength	D 2344	**RM 8**
Flexure	[(c)]	**[(c)]**

Open-hole compression	D 6484	**RM 3**
Open-hole tension	D 5766	**RM 5**
Single-shear bearing	D 5961	**…**
Double-shear bearing	D 5961	**…**
Compression after impact	(Draft)	**RM 2**
Mode I fracture toughness	D 5528	**…**
Mode II fracture toughness	(Draft)	**…**
Tension/tension fatigue	D 3479	**…**
Tension/compression fatigue	**…**	**…**

(a) SACMA (Suppliers of Advanced Composite Materials Association) test methods, in many cases, are subsets or supersets of the referenced ASTM test methods and, in other cases, have either a different scope or use a different testing methodology. For cases where a SACMA test method exists and either there is no ASTM test method covering the same property or the existing ASTM test method uses a different methodology, ASTM is considering adopting a form of the SACMA test method. For properties where there is more than one test method listed for either ASTM or SACMA, the different test methods either apply to different material forms or use different testing methodologies. SACMA is no longer active, and its test methods are not being maintained.
(b) ASTM D 4255 will also be accepted for in-plane shear modulus of flat panels.
(c) See MIL-HDBK-17, Volume 1, Section 6.7.7

Test Program Planning

Carl Rousseau, Bell Helicopter

Specimen Preparation

After the test matrices and test methods have been developed/identified, the next step in test planning is to ensure representative and repeatable specimen preparation. As discussed elsewhere in this Volume, composite materials and structures are the products of complex multistep manufacturing processes. Thus, there are many sources for property variation simply in the preparation of test specimens. This variation must be identified and controlled to the greatest extent possible. Variations inherent in the normal product manufacturing process should be faithfully reproduced in the various levels of certification testing. Variations unique to test specimen fabrication and testing should be minimized or eliminated. To this end, ASTM Committee D-30 produced and maintains ASTM D 5687, “Standard Guide to the Preparation of Flat Composite Panels with Guidelines for Specimen Preparation” (Ref 3). While this standard is specific to organic matrix composites, much of its guidance is also applicable to laminated continuous fiber- metal and ceramic-matrix composites.

ASTM D 5687 describes the general process flow for preparation of flat composite panels and provides specific recommended techniques that are generally suitable to laminated fibrous organic polymer-matrix composites for each of the process steps in test specimen fabrication. The specific techniques included in this guide are the minimum recommended for common composite material systems as represented in the scope of this guide. For a given application, other techniques may need to be added or substituted for those described by this guide.

Specimen preparation is modeled in the 8-step process presented in Fig. 3. Laminate consolidation techniques are assumed to be by press or autoclave. It is assumed that the materials are properly handled by the test facility

to meet the requirements specified by the material supplier(s) or specification, or both. Proper test specimen identification includes designation of process equipment, process steps, and any irregularities identified during processing.

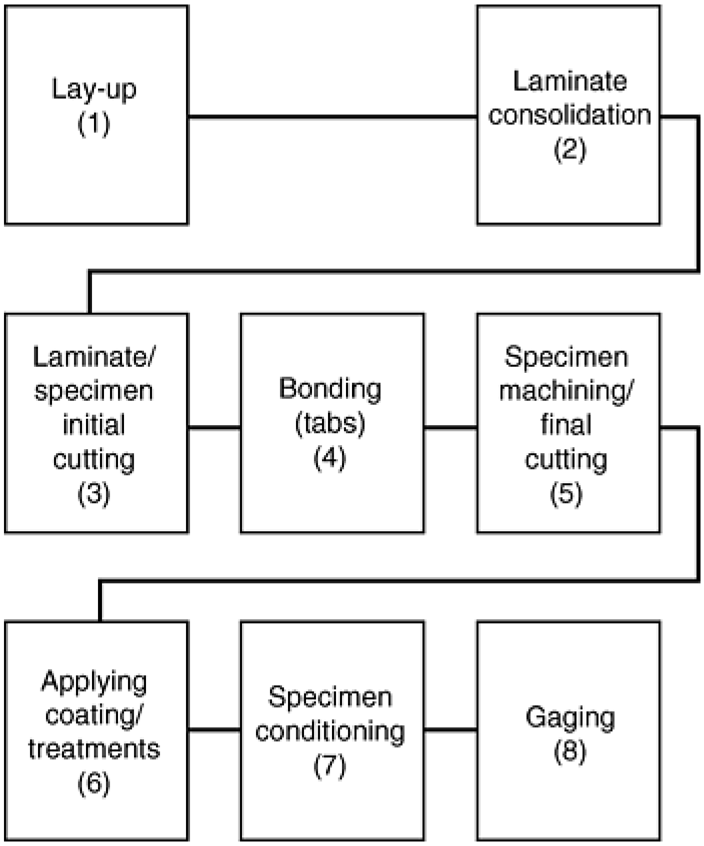

Fig. 3 Eight-step test specimen preparation model. Material identification is mandatory. Continuous traceability of specimens is required throughout the process. Process checks may be done at the end of each step to verify that the step was performed to give a laminate or specimen or satisfactory quality. Steps 4 and 5 may be interchanged. For aramid fibers, step 5 routinely precedes step 4. Steps 6, 7, and 8 may be interchanged. Source: ASTM D 5687

The techniques described in ASTM D 5687 are recommended to facilitate the consistent production of satisfactory test specimens by minimizing uncontrolled processing variance during specimen fabrication. Steps 3 through 8 of the process may not be required for particular specimen or test types. If the specimen or test does not require a given step in the process of specimen fabrication, that particular step may be skipped. A test specimen represents a simplification of the structural part. The value of a test specimen lies in the ability of several sites to be able to test the specimen using standard techniques. Test data may not show properties identical to those obtained in a large structure, but a correlation can be made between test results and part performance. This may be due, in part, to the difficulty of creating a processing environment for test specimens that identically duplicates that of larger scale processes.

Specimen preparation practices should reflect those used on an applicable part, to the greatest extent practical. However, due to scaling effects, processing requirements for test laminates may not exactly duplicate the processes used in larger scale components. The user should attempt to understand and control those critical process parameters that may produce a difference in material response between the test coupon and the structure. It is important to also note that laminate quality is directly related to the prevention of contamination during lay-up and processing.

Regarding the eight steps shown in Fig. 3, the ASTM D 5687 procedure section provides guidance on the following:

- *Laminate lay-up:* Clean room requirements, dimensional considerations, lay-up materials and tooling, ply cutting and stacking (e.g., assuring proper ply orientations and staggering butt-spliced plies), and

bagging considerations. In particular, standard nomenclature, notations, and coordinate systems are specified (consistent with those shown elsewhere in this Volume).

- *Laminate consolidation:* Recommended practices for temperature, pressure, and vacuum
- *Initial cutting of laminates/specimens:* Guidance on cutting and machining equipment.
- *Bonding of tabs:* If required, test specimen tabs strongly influence the success or failure of a particular test. This is because tabs are generally used to introduce load into very notch-sensitive orthotropic materials. Thus, failure to properly tab specimens generally results in tab-section rather than gage-section- failures. ASTM D 5687 provides detailed guidance on tab design, application, and machining.
- *Specimen machining/final cutting:* Further machining guidance focused on tolerance and quality control issues
- *Applying coatings/treatments:* Coatings are sometimes required prior to environmental conditioning. ASTM D 5687 simply states that coating manufacturer recommendations be followed.
- *Specimen conditioning:* ASTM D 5687 guidance simply consists of references to other documents. This subject is addressed in more detail elsewhere in this section.
- *Strain gaging:* ASTM D 5687 guidance points to other references, and this issue is also addressed elsewhere in this section.
- *Process checks:* Finally, ASTM D 5687 also provides quality control guidance as described subsequently.

Each facility may develop a set of nondestructive examination (NDE) or other processing checks to assure that each step of the specimen preparation process has been performed satisfactorily. If the specimen fabrication process is shown to be sufficiently controlled to eliminate deviations from acceptable specimens, then control of the process indicates control of the specimen. In these cases, inspection is only an occasional verification of the process. In cases where the process has not shown that acceptable specimens are made by following process steps, inspection protocol, which defines inspections to be performed, should be initiated and every specimen evaluated until there is confidence that the process shall make adequate specimens. Process capabilities should be periodically checked if there is any doubt that specimens will meet the requirement. Nondestructive and destructive process checks are described in ASTM D 5687.

The contact surface of the material and the measuring device will determine the measured dimensions. Bridging of surface discontinuities and accounting for dimples (less than 0.8 mm, or 0.03 in.) can substantially affect the data produced. Figure 4 demonstrates this effect. Use of nonstandard devices on the same tests within a facility can create typical test data variations (not material variations) of 5 to 15%, due solely to measurement inconsistencies. Calibration of the measurement devices should, therefore, be traceable.

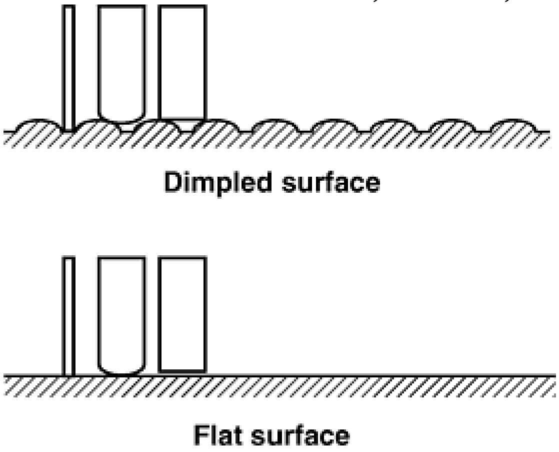

Fig. 4 Measuring of laminate surfaces. Each example shows the use of two different sizes and two different types of measuring probes. For a dimpled surface, if when too narrow a probe is used, minimum thickness rather than average thickness will be measured; if when too wide a probe is used, maximum thickness rather than average thickness will be measured. For a flat surface, probe width has minimal effect. Source: ASTM D 5687

The precision of the dimensional examination of the specimen required depends on the specific type of measurement device. In performing dimensional examinations, the accuracy of the overall test should be

considered. A propagation of error analysis for the test may demonstrate the level of accuracy required in the dimensional tolerances of a specific test.

Test Program Planning

Carl Rousseau, Bell Helicopter

Environmental Conditioning

Another step in test planning is specifying the details required to environmentally condition the test specimens. This testing should include all relevant environmental effects on material and structural behavior and may be necessary to establish the material operational limit (MOL). Properties of polymer-matrix composites are influenced markedly by temperature and moisture. Generally, matrix-dominated mechanical property values decrease with increases in moisture content and increases in temperature above room temperature. For properties that are highly dominated by reinforcement (fiber) properties (unidirectional tension, for example), this reduction may be reversed, absent, or minimal over reasonable temperature ranges. For properties influenced by the organic matrix (shear and compression, for example), the degradation of properties can be significant. Furthermore, the degradation is not linear. At a given moisture content, it becomes more severe with increasing temperature until a temperature is reached where dramatic property reductions begin to occur and beyond which these reductions may become irreversible. It is desirable to specify this onset of dramatic reduction as a characteristic temperature, which is also defined as the MOL or the maximum operating temperature. The purpose of establishing the MOL is to assure that materials are not operated in service under conditions where a slight increase in temperature might cause a significant loss in strength or stiffness and to absolutely avoid irreversible property changes. Similar operational limitations, due to temperature and oxidation rather than moisture, are also observed in ceramic-matrix composites.

There are not yet any fixed criteria for establishment of a MOL. One method (Ref 4, 5, and 6) utilizes the glass-transition temperature (T_g) as determined from dynamic mechanical analysis (DMA) or similar data, reduced by some temperature margin ΔT. For epoxy-matrix composites, 28 °C (50 °F) is commonly used for the value of the temperature margin, but it can be argued that smaller margins may be acceptable for particular applications when supported by other data. While T_g is a useful tool, it should not be the sole basis for establishing MOL. Glass transition frequently occurs over a range of temperatures, and it is well known that measurement of T_g is test method dependent. Other data that are useful in establishing MOL include field experience (for established materials) and mechanical testing conducted over a temperature range that includes the $\pm\Delta T$ range around the measured T_g.

Evaluating the behavior of a matrix-dependent mechanical property in the appropriate wet condition as a function of temperature is considered a reliable method for verifying a MOL that has tentatively been determined from T_g data. Various investigators have used short beam strength, in-plane shear strength, in-plane shear modulus, and quasi-isotropic open hole compression strength for this purpose, with the latter two being most successful as MOL indicators. Four or five temperatures are typically chosen to provide trend lines for the selected property. Figure 5 shows three possible scenarios where mechanical testing is used to verify the MOL determined from T_g data. In the first instance, mechanical data corroborate the chosen T_g. In the second case, mechanical data suggest that the MOL predicted by T_g is conservative. In the third example, mechanical data do not support the MOL determined from T_g data and indicate that a lower MOL should be chosen. One approach to determining the MOL from mechanical property data is to use the temperature at which the property versus temperature plot deviates from linearity by a given percentage. An example of this can be found in Ref 7.

However, a specific criterion for determining MOL that includes results from both T_g and mechanical testing has not been standardized and is still being discussed. Nevertheless, the MOL value predicted from T_g measurements that are verified or modified by mechanical property data provide a practical approach for defining the MOL of a material.

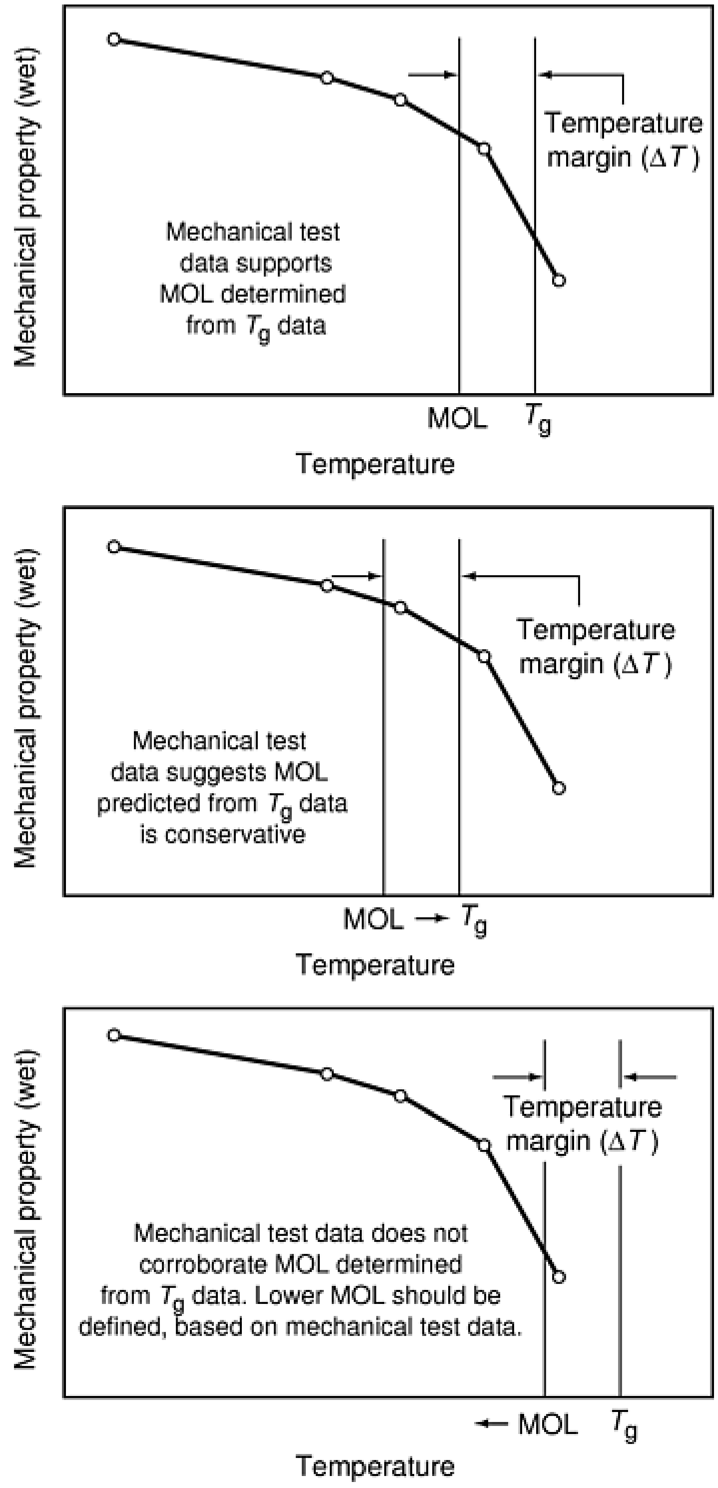

Fig. 5 Use of mechanical and glass-transition temperature (T_g) data to determine material operational limit (MOL). Source: MIL-HDBK-17

In addition to establishing the MOL, environmental testing must also be planned to quantify all critical physical and mechanical property changes that are the result of environmental effects. These effects can be broadly categorized as temperature, moisture (water), and fluid (other than water). The following three sections address test planning details for each category.

Temperature. Test planning for environmental conditions should include testing at room temperature, the maximum and minimum service temperatures, and intermediate and/or elevated (beyond service use) temperatures, as well. Guidance is usually available from the certifying agency regarding what temperatures are

required. All critical physical and mechanical properties should be measured at the first three noted temperatures, at least. As noted in the MOL discussion, the combined effects of elevated temperature and moisture often dictate the critical design conditions for composites; thus, testing is often conducted under hot-wet conditions. Elevated temperature testing at dry conditions is sometimes performed in order to get an early indication of hot-wet performance, since moisture conditioning of test specimens may take a month or more. For example, 120 °C (250 °F)/dry and 80 °C (180 °F)/wet conditions yield similar laminate strength results for certain 175 °C (350 °F) curing carbon/epoxy prepregs. Minimum service temperature for many air vehicles is specified as –55 °C (–65 °F), thus, the majority of cold-temperature data resulting from atmospheric air vehicle programs are derived at this temperature. Since moisture effects at cold temperatures are less critical, these specimens usually are not moisture conditioned.

Moisture. Absorbed moisture itself can be considered a separate environmental condition that must be addressed in test planning. Most polymeric materials, whether in the form of a composite matrix or a polymeric fiber, are capable of absorbing relatively small but potentially significant amounts of moisture from the surrounding environment. The physical mechanism for moisture gain, assuming there are no cracks or other wicking paths, is generally assumed to be mass diffusion following Fick's law, the moisture analog to thermal diffusion. While material surfaces in direct contact with the environment absorb or desorb moisture almost immediately, moisture flow into or out of the interior occurs relatively slowly. The moisture diffusion rate is many orders of magnitude slower than heat flow in thermal diffusion. Nevertheless, after a few weeks or months of exposure to a humid environment, a significant amount of water will eventually be absorbed by the material. This absorbed water may produce dimensional changes (swelling), lower the glass transition temperature of a polymer, and reduce the matrix and matrix/fiber interface-dependent mechanical properties of the composite. This effectively lowers the maximum use temperature of the material.

Since the amount of moisture absorbed by a material depends upon the thickness and time of exposure, fixed-time conditioning methods should not be followed for small, flat test coupons on which most moisture-conditioned testing is done. (However, fixed-time conditioning may be appropriate for thick components.) Instead, a conditioning procedure such as ASTM D 5229/D 5229M (Ref 8) should be followed because it accounts for the diffusion process and terminates with the moisture content nearly uniform through the thickness. Moisture equilibrium content is weakly related to temperature and is usually assumed to be a function only of relative humidity. The largest value of moisture equilibrium content for a given material under humid conditions occurs at 100% relative humidity; this is also often called the *saturation content.*

Another point to be emphasized is that moisture absorption properties under atmospheric humidity conditions are generally not equivalent to exposure to either liquid immersion or pressurized steam. These latter environments alter the material diffusion characteristics, producing a higher moisture equilibrium content, and should not be used unless they simulate the application environment in question.

To evaluate worst-case effects of moisture content on material properties, tests are performed with specimens preconditioned to the design service (end-of-life) moisture content, which is assumed equivalent to equilibrium at the design service relative humidity. The preferred conditioning methodology uses ASTM D 5229/D 5229M. Unless specified by the procuring or certifying agency, the design service moisture content is determined in one of several ways. It can be derived from semiempirical calculations that consider secondary effects on a particular type of structure, or it can be more conservatively established by simpler assumptions.

An example of the first case (semiempirical calculations) is documented in Ref 6, where worldwide climatic data and United States Air Force (USAF) aircraft-basing data were combined to define runway storage environmental spectra for each of the three classes of USAF air vehicles—fighters, bombers, and cargo/tankers. The study applied a ranking procedure to select baseline and worst-case locations with respect to the absorption of moisture by typical carbon/epoxy composite structures. Such data can be used to establish design service moisture content for a particular application; a typical specific design service relative humidity (RH) might be 81% RH for a tropically-based supersonic aircraft.

Another, more conservative, approach is to use the average relative humidity for a selected diurnal cycle taken from a reference such as MIL-STD-210 (Ref 9), the United States military guide to worldwide environmental exposure conditions. This usually leads to a higher design service relative humidity (88% RH is typical), since dry-out due to solar radiation, flight excursions (supersonic excursions, in particular), and seasonal climatic changes are not considered.

Given these and other historical considerations, the MIL-HDBK-17 Coordination Group has agreed that a reasonable upper-bound value for aircraft design service relative humidity is 85% and that this value may be

used when a specific determination of design service moisture content has not been established for a specific aircraft application. Use of a design service moisture content of 85% RH will obviate extrapolation of data when test coupons are conditioned to equilibrium at this moisture level. Accepted design service moisture levels for other applications have not yet been established.
Fluids. Finally, it is important to characterize the physical and/or mechanical property degradation effects of fluids (or other forms of chemicals) commonly found in contact with the composite structure. The evaluation should account for different exposure levels of aircraft structure to fluids.
Two fluid exposure classifications are suggested, with example fluids cited for each group (Table 4). Group I fluids have the potential to pool or be in contact with the material for an extended period of time. Group II fluids include those that are applied and wiped off, those that evaporate or those that do not contact the material for an extended period of time. Exposure by immersion prior to testing or before evaluating weight loss is also recommended: a different exposure level should be used for each group:

- *Group I:* Immerse material in fluid until it reaches equilibrium weight gain (saturation). The MIL-S-8802 Sump Water corrosion test is an exception.
- *Group II:* Immerse material in fluid for 15 days to determine worst case effects.

Follow up with tests that simulate a more realistic exposure including accidental extended exposure. Both mechanical and physical testing should be done.

Table 4 Fluid exposure classifications

Fluid	Specification
Group I fluids	
JP-4 jet fuel	**MIL-PRF-5624**
JP-5 jet fuel	**MIL-PRF-5624**
JP-8 jet fuel	**MIL-DTL-83133**
Hydraulic fluid	**MIL-H-5606**
	MIL-H-83282
Polyalphaolefin (PAO) cooling fluid	**MIL-C-87252**
Engine lubricating oil	**MIL-PRF-7808**
	MIL-PRF-23699
Ethylene glycol/urea deicer (Class I)	**SAE AMS 1435 (superseding SAE AMS 1432 and MIL-D-83411)**
Sump water	**SAE AMS S-8802 (superseding MIL-S-8802)**
Methylene chloride	**ASTM D 4701 (superseding MIL-D-6998)**
SO_2/salt spray	**…**
Group II fluids	
Alkaline cleaner (Types 1 and 2)	**MIL-C-87937 (superseding MIL-C-87936)**
Methyl ethyl ketone (MEK) washing liquid	**ASTM D 740 (superseding TT-M-261)**
Dry cleaning solvent (Type 2)	**MIL-PRF-680 (superseding P-D-680)**
Hydrocarbon washing liquid	**ASTM D 471 (superseding TT-S-735)**
Polypropylene glycol deicer (Type 1)	**MIL-A-8243**
Isopropyl alcohol deicing agent	**TT-I-735**

Mechanical testing should include open hole compression tests on quasi-isotropic lay-up specimens and ±45° tension specimens. The open hole compression test has a meaningful relationship to design values and is sensitive to matrix degradation. The use of a ±45° tension test is commonplace in industry for comparison of matrix properties. It is a sensitive test that will identify potentially harsh fluids. It provides an indication of whether sufficient shear stiffness has been retained to ensure acceptable matrix- fiber property transfer. While a material stiffness loss criterion is material and application specific, a 20–40% loss in shear modulus is generally considered significant and should be further investigated. A minimum of five specimens should be tested after exposure at room temperature and at the maximum use temperature. The results should be compared with unexposed controls. A more economical alternative to open hole compression and ±45° tension testing is

interlaminar or short beam shear tests. The specimens for these tests are easily fabricated, machined, conditioned, and tested. Although not as generally related to design properties, short beam strength tests are sensitive to matrix degradation and can be valuable indicators for material evaluation. As with the ±45° tension tests, results after exposure should be compared to unexposed controls at room and elevated temperature to obtain fluid exposure effects.

Physical testing should include weighing to measure weight change, taking photomicrographs to examine for microcracks, and, where practical, using scanning electron microscopy to examine for surface crazing. Relative to the former, it should be noted that, because a saturation condition has apparently been reached, it does not automatically follow that further degradation of properties has ceased. Especially where new matrix systems are involved, tests with long- term exposure to critical fluids should be conducted. Due to the long exposure times involved, these tests should be started early in the evaluation process.

If water or moisture is proven to be the most property-degrading fluid, then fluid exposure tests involving other than moisture conditioning are not included in subsequent design testing; this has been the acceptable standard in the past. In effect, if the properties of the material after fluid exposure are better than after moisture exposure, then subsequent testing accounts for moisture only. If a fluid other than water is more critical, then subsequent testing must include evaluation with that fluid. In the case of Group II wipe on/wipe off fluids, the procedure is somewhat different, since water is not a good comparison. Consequently, comparison to a matrix that has an acceptable service history is recommended.

Test Program Planning

Carl Rousseau, Bell Helicopter

Instrumentation and Data Acquisition

A final step in test planning is specifying the necessary instrumentation and data acquisition. Instrumentation such as multi-element strain gages, can significantly increase the cost of any test; plan on 1-to-1.5 ratio for installation personnel hours per gage element, including the associated wiring. Thus, the test planner needs to have a clear understanding of the purpose (or multi-faceted purposes) of each test being specified, in order to efficiently plan the instrumentation needs. Similarly, the test planner also needs an a-priori understanding of the

intended use of the resulting test data, in order to specify an appropriate form and format for the test data acquisition. This point is important, since a great deal of manpower can be expended (i.e., wasted) in simply handling and reformatting the large volume of certification test data to get it in a usable form for the necessary post-test engineering analysis. This manpower requirement can be greatly reduced if the experimental data is acquired, processed, and stored in a useful format to begin with. The two following sections give additional details regarding these topics.

Instrumentation. The purposes for doing the different types of certification testing vary widely, but the most common measurement categories are physical property, strength, and strain/ displacement field correlation (with analytical/ numerical models). Most physical property testing (density, coefficient of thermal expansion, T_g, elastic properties, etc.) is done via standardized coupon testing and the test standards provide detailed guidance regarding instrumentation. Strength testing always requires load monitoring and sometimes requires strain/displacement measurement, as well, in order to isolate multiple damage modes and/or reduce data. However, the large test matrices required to get high statistical confidence in basic lamina- or laminate-level strength properties offer a good opportunity to minimize strain-gage instrumentation, since strength-only measurements are often all that is needed. Strain/displacement field correlation is often, but not always, done on large, complex element and component tests. Careful up-front coordination with the stress analyst (and the certifying agency) is required for this aspect of test planning in order to capture critical forces, moments, surface strains, out-of- plane displacements, and structural stiffnesses in the test article without using an excessive amount of unnecessary instrumentation. Good generic guidance on experimental mechanics of composites is given in Ref 1.

Data acquisition techniques can range from manually reading instruments and recording the results in a lab notebook to use of specialized million dollar digital signal processing/computing/storage devices. The techniques chosen for use should simply be the ones most appropriate for the intended use of the data. The lab notebook approach is often suitable when a few raw data points will be used directly by the analyst. Simple non-strain-gaged subelement strength tests often fall into this category. On the other hand, a digital system that can automatically postprocess and store a large volume and/or high rate of data is essential for both complex full- scale test articles and large (more than 10,000 specimens) statistical design data coupon-testing programs. In both of these cases, it is important to efficiently and automatically transform the tremendous amount of raw data into useful engineering information, as well as archive the raw data for future unanticipated needs. Careful up- front planning of this task is essential, since it strongly influences the cost and schedule of what is often a program-pacing effort (i.e., structural allowables development).

Failure Modes

An important consideration in interpreting and reporting all composite material and structural test results is the isolation of one or more dominant failure modes. Standardized coupon test methods generally yield only one dominant failure mode; many test methods provide specific guidance in identifying failure modes and, thus, verifying the validity of a particular data point. In structural element and component testing, multiple failure modes are acceptable and often the norm. One of the most common uses of element and component test data is validation of analytically predicted failure mode (and load), or, conversely, the issue of identifying/isolating

failure modes other than those predicted by analytical methods. Thus, correctly identifying and isolating the failure mode or modes is of prime importance and must be carefully documented in post-test data reports. Further details of failure mode identification are provided in the articles “Lamina and Laminate Mechanical Testing” and “Element and Subcomponent Testing” in this Section. A useful global reference for structural failure is the USAF Composite Failure Analysis Handbook (Ref 10, 11), which contains fractographic data from failed test specimens, as well as case histories of failed composite structures.

Carl Rousseau, Bell Helicopter

Data Interpretation and Recording

Finally, the overall issues of data interpretation, recording, and reporting require consideration. Assuming that specimen preparation, environmental conditioning, testing, and laboratory reporting of relevant issues such as failure modes are properly completed, post-test data analyses are typically performed in order to interpret the data in a manner useful to the design engineer and/or certifying agency. This data analysis necessarily includes appropriate recording and reporting. Few standards for composite material data recording exist, other than ASTM E 1309 (Ref 12) and E 1434 (Ref 13) for coupon- level electronic database architecture. Good engineering practice should be used in determining the details of structural test data recording. Reporting should be documented in a manner that complements the test planning document(s) and meets all customer and/or certifying agency requirements. The following sections detail technical issues of post-test data analysis that require careful consideration and appropriate documentation.

Issues of Data Equivalence. Evaluation for data pooling (i.e., whether data from two possibly different subpopulations are enough alike to be combined) and material equivalence (i.e., whether a material with common characteristics to another is sufficiently alike to use its data for design) are similar issues of data equivalence. Both require statistical procedures to assess the similarities and differences between two subpopulations of data. These, and other related issues, are covered in more detail in MIL-HDBK-17, Volume 1.

Assessment of data equivalence begins by examining key properties for various within-batch and between-batch statistics. The ability to pool different subpopulations of test data is highly desirable, if for no other reason than to obtain larger populations that are more representative of the universe. Equally desirable is the ability to show one material without basis values equivalent to another that already has established basis values. Requirements for the use of pooled data or equivalent materials are normally established for each application during discussions with the certifying agency.

Before determining statistical degree of equivalence, basic engineering considerations should be satisfied; the two materials should be of the same chemical, microstructural, and material form families. To some extent, the criteria for this may be application-dependent. For example, property data from two composite systems with the same matrix and similar fibers may not warrant pooling if the fiber/matrix interface is distinctly different, even if the fibers have similar modulus and tensile strength. Data equivalence is typically evaluated for datasets that differ due only to relatively minor changes in precursor manufacturing or material processing. These changes include the following:

- Minor changes in constituents or constituent manufacturing processes
- Identical materials processed by different component manufacturers
- Identical materials processed at different locations of the same manufacturer
- Slight changes in processing parameters
- Some combination of the changes listed previously

Statistical data equivalence methods currently assume that between- and within-laboratory test method variation is negligible. When this assumption is violated, this test-method-induced artificial variation severely weakens the ability of the statistical methods to meaningfully compare two different datasets.

Hot Wet Testing—Reporting Moisture Content at Failure. Specimen static strength, tested hot/wet, is usually preconditioned to equilibrium moisture content. Typically, the test results report this equilibrium moisture content rather than the actual content at failure. One consideration during testing should be to minimize dry-out during the process and, thus, the potentially severe through-thickness moisture distribution at failure. This consideration must be traded off against others, such as heat-soaking the specimen long enough prior to testing to ensure a uniform thermal profile through the thickness. There are several ways to minimize the moisture dry out during hot/wet testing. These include testing in a humidity cabinet, using high-rate heating (via quartz lamps, for instance) to minimize total environmental chamber out-time, and/or using relatively thicker test specimens. Although these procedures are not practical to perform on every test specimen, it is important that for each series of hot/wet tests, some indication of moisture content at failure be obtained. This data may be obtained via (a) witness or traveler coupons that follow a test specimen through a representative testing process, (b) use of modeling to predict dry-out, given specimen time-temperature history from environmental chamber to failure, or (c) post- test moisture content measurement on an undamaged portion of an actual test specimen. This moisture content at failure should always be reported in conjunction with each series of hot/wet tests.

Strain Gage Calibration for Structural Test Articles. Another post-test data interpretation issue, which is specific to complex structural test articles, is strain gage calibration with associated internal loads models. While properly installed and instrumented strain gages give relatively accurate direct indications of point surface strains, this information is of limited use on complex multiaxially loaded static and fatigue test articles. Rather, relevant information from these test articles must generally be in a form compatible with the associated internal loads models, verification of which is often a primary objective of the structural testing. Thus, surface strain data must be converted into pointwise forces, moments, and displacements, since these are the fundamental results of typical plane-stress two- dimensional finite element models. In order to perform these calibrations, both local and overall elastic response of the structure is required. Detailed pointwise laminate analysis of the structure, as well as global finite element results, are required to obtain this calibration input. In order to accurately match structural test data, these analyses must often be run with separate tensile or compressive ply moduli, rather than the average values used in the internal loads and stress analysis activities performed for overall certification. Once the calibration factors are obtained to transform raw strain gage data into the required forces, moments, and displacements, they may be automatically applied, via computerized post-processing, to the raw stain data files from a large number of applied load cases and load levels.

Constituent Materials Testing

Shari Bugaj, FiberCote Industries, Inc.

Introduction

A COMPOSITE is composed of some form of reinforcement combined with a matrix material, and the performance of the composite depends to a large part on the properties of these constituent materials. This article describes the most significant chemical, physical, and mechanical tests used to characterize the properties of constituent materials; the focus is on constituents for resin-matrix composites reinforced with continuous fibers or fabrics, but many of the techniques apply to constituents of other types of composites as well. Additional information on fibers, fabrics, matrix resins, and prepregs is available in the Section "Constituent Materials" in this Volume.

Constituent Materials Testing

Shari Bugaj, FiberCote Industries, Inc.

Tests for Reinforcement Fibers and Fabrics

Reinforcing fibers can be tested in the form of single filaments, tows, unidirectional tape, or fabric. While typical reinforcements are made up of bundles of filaments, it is possible to isolate single filaments to determine their properties. Academically this is interesting, but such testing has not allowed prediction of composite performance. Testing the single tow or bundle allows an evaluation of the reinforcing fiber in its simplest form and is valuable in across-the-band variability studies. Because many fibers are woven into fabrics for use in composites, physical tests may be used to characterize the fabrics, but it is recommended that mechanical tests also be performed on laminates of impregnated material. Unidirectional tapes are a convenient form for testing mechanical properties of fibers. Columnated tows of fiber are impregnated with an appropriate resin, and the resultant tape is cured with heat and pressure to form a laminate, which is subsequently machined into test specimens.

Chemical Tests

Surface characteristics and polymer analysis can be accomplished with x-ray photoelectron spectroscopy (XPS), generally regarded as an important technique. Also known as electron spectroscopy for chemical analysis, this key technique provides a total elemental analysis, with the exception of hydrogen and helium, of the top 10 to 200 Å (depending on the sample and instrumental conditions) of any solid surface that is vacuum stable or can be made vacuum stable by cooling. It also provides chemical bond information. Of all the presently available instrumental techniques for surface analysis, XPS is generally regarded as being the most quantitative, the most readily interpretable, and the most informative with regard to chemical information. It is relatively simple and straightforward. It can be used to determine surface sensitive (10 to 200 Å) characteristics and elemental sensitivity (parts per 1000) for all elements, except hydrogen and helium. Although the method requires relatively sophisticated and expensive instrumentation, many universities, industrial research and development groups, and commercial service laboratories provide access to their instruments on a collaborative or fee-for-service basis.
The information content in a typical XPS spectrum is enormous. There are various hierarchies of spectral interpretation: simple elemental analysis, detailed considerations of chemical shifts and chemical bonding nature in the surface region, and loss or relaxation structures that provide further information on the chemical

nature of the surface. Many potential artifacts, often related to the preparation of samples, are also made available in an XPS experiment. The interpretation becomes progressively more difficult as one considers more-complex surfaces, such as those of multicomponent and multiphase materials. Some disadvantages of XPS include the need for a large analysis area of several mm^2 (although an instrument being developed will have an analysis area of about a 150 μm, or 5900 μin., diameter), a high vacuum requirement (10^{-6} to 10^{-9} Pa, or 10^{-8} to 10^{-11} torr), lengthy test time ($\frac{1}{2}$ to 8 h per sample), and low resolution (• 0.1 to 1.0 eV). Charging and energy referencing can also be a problem. It may be necessary to consult the literature and examine a large number of spectra to obtain practical experience with spectral interpretation and analysis for a wide range of sample types. Other instrumental surface analysis techniques that are available and widely used include Auger electron spectroscopy (AES) and secondary ion mass spectroscopy. The Auger technique is actually much older in practical application than XPS. Because AES uses an electron beam, it is generally highly damaging to organic polymer surfaces, but, as a form of electron spectroscopy, it is complementary to XPS. Secondary ion mass spectroscopy has been applied to polymer surfaces, but is not yet used routinely nor is it as easily interpreted as XPS. Secondary ion mass spectroscopy is undergoing extensive development and may prove to be useful for routine polymer surface analysis. Table 1 compares the features of numerous techniques.

Table 1 Comparison of instrumental techniques for surface analysis of fibers

Technique	**Quantitative analysis**	**Structure**	**Electronic levels**	**Vibrational levels**	**Depth profiling**	**Spatial resolution**	**Adsorption energy**	In situ fingerprint
Auger electron spectroscopy	+	+	+		+	+		
Low-energy electron diffraction		+						
X-ray photoelectron spectroscopy	+	+	+					
Electron energy loss spectroscopy		+		+	+			
Secondary ion mass spectroscopy	+				+	+		
Scanning electron microscopy						+		
Thermal desorption mass spectroscopy	+						+	
Fourier transform infrared spectroscopy		**+**		**+**				**+**

The carbon assay is done according to ASTM C 571 (Ref 1, discontinued in 1995) or ASTM C 831 (Ref 2) and basically involves combustion of the product to form carbon dioxide and an absorption train to collect and compute the original carbon content.

Sizing/Finish Content. High-strength fibers may have sizing applied to their surfaces to improve bonding, handling, or resin-fiber interface characteristics. Determining sizing content is very direct: the fibers are weighed, the sizing removed, and the fibers are weighed again. Typical methods include extraction with an appropriate solvent to achieve total solvation of the size, but with no attack on the fiber, and pyrolysis at a temperature that will burn off the sizing but not affect the fiber. It should be noted that both methods are overly idealistic from a practical viewpoint. Extraction frequently does not solvate all of the sizing, while pyrolysis frequently results in fiber weight loss.

For glass or quartz fibers, a size is typically applied in the fiber manufacturing stage to aid in processing the fibers into the final fabric form. The sizing may then be removed and a coupling agent added to aid resin-fiber bonding. This final application is typically referred to as a “finish” for these fiber types.

Physical Tests

Seven physical characteristics of reinforcements and the tests that measure them are described subsequently.

Density is best measured by means of ASTM D 792 (Ref 3) using displacement, ASTM D 3800 (Ref 4) using Archimedes principle, or ASTM D 1505 (Ref 5) using a density gradient column. These are all well-established methods that can be used with confidence.

Weight Per Length (Yield). A simple test is accomplished by weighing a known length of fiber. It is typically reported in g/μm (lb/μin.).

Filament diameter can be measured in two ways, direct and calculated, both of which are limited to round cross sections. The direct method is to view the fiber under a microscope or by microprojection in accordance with ASTM D 578 (Ref 6). Alternatively, the average filament diameter can be calculated from the following equation:

$$D = (4WPL)^{1/2}/(\pi \cdot \rho_f \cdot k)$$

where D is the filament diameter, WPL is the weight per length, ρ_f is fiber density, and k is the number of filaments per tow. Other methods of measurement include cross-sectional microscopy and image analysis with a vibroscope. Irregular cross sections are microphotographed and measured planimetrically.

Electrical conductivity can be measured by means of a simple resistance probe. A test setup similar to Fig. 1 may be used. The weight is hung to preclude wrinkling of the fiber. The resistance is measured at 25, 50, 75, and 100 mm (1, 2, 3, and 4 in.) intervals. Resistance versus distance plotted and the slope of line indicate the resistivity of the fiber. Because the resistivity is also a function of the cross-sectional area, the necessary filament data, that is, the number of filaments per tow and the filament diameter, should also be reported.

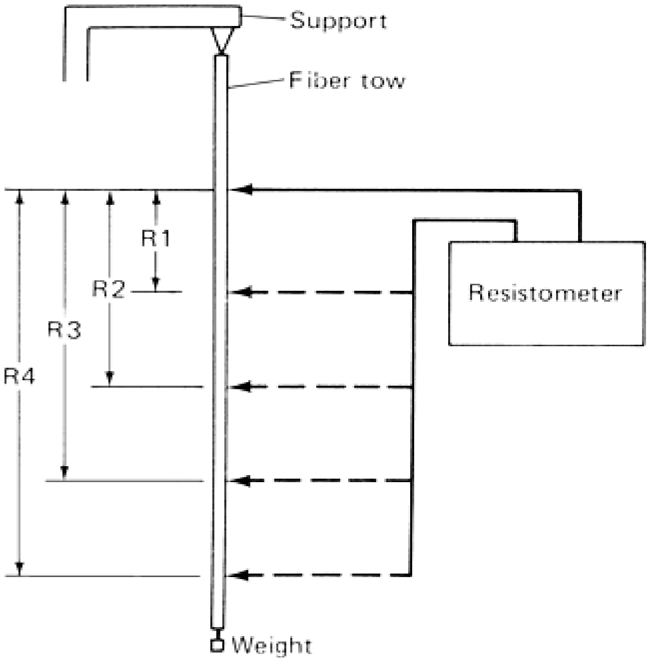

Fig. 1 Typical test setup for measuring electrical conductivity of fibers

Thermal Expansion. Many thermal expansion procedures exist, but none give consistent, reproducible data when measuring fibers.

The number of twists per unit length of a carbon-fiber tow is determined by a twist test. The sequence is:

- Any frayed surface fiber is removed from the carbon fiber to be tested.
- Spool to be sampled is placed on spool holder.
- Fiber is unspooled, while being kept from twisting, and locked in the fixed clamp at the end of the cutting board.
- The free clamp is attached at the 1220 mm (48 in.) cutting edge, but sample is not cut from spool.
- A fine, pointed, polished stylus is inserted into the center of the sample at the opposite 1220 mm (48 in.) cutting edge, where the free clamp is located.
- The stylus is drawn down the sample, splitting the tow to the free clamp (making sure the movable clamp does not rotate).
- The stylus is backed off approximately 25 mm (1 in.) from the free clamp, and the number of fiber rotations to the free clamp is observed. The twist per mm (in.) (tpmm, or tpi) equals the number of rotations of fiber/1220 mm (48 in.).
- Results are reported to two significant digits. Example: 1.5 rotations/1220 mm (48 in.) = 0.0012 tpmm (0.031 tpi)

Fabric Weave. When fibers are woven into fabrics, the physical properties listed subsequently are measured.

Yarn count is defined as the number of tows/ mm (tows/in.) in both the warp and fill directions. This is done by simply measuring the dimensions of an undistorted fabric and removing and counting each thread. Data should be reported as the number of warp threads/mm (warp threads/in.) and number of fill threads/mm (fill threads/in.).

Fabric areal weight is measured by weighing a piece of undistorted fabric and measuring its surface area. The data is reported as g/m^2 (oz/yd^2).

Tensile strength of dry fabric may be measured using ASTM D 579 (Ref 7); however, it would be better to measure the tensile strength of an impregnated laminate, because the translation of dry fabric properties to composite properties is poorly understood.

Mechanical Tests

It is important to note that mechanical properties of fibers are very test-dependent. For example, Table 2 shows the difference in tensile strength of a typical fiber tested as a filament, tow, and laminate, all reduced to 100% fiber volume. These data emphasize the importance of identifying the test method when reporting test data.

Table 2 Effect of test method on fiber properties

Test	Nominal tensile strength					
	AS4		**IM6**		IM7	
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	ksi
Filament	4100	595	4950	715	5400	**780**
Tow	4000	580	5050	730	5450	**790**
Laminate	**3850**	**555**	**4300**	**625**	**4600**	**665**

Single-filament tensile strength can be determined using ASTM D 3379 (Ref 8), which can be summarized as a random selection of single filaments made from the material to be tested. Filaments are centerline-mounted on special slotted tabs (Fig. 2). The tabs are gripped so that the test specimen is aligned axially in the jaws of a constant-speed movable-crosshead test machine. The filaments are then stressed to failure at a constant strain rate. For this test method, filament cross-sectional areas are determined by planimeter measurements of a representative number of filament cross sections as displayed on highly magnified photomicrographs. Alternative methods of area determination include the use of optical gages, an image-splitting microscope, or the linear weight-density method.

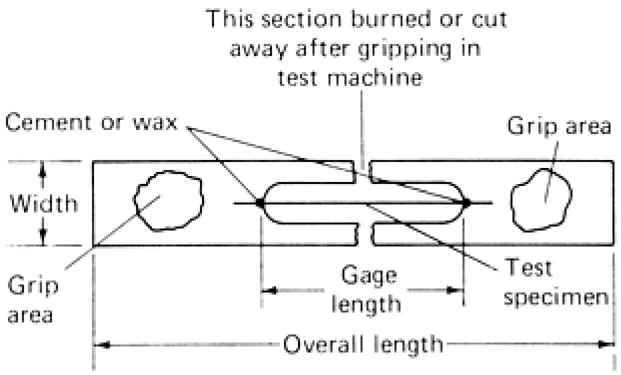

Fig. 2 Schematic showing typical specimen-mounting method for determining single-filament tensile strength

Tensile strength and Young's modulus of elasticity are calculated from the load/elongation records and the cross-sectional area measurements. Note that a system compliance adjustment may be necessary for single-filament tensile modulus.

Tow Tensile Testing. Using ASTM D 4018 (Ref 9) or an equivalent is recommended. This is summarized as finding the tensile properties of continuous filament carbon and graphite yarns, strands, rovings, and tows by the tensile loading to failure of the resin-impregnated fiber forms. This technique loses accuracy as the filament count increases. Strain and Young's modulus are measured by extensometer.

The purpose of using impregnating resin is to provide the fiber forms, when cured, with enough mechanical strength to produce a rigid test specimen capable of sustaining uniform loading of the individual filaments in the specimen.

To minimize the effect of the impregnating resin on the tensile properties of the fiber forms, the resin should be compatible with the fiber, the resin content in the cured specimen should be limited to the minimum amount required to produce a useful test specimen, the individual filaments of the fiber forms should be well collimated, and the strain capability of the resin should be significantly greater than the strain capability of the filaments.

ASTM D 4018 method I test specimens require a special cast-resin end tab and grip design to prevent grip slippage under high loads. Alternative methods of specimen mounting to end tabs are acceptable, provided that test specimens maintain axial alignment on the test machine centerline and that they do not slip in the grips at high loads. ASTM D 4018 method II test specimens require no special gripping mechanisms. Standard rubber-faced jaws should be adequate.

Laminate Properties. The most generally representative procedure for measuring composite properties is to combine the fiber and resin and to test the composite as a cured laminate, because this is the form in which the materials are used. It is important to understand that laminate properties are a function of fiber, resin, and interface properties. Table 3 shows the dependence of mechanical properties on the resins used. Another factor to consider is the fiber volume fraction of the laminate. A fiber volume of 55 to 65% has been found to allow consistent measurement of properties. Because tensile properties are fiber-dominated, it is recommended that tensile strength and modulus be normalized to a constant fiber volume. A normalized fiber volume of 100% is common. This is done simply by using the following equation:

$$\text{Property (100\%)} = (\text{property} \times 100)/(\text{fiber volume, \%})$$

Table 3 Effect of resin on laminate properties

Material		**Tensile strength**		**Tensile modulus**		Short beam shear	
Fiber	**Resin**	**MPa**	**ksi**	**GPa**	**10^6 psi**	**MPa**	ksi
AS4	2220-3	3650	527	221	32.1	106	**15.4**
AS4	3501-6	3450	500	225	32.7	124	**18.0**
AS4	3502	3000	435	223	32.4	134	**19.4**
AS4	**4502**	**3000**	**432**	**220**	**31.9**	**102**	**14.8**

Note: Tensile data normalized to 100% fiber volume

Laminate tensile testing should be conducted in accordance with ASTM D 3039 (Ref 10) or ASTM D 638 (Ref 11) for quartz or glass. Major concerns when conducting this test are:

- *Verification of collimation of fibers*: The specimens should be cut 0°± $\frac{1}{4}$° from the fiber direction
- *Machining quality*: Specimens should be cut with a diamond blade circular saw, 180 grit minimum, using a water coolant. Specimens should be inspected to verify that no specimen damage was caused by machining.
- *Surface quality*: The panel should have a resin-rich surface to preclude fiber splitting. This can best be done by using an appropriate peel ply. Burlington peel ply 51789, style 52006, has been found to yield excellent results.

The apparent interlaminar shear test (previously referred to as a "short beam shear" test) is of little value to a designer, because apparent interlaminar shear strength is not necessarily representative for a pure shear test. However, this test is an inexpensive, easily done measurement of the quality of the laminate and fiber interface. It should not be used to compare fiber-resin systems. For example, a true shear test run on the systems shown in Table 3 would show 2220-3 resin-AS4 fiber to have higher shear strength than 3501-6 or 3502 resin. The test, however, is sensitive to changes within a product; because it has been shown to be a very valuable quality control test to identify changes in fiber-resin interfacial quality, it may be used to monitor product changes.
The short beam shear strength should be determined in accordance with ASTM D 2344 (Ref 12). This is a simple three-point bending test with a span-to-depth ratio of 4 to 1 and a nominal thickness of 2.03 mm (0.08 in.).
See the article "Lamina and Laminate Mechanical Testing" in this Volume for additional information on generating laminate mechanical property data.

Constituent Materials Testing

Shari Bugaj, FiberCote Industries, Inc.

Tests for Matrix Resins and Prepregs

This section defines some of the basic materials used for thermoset and thermoplastic resin matrices and their most significant chemical and physical tests. The individual characteristics are identified along with the test methods normally used for their determination. Many of the recommended tests are directed at the chemical properties of the resin. A complete evaluation of physical properties must also be performed to ensure that controls are adequate. Properties can be varied rather widely by the selection of the matrix resins, curing agents, and modifiers. Therefore, it is important to understand what these properties are and what effect they have on the resin matrix, impregnated fiber, and processing of the product. All tests described in this article are relative to uncured components and uncured and cured matrix systems. More detailed information about these resins is available in the Section “Constituent Materials” in this Volume.

Thermosets

The term *matrix* refers only to the nonfiber component of a composite. The key function of the matrix is to aid in the handling and processing of the fibers while translating the properties of the fibrous component in the composite. The matrix must also perform in a desired temperature envelope specified by the end-use application. The thermoset resins most widely used for composite matrices are epoxies, bismaleimides, phenolics, polyesters, vinyl esters, and polyimides. The properties of the uncured resins that are of most interest are the equivalent weight and viscosity, or rheological, values. When the equivalent weight is known, it is possible to calculate the optimal amount of curing agent required for the resin. The viscosity of the resin is a convenient index for its handling and flow characteristics during cure. Other properties of more limited interest include softening point, melting point, molecular weight, molecular weight distribution, specific gravity, refractive index, and chlorine content.

Of the thermoset systems being considered, only polyesters, vinyl esters, and epoxies require the addition of other ingredients to facilitate polymerization. There are other ingredients in some systems, particularly epoxies and bismaleimides, that serve as modifiers and, as such, may or may not enter into the chemical reactions during curing.

Epoxies are among the most widely used resins, because of their overall balance of properties. Their mechanical properties are superior to those of polyesters and phenolics, and they offer improvements in environmental/moisture resistance, fatigue resistance, and interlaminar shear strength. They also provide a combination of cross-link density and elongation that yields a balance of suitable properties over a broad temperature range. Because of this versatility, epoxies are finding increased use as matrix materials.

There are a large number of epoxy resins commercially available. The diglycidyl ether of bisphenol A (DGEBA), epoxy novolac, and tetraglycidyl-4,4′ diamino diphenyl methane (TGDDM) are the most commonly used epoxy resins for matrix formulation. Key property tests are listed in Table 4.

The bismaleimide (BMI) resins available commercially are limited. These resins have backbones similar to those of epoxies, but contain different functional end groups. The most basic and widely used resin is the bismaleimide of methylene dianiline (bis F). Bismaleimide resins cure by means of addition polymerization with little or no evolution of volatiles. They are prime candidates for matrix resins because of their high-temperature resistance, environmental stability under hot/wet conditions, superior smoke/toxicity properties, and epoxy-like processing. They tend to be more brittle than epoxies, but can be formulated to achieve various combinations of cross-link density and elongation that provide matrix resins with balanced properties.

Bismaleimides are being used in applications that require temperature performance between that of state-of-the-art epoxies and polyimides. Key property tests are listed in Table 4.

Phenolic resins are available commercially in a wide variety of types. The two main types are a single-stage resole and a two-stage novolac. The resole phenolic is the most widely used, because of its handling characteristics in the impregnated form. It cures by means of a condensation-type reaction in which water is formed as a by-product. The resultant matrix is highly cross linked, but can be formulated with a wide variety of materials. The volatile by-products limit the use of resole phenolic for some composite applications. Phenolics have high heat and chemical resistance, good dielectric properties, dimensional and thermal stability, and surface hardness. They yield low smoke and toxicity properties after combustion, which is important for many applications. Key property tests are listed in Table 4.

Polyesters. Of the wide variety of polyester resins commercially available, those most commonly used are alkyd and unsaturated polyesters. These resins can be combined with monomers, such as styrene, to form a

cross-linked matrix. Both alkyd and unsaturated polyester matrices can be used for diverse composite applications. Alkyd polyesters have good arc-track resistance and show outstanding retention of dielectric strength up to 175 °C (350 °F). Their highly cross-linked resin structure gives good dimensional stability at elevated temperatures. However, the percentage strength retention at elevated temperature is not as great as for some of the other matrix resins. In general, polyesters yield moderate composite properties and have poor chemical and hydrolytic resistance compared to other materials. Higher levels of matrix shrinkage during cure are also a detriment for some applications. Because polyesters can be cured quickly by means of a free-radical process and generally are less costly, there is incentive for using them in composites when their mechanical properties suit the application. Key property tests are listed in Table 4.

Polyimides. There are a limited number of polyimide resins available for use as composite matrices. These systems cure by means of a condensation reaction with evolution of a high level of volatiles. The two types of polyimide resins most widely used are PMR-15 and the family of pyromellitic dianhydride/oxydianiline polymers. These materials possess exceptionally high thermooxidative stability. However, the higher the oxidative stability, the more difficult they are to process. Polyimides are being used in composites applications that require temperature performance at temperatures (110 to 190 °C, or 230 to 375 °F) above the capabilities of BMIs. Their use is limited, because of the high volatile levels given off during cure. These volatiles pose severe processing problems for applications requiring large, thick composite parts. Nevertheless, the commercial success of polyimides in a variety of high-technology applications can be attributed to resin matrices with a good balance of thermooxidative stability, high glass transition temperature, and processing parameters. Key property tests are listed in Table 4.

Cyanate Esters. Another thermoset resin that is currently finding increasing potential as a matrix material is the cyanate ester. These resins perform in the same temperature range as epoxy resins, but offer a different balance of properties. Cyanate esters provide different formulation opportunities, because of their unique cure chemistry. They also are capable of co-curing with certain other thermosets, thus increasing formulation latitude.

Other Thermoset Resins. A wide variety of other matrix materials is also commercially available to provide specific end-use properties. For example, polybutadiene has excellent low- loss electrical properties with very flexible processing.

Formulations

Matrices or neat resin systems are mostly blended with ingredients that are added to impart a desired property to the prepreg and/or cured composite. Proper formulation of resin compounds requires knowledge of the molecular structure of the resins as well as their chemical/ physical properties and curing reactions. The structure of the resin determines its physical and chemical properties. The number and location of the reactive sites determine the functionality and the cross-linking density. These properties establish the rigidity, thermal stability, solvent resistance, and other properties of the cured system. Resin structure also determines the viscosity of the resin, an important factor for processing. Resins are only building blocks in the development of a matrix formulation. A formulation may ultimately involve several resins combined with curing agents, catalysts, and modifiers such as fillers, flow control agents, or flexibilizers. Each component contributes to the final properties of the prepreg and cured composite and represents a major variable. Once the performance requirements of an application are known, an appropriate neat resin matrix can be formulated.

It is essential to identify key properties and define an acceptable range for each one before assigning a suitable test to measure those properties. Tests are typically performed on the individual components as well as on the uncured final formulation in order to better understand and characterize the resin system. Various chemical and physical tests are run on all types of resin matrices to ensure overall consistency and correct ingredient amounts, functional groups, molecular weight distribution, kinetics, and advancement levels.

To exemplify a neat resin matrix formulation, a typical epoxy matrix would contain epoxy A, epoxy B, a catalyst, and a curing agent. For example, most applications requiring a service temperature up to 120 °C (250 °F) would combine DGEBA (epoxy A) and/or DGEBA with epoxidized phenol novolac resins (epoxy B) with a dicyandiamide curing agent and tertiary amine salt catalyst.

An example of a current state-of-the-art epoxy-matrix system suited to a service temperature up to 177 °C (350 °F) would have TGDDM as epoxy A, diaminodiphenylsulfone as the curing agent, and a salt of BF_3 as the catalyst. Elastomer modifiers or flexible resins would be added as needed to improve toughness. For both of

these examples, high-performance liquid chromatography (HPLC), differential scanning calorimetry (DSC), infrared spectroscopy, and rheometric dynamic scanning (RDS) viscosity tests are run to characterize the resin and ensure the quality of the molecular weight distribution, cure kinetics, functional groups, and rheological behavior for each batch of material. The chemical properties normally reported for these neat resin systems are those given in Tables 4 and 5. Chemical and physical property testing is performed on uncured neat resin systems prior to impregnation and on impregnated systems after cure. During system development, some properties are also measured on cured neat resin.

HPLC, high-performance liquid chromatography; GPC, gel permeation chromatography; RDS, rheometric dynamic scanning; DSC, differential scanning calorimetry; ARC, accelerated rate calorimeter; TGA, thermogravimetric analysis

A typical BMI could contain a bis F, divinyl benzene (DVB), and thermoplastic resin. This example is a formulated matrix for applications requiring service temperatures up to 230 °C (445 °F). The bis F resin provides high-temperature properties, the thermoplastic resin modifies the rheology, and the DVB provides both matrix toughness (elongation) and tack. Applicable property tests are listed in Table 5.

A typical phenolic matrix would combine resole phenolic, ethyl alcohol, polyamide resin, and a catalyst. Resole phenolics, available in an alcohol solution, can be used directly as a matrix material with an inorganic acid catalyst. Nylon 6,6 polyamide resin can be added to improve matrix toughness and flow characteristics. Applicable property tests are listed in Table 5.

A typical polyester matrix would have an unsaturated polyester resin, styrene monomer, hydroquinone, and a promoter. A large variety of thermoset polyesters are commercially available that already contain styrene monomer. Inhibitors (such as hydroquinone) and promoters are added for gel- and cure-time control. Additional resins, such as isocyanates, can be added to improve toughness. Applicable property tests are listed in Table 5.

As discussed previously, only a limited number of polyimide resins are available for use as a matrix for composites. The complex processing technology required narrows the number of resins that would be useful for a matrix resin. One of the most commonly used resins is PMR- 15. Applicable property tests are listed in Table 5. The presence of MDA (methylene dianiline), a suspected carcinogen, in PMR-15 has severely limited the number of end-use applications of PMR-15 in recent years. Some polyimide resins that do not contain MDA have been developed (see the article “Polyimide Resins” in this Volume).

Prepreg Forms

All five of the major families of matrix resins can be used to impregnate various fiber forms. The resin is then no longer in a low-viscosity stage, but has been advanced to a B-stage level of cure for better handling characteristics. The type of prepreg form is highly dependent on the end-use requirement. Four of the main forms of composite materials are unidirectional fiber tapes, woven fabrics, roving, and chopped mat. Fiber reinforcement may be in the form of strands that are composed of a number of very fine filaments. Strands can be gathered into continuous roving, chopped to provide mats, or twisted into yarns and woven into cloth. Fiber type can be glass, carbon, quartz, or aramid. Resin content in all forms must be tested, because it is one of the critical parameters for composite performance. The resin content is dependent on the laminating pressure and is of major importance, because, in conjunction with the fiber, it determines the strength of the ultimate laminate. Likewise, fiber areal weight is monitored, because the amount of fiber present in a composite laminate affects the ultimate strength. Property tests for the four prepreg forms are discussed subsequently.

Composites may also be processed by other techniques, such as wet lay-up or resin transfer molding, where the composite is made by combining the dry reinforcement directly with the liquid resin and curing—eliminating the preimpregnation step. These techniques offer particular advantages in appropriate situations and also allow a greater variety of reinforcement forms to be used, such as net-shape three-dimensional braids. For these process techniques, the resin and reinforcement are characterized separately, using the following guidelines as appropriate. The final composite properties are then determined as appropriate, often via element or subelement testing.

Unidirectional Tapes. Numerous fiber strands (tows) are creeled and spread while being combined with the resin matrix to produce a unidirectional tape prepreg. Once a tape is produced, the physical tests of resin content, fiber areal weight, volatile content, gel time, and flow can be run to characterize the system and ensure consistency. Chemical tests performed include HPLC, DSC, and infrared spectroscopy, as shown in Table 5. Unidirectional tapes are more commonly fabricated via a hot-melt method, although some solvent production lines are currently in use.

Woven fabrics provide more-uniform but lower composite strength properties than do tapes, but are nonetheless used extensively, because of the ease of fabrication and strength in both directions. Fabrics are produced in a broad range of styles, widths, and lengths. Woven fabrics can be impregnated either by means of a hot- melt or solution method, with the solvent being subsequently removed. The physical and chemical tests used to characterize woven fabrics are the same as those used for tapes.

Continuous strand rovings lend themselves to automated fabrication techniques by means of winding. Rovings may be impregnated in a solvent process and then wound on a core after the removal of solvent. Wet winding of low-viscosity blends of completely reactive components (containing no nonreactive solvents) is also widely done. Prepreg rovings typically provide better resin content control than that provided by wet winding. Physical tests include resin content, volatiles, band width, gel time, and yield (m/kg). Chemical tests are the same as those used for tapes and fabrics.

Chopped mat is a form that produces lower- cost structures with uniform strength characteristics. Composite strength properties are generally lower than those of woven fabrics. Physical tests should include resin content, areal weight (g/m^2), volatiles, gel time, and flow. Chemical tests should be run according to the applicable resin family (Table 5).

Thermoplastics

In conventional applications of thermoplastics, data from the physical and chemical property tests listed subsequently are usually offered by the resin supplier to inform the user of the behavior of the material:

- Tensile strength, yield, and break
- Elongation, yield, and break
- Tensile modulus
- Linear thermal expansion
- Electrical properties, including dielectric strength, dielectric constant, volume resistivity, dissipation factor
- Flexural strength, yield, and break
- Compressive strength
- Izod impact, notched
- Hardness (Rockwell)
- Water absorption, 24 h
- Thermal conductivity
- Continuous service temperature
- Processing temperature or melting point
- Heat-deflection temperature
- Solvent and chemical resistance
- Environmental resistance

Each thermoplastic polymer application has a need for some data from this list of tests. The processing method or the end use usually requires specific information about the chemical and physical nature of the material.

Impact Strength. Some of these tests assume special importance and even criticality for fiber- reinforced thermoplastics. For instance, the consideration of impact strength is significant in advanced composite applications. In fact, the behavior of thermoplastics in terms of their stress-strain relationship is the underlying reason for their consideration in impact-resistant and damage-tolerant applications. Looking at the stress-strain behavior of neat conventional thermosets, such as diaminodiphenysulfone-cured epoxies, one sees low strain and a steep curve all the way to failure. In the case of thermoplastics, strain is usually greater, but a unique behavior is observed before failure.

This phenomenon is the special involvement and the changes in molecular orientation that are known as yield. At the yield point, the average axis of molecular orientation begins to conform increasingly with the direction of the stress. Other terminology, such as draw, is sometimes used. There is usually a break in the stress-strain curve as it begins to flatten out, and more strain is observed with a given increased stress. The result is that the macromolecules begin to align and cooperate in their resistance to the applied stress. Frequently, there is a final increase in the slope of the curve (*strain hardening*) just before ultimate failure (Fig. 3). The extent to which this orientation takes place varies from one linear thermoplastic to the next, but the effect is quite significant in the behavior of such materials in these fiber-reinforced systems. Even the smallest amount of the orientation effect imparts greatly improved impact resistance and damage tolerance. In thermoplastics, there is much more area under the stress-strain curve; this area is a direct function of the work-to-failure.

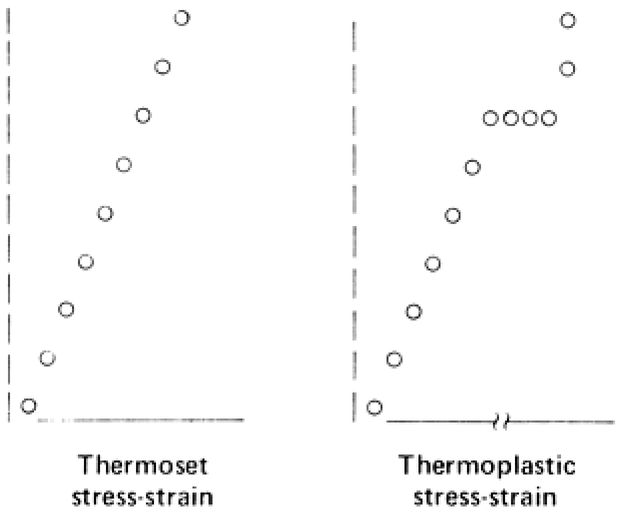

Fig. 3 Thermoset versus thermoplastic stress-strain behavior

Conventional thermosets do not behave this way and can be thought of as rigid networks that have a more glassy failure mode with much less area under the stress-strain curve. Thermoplastic resins being considered today as matrices for composites have relatively high values for their modulus or low strain-stress ratios. The molecular orientation effects are small but nevertheless quite important in their effect on toughness. Values for Young's modulus approaching 3450 MPa (500 ksi) have been reported. Such numbers are comparable to those of the thermosets. When these new, stiffer, and tougher resins began to appear, the need developed for more discriminating testing to evaluate the toughness and damage tolerance of composites fabricated with them.

Toughness and Damage Tolerance. Both National Aeronautics and Space Administration (NASA) and industry representatives have selected and standardized a set of five common tests for characterizing the toughness of fiber- resin composites. As the development of new, tougher thermoplastic-matrix resins is reduced to specific applications, these identified tests will become the standards for characterizing the new thermoplastic-based composites.

For interlaminar fracture toughness (G_{Ic}), the edge delamination and double cantilevered beam tests have been defined as appropriate. For damage tolerance, open-hole compression, open-hole tension, and compression after impact have been defined.

It should be noted that each test has its own set of problems. For example, failures in the double-cantilever beam test seldom occur solely in mode I (peel). In the past, different laboratories have used composite specimens with different resin content and fiber types, as well as different specimen dimensions and impact stress levels. In spite of these problems, test refinements have been made and reliable test data have begun to emerge. See Table 6 for G_{Ic} values.

Table 6 Interlaminar fracture toughness (G_{Ic}) values of thermoplastic resins

Material	**J/m²**	ft · lbf/ft²

Polyamideimide	1050	**70**
Polysulfone	1175	**80**
Polyether etherketone	**1600**	**110**

Creep and Environmental Resistance. Special supplemental tests will be needed to assess thermoplastic resins as advanced composite matrices and to provide design assurances in the areas of temperature versus creep and environmental-stress cracking. Because the uncross- linked nature of thermoplastics means a departure from the familiar behavior of thermosets, tests will be needed to provide assurance of service life and reliability. For example, the differences in the failure behavior of many thermoplastics in the stressed and unstressed condition are dramatic, especially when the environmental effects of agents such as solvents and surface- active organics are present.

Creep in thermoplastics will have to be appropriately addressed if these resins are to become reliable matrices for advanced composites. The rigid, random network of the thermosetting resin is, by nature, a significantly

different system than the collection of amassed, large, linear molecules in a thermoplastic. Test procedures and a test data bank will be required.

Creep occurs in thermoplastics, because, unlike thermoset molecules, the molecules of thermoplastics are not bonded together by primary (covalent) bonds. Thus, thermoplastic molecules can make, break, and remake associations with their molecular neighbors. Such behavior allows subtle changes in form and shape. Corresponding reversible changes in thermosets are not possible, because the primary covalent chemical bond is the mainstay for retention of form and shape; once the limit of load-carrying ability is reached, bonds break and the thermoset fails catastrophically. Break and remake of bonds is not possible. The integrity of thermoplastic molecules can be attributed to simple mechanical entanglement, but a great deal of this integrity is due to reversible associations of ordered molecules by van der Waals forces, dipole-dipole interactions, and crystalline lattice energy. Some of the new thermoplastics rely on a high crystalline content for stiffness and creep resistance. The polyphenylene sulfides, for example, exhibit some of the best of both worlds and seem to be tough and damage tolerant.

One of the most difficult test configurations that could be used to define thermoplastic-matrix creep behavior would be a static load on a ±45° tensile coupon. This test would place a sustained load on the thermoplastic polymer, which would require the association forces within and between the polymer molecules to have enough strength and integrity to resist slow deformation and maintain the spatial configuration in this scissoring plane. This situation, difficult enough for the thermoplastic polymer, would be made even more severe by the imposition of an elevated temperature. Unfortunately, this most-difficult scenario for a test coupon can be a real-life load situation for an advanced composite structural component. Similarly, a beam in a static flexing load represents another very difficult real-life configuration in which retention of shape and form would be of critical importance. The influence of the composite designer can be significant in terms of selecting fiber configurations in the composite lay-up that would permit the fiber to handle this stress and let the thermoplastic resin synergistically contribute its best innate features.

Solvent and Chemical Resistance. Because the associative forces of thermoplastics are, by nature, completely different from the strong covalent chemical bond acting as the principal associative force in thermosets, the weaker forces of the thermoplastics can be much more susceptible to disruption by solvents. For example, any solvation around a polar site would alter molecular spacing and upset van der Waals association. Similarly, the strongest of these forces, the crystalline lattice energy, would also be disrupted if a solvent were present with enough solvating ability to come into the interstices in the crystalline structure of the ordered polymer. Thermosets are not immune to such disruption of molecular associative forces, however. It is well documented that the intrusion of water will reduce the glass transition temperature of a typical epoxy system. In fact, water is an agent that also must be considered in thermoplastic matrices.

Resistance to hydraulic fluids, lubricants, fuel, and solvents, especially when under stress, is an important requirement of composites used on aircraft. Many amorphous thermoplastics, such as polyetherimide and polysulfone, are prone to attack by hydraulic fluid and paint strippers, such as methylene chloride. When the crystallinity of a polymer is increased, its resistance to solvents improves. Consequently, polymers such as polyphenylene sulfide and polyether etherketone show better solvent resistance than other, less-crystalline polymers. The long-term suitability of such crystalline polymers in contact with solvents is yet to be determined.

Tests to evaluate solvent resistance have usually been before-and-after assessments of a given mechanical property after immersing the thermoplastic resin in the solvent or agent. A quick, reliable test consists of determining the weight picked up after a period of immersion. Also, dimensional changes can be measured after exposure, especially on neat resins. As described previously, solvent intrusion into polymer matrices disrupts the associative forces and consequently, swells the polymer. This can be detected by a simple measurement of sample dimensions and a calculation of volume change. This will provide an indication of the extent to which the composite may be affected by the solvent; however, mechanical testing is required to determine the true impact on performance. Screening may be done by apparent interlaminar shear testing in accordance with ASTM D 2344 in order to determine the worst- case solvent, which is most commonly water for thermosets. If required, a one-batch mechanical test matrix is then run after exposure to determine the potential knockdown during service. Some thermoplastic resin suppliers provide some information on water, with data on weight increase after a 24 h immersion in water. A more severe test is the 24 h water boil; however, there is some disagreement as to whether the water-boil test is representative of real-life aging.

The intrusion of solvent or any other agent, including water, may also interfere with the associative or adhesive forces at the interface between the resin and the fiber. This is true for both thermosets and thermoplastics. Such interference may be more severe for thermoplastics, because there is typically less functionality to assist in forming special adhesion sites on the fiber. With thermoplastics, the surface-surface strength is more a problem of physical interactions and classical adhesion. Testing interlaminar shear or transverse mechanical properties can assess the detrimental effects of such solvent or water intrusion.

Thermal Expansion. In another volume- change phenomenon, thermosets undergo a significant amount of volume shrinkage when the polymer is formed from its monomeric precursors. This change can be in the range of 3 to 5% of the volume of epoxies. In some addition-type unsaturated polymers, such as BMIs, it can be even higher and can become a source of difficulty by initiating microcracks. This behavior represents a potential advantage for thermoplastics in that such shrinkage is a possible source of microcracking in composite fabrication, especially in fabric or cross-plied laminates. Because the polymerization of thermoplastics is already over at the processing stage, the shrinkage caused by packing improvements on a molecular scale is minimal. The shrinkage that remains is due to contraction upon cooling, which is reported in the supplier's standard data as mold shrinkage or as a coefficient of linear thermal expansion.

Viscosity measurements on thermoplastic candidates for composite matrices are all taken at elevated temperature and, consequently, are not routinely provided by the resin suppliers. The melt values reported in Table 7 give some information as to how the resin will flow under laminating conditions, but the real nature of flow is important in good composite fabrication. If the flow is merely a sintering, there will be a discontinuity between plies, and voids will most likely be present. In processing composites, a good rule of thumb is that some degree of edge flow or bleed will be visible. If this is not the case, voids are likely to be present, because of air entrapment. Some fabricators use unrealistic pressures to prepare study samples; resins that require such treatment will not be suitable for producing good-quality composite structures. Brute force and the preparation of 75 × 75 mm (3 × 3 in.) test laminates are not suitable approaches for evaluating a resin for use in composite fabrication. In addition to the requirement for flow, there is a need for a workable viscosity for good tow wet-out during the initial prepreg process. The viscosity test values shown in Table 7 will change, usually downward, if thermal mistreatment of the polymer occurs during the prepreg or lamination processes or during rework of the finished composite.

Table 7 Melt values of viscosity for selected thermoplastic resins

Material, temperature	Viscosity	
	Pa · s	P
Polyamideimide at 350 °C (662 °F)	10^6	$\mathbf{10^7}$
Polysulfone at 300 °C (570 °F)	10^4	$\mathbf{10^5}$
Polyetherimide at 305 °C (580 °F)	10^5	$\mathbf{10^6}$
Polyphenylene sulfide at 313 °C (595 °F)	10^4	$\mathbf{10^5}$
Polyether etherketone at 400 °C (750 °F)	$\mathbf{10^3}$	$\mathbf{10^4}$

When melting a thermoplastic resin in the prepreg process or, more importantly, in the final fabrication step, all crystalline order is erased (except in unique liquid crystalline polymers). Subsequently, during cooldown, the polymer reestablishes crystalline lattice order. The degree to which this order is reinstated is a function of the viscosity and mobility of the cooling system. If the cooling is fast, there is little time for the molecules to find their appropriate positions in the growing lattice structure. Many of the molecules will lose their mobility as the temperature is decreased and, being unable to move into the proper position to form the crystalline state, will be stranded in an amorphous condition. Conversely, if the cooling rate is slow, most of the molecules, or segments of molecules, will maintain freedom long enough to find their appropriate position in the crystalline state.

Characterization Methods. Some common characterization tests used for oligomers and polymers are not appropriate for the class of thermoplastics being considered for high-performance composite matrices, because the test methods require that the material be in solution. If the thermoplastic composite is to have solvent resistance, it cannot be soluble in any solvent. This is the case for inherent viscosity, for example, because this measurement is made in solution. Similarly, HPLC cannot be used as a characterization method. In composite applications that do not require a high degree of solvent resistance, the methods described might be used. With thermosets, HPLC has been used as a fingerprint characterization and quality- control tool. This analytical technique could be used for soluble thermoplastics.

Other methods, such as infrared spectroscopy, are more suitable for routine characterization or fingerprinting of thermoplastics. Before the advent of Fourier transform infrared (FTIR), infrared spectroscopy was difficult to use as a quantitative tool for measuring subtle changes in structure and concentration. Now that FTIR has been supplemented with improved surface reflectance methods, this technique has become very viable for characterizing and studying thermoplastic resins and is informative for finished thermoplastic composites.

Perhaps the most important characterization methods for both thermoplastic and thermoset composites and composite precursors are gravimetry and mensuration. The values obtained are the criteria most critical to the outcome of successful composite components. Table 8 gives the type of data that are of vital significance to the prepregger, designer, and fabricator.

Table 8 Useful property data for a typical carbon-resin composite

Property	Typical value
Fiber density, g/cm^3	**1.80**
Tow yield, m/kg (yd/lb)	**1100 (565)**
Cured resin density, g/cm^3	**1.2**
Prepreg density, g/cm^3	**1.5**
Prepreg thickness/ply, mm (in.)	**0.15 (0.0067)**
Resin film thickness, mm (in.)	**0.085 (0.0034)**
Resin film areal wt, kg/m^2 (oz/yd^2)	**0.099 (2.946)**
Fiber areal wt, kg/m^2 (oz/yd^2)	**0.149 (4.420)**
Prepreg resin content, %	**40**
Tow count, tows/mm (tows/in.)	**0.17 (4.3)**
Fiber volume fraction, %	**49**
Prepreg yield, m^2kg (ft^2lb)	**4.00 (19.55)**
Flow, %	**5**
Cured ply thickness, mm (in.)	**0.15 (0.0061)**
Fiber vol% (cured), %	**53**

The basic mechanical performance and/or quality of polymer, fiber, prepreg, or composite is primarily determined by mechanical testing of a test coupon to attain the truest assessment of the performance of the material. The coupon test method is thoroughly described in the article “Lamina and Laminate Mechanical Testing” in this Section of the Volume.

Quality Conformance Testing. The previous discussion did not distinguish between characterization, qualification, and quality conformance testing. Quality conformance tests are needed to assure the continued integrity of a previously characterized material system. The tests performed must be able to characterize each batch/lot of material, so that a proper assessment of critical properties of a material system can be made. These critical properties provide information on the integrity of a material system with regard to material properties, fabrication capability, and use. Additionally, the test matrix must be designed to economically and quickly evaluate a material system.

Quality control in a production environment involves inspection and testing of composites in all stages of prepreg manufacture and part fabrication. Tests must be performed by the material supplier on the fiber and resin as separate materials, as well as on the composite prepreg material. The user of the prepreg must perform receiving inspection and revalidation tests, in-process control tests, and nondestructive inspection tests on finished parts. The sampling frequency and specific tests performed for a given resin system may well depend on a statistical analysis of the history of the material. Table 9 provides the typical test scenario required.

Table 9 Typical acceptance and revalidation tests required for suppliers and users

Property	**Testing required**			Specimens required per sample
	Production acceptance (supplier)[(a)]	**Production acceptance (user)[(a)]**	**Revalidation (user)[(a)]**	
Prepreg properties				
Visual and dimensional	X	X	…	**…**
Volatile content	X	X	…	**3**
Moisture content	X	X	X	**3**

Per ply thickness	X	X	X	**1**
Glass transition temperature	X	X	X	**3**
Short beam shear or ±45° tension	X[(b)]	X[(b)]	X[(b)]	**6**
90°/0° compression strength	X[(c)]	X[(c)]	X[(b)]	**6**
90°/0° tension strength and modulus	**X[(b)]**	**X[(b)]**	**X[(b)]**	**6**

(a) Supplier is defined as the prepreg supplier. User is defined as the composite part fabricatior. Production acceptance tests are defined as tests to be performed by the supplier or user for initial acceptance. Revalidation tests are tests performed by the user at the end of guaranteed storage life or room-temperature out-time to provide for additional use of the material after expiration of the normal storage or out-time life.
(b) Tests shall be conducted at room temperature/dry.
(c) Tests shall be conducted at room temperature/dry and maximum temperature/dry (see MIL-HDBK-17 Volume I, Section 2.2.2).

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Introduction

CHARACTERIZATION of nonmechanical properties is performed in the testing and certification of composite materials for two primary purposes:

- To provide the designer with information of a nonmechanical nature that may be important in the final application. Among these are physical attributes such as thickness and density, thermal properties such as thermal conductivity and diffusivity, electrical properties, and flammability properties.
- To provide quality control characteristics of laminates for certification of materials and for quality assurance and control of final parts

In this article, properties with general interest that are commonly investigated will be discussed:

- Per ply thickness
- Constituent content

- Density
- Coefficient of thermal expansion (CTE) and coefficient of moisture expansion (CME)
- Glass transition temperature (T_g)
- Thermal conductivity, diffusivity, and specific heat

Unlike fabrication of parts using metallic materials, fabrication using composites generally involves a final cure of the material. Because this final cure step is often performed by the fabricator, and because the composites materials properties depend on this step, rigorous process quality control is required for critical parts. The physical attributes and constituent measurements described in this article can be used as quality verification tools.

Also in contrast to metallic alloys, the characterization of the composite material is dependent upon the size level at which the material is tested. As explained earlier in this Volume in the article “Overview of Testing and Certification,” testing can be carried out at the constituent, lamina, laminate, and larger levels. Usually, economy is achieved by testing at the lowest level for which results can be analyzed and applied to the finished part.

MIL-HDBK-17, *Polymer Matrix Composites*, Volume 1, *Guidelines* considers all of the previously mentioned nonmechanical properties to be lamina physical properties. Certainly care must be taken in applying properties such as CTE derived at a lamina level to a full-sized component. Variations in the makeup and cure of a large part, intended and unintended isotropy, and residual stresses could affect the CTE of the final part.

It is recognized that there are composites for which the lamina and laminate distinction is not applicable. Small, representative samples of composite materials, such as bulk molded compounds or ceramics reinforced with discontinuous fibers, can be used for materials characterization.

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Per Ply Thickness

The thickness of a composite part is an important property from the standpoint of weight and dimensional compliance and fit in applications that interface other parts, such as hardware. Additionally, thickness per ply is useful as a measure of resin content achieved during cure or consolidation. Part thickness is governed by the number of plies in the lay-up, the amount of matrix resin present (resin content), the amount of reinforcing fiber (fiber volume), and the amount of porosity (void volume). In the case of resin transfer molding, the tool dimensions dictate thickness (by controlling resin content). If it is assumed that the amounts of resin, fiber, and porosity do not vary from one ply to another within the structure, then the thickness per ply times the number of plies is representative of the part thickness. In practice, the proportions of resin, fiber, and porosity may vary somewhat from ply to ply. The magnitude of this variation is largely a function of processing parameters. Generally there is a nominal target thickness per ply that is achieved under normal processing. If more resin is bled off, the final thickness will be lower, the resin content lower, and the fiber content higher.

Measurement of per ply thickness is useful as an indication of resin content and a quality control check on the fabrication process. Thickness measurements are required for mechanical properties testing to determine the cross-sectional area of material under test. Methodology for this measurement is given in Suppliers of Advanced Composite Materials Association (SACMA) SRM 10R-94. This group is no longer active, but the standards are still in use.

In measuring thickness per ply, consistent use of the same type of measuring device is required. A double ball micrometer with 6 mm (0.25 in.) diameter balls is called out in the SACMA standard and is commonly used. Note that a flat anvil micrometer will generally give thicker readings, especially on fabrics, due to the weave causing local regions of the part to be thicker. Other surface texture properties may also give rise to local variations in thickness measurements. The micrometer should have a deep throat, allowing measurement of the center of larger panels. In making the measurement, care should be taken to keep the panel perpendicular to the

micrometer. This becomes a greater issue with larger panels. Other methods for measuring thickness include ultrasonic and noncontacting optical methods.

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Constituent Content

Polymer-matrix composites may contain two or more of the following: a polymer or resin matrix; fibers of polymer, carbon, glass, or other inorganics; and inorganic fillers. Most commonly, the composite consists of one type of fiber and one type of resin. Determination of resin content, along with void content, is useful in characterizing cure and in evaluation of mechanical test results. Reliable test methods exist for determining constituent content in simple composite systems with one fiber and one resin.

ASTM D 2584. For resin matrix/glass composites, ASTM D 2584, "Test Method for Ignition Loss of Cured Reinforced Resins," is commonly used. In this method, a composite specimen is predried and weighed. The specimen is then placed in a tared crucible and inserted in a muffle furnace to burn off all organic material. Following ignition in the furnace, the crucible is cooled in a dessicator and reweighed. The remaining material will include glass reinforcement along with inorganic fillers.

In some cases, the procedure may be modified to differentiate between the inorganic fillers and the glass fibers. The inorganic fillers may be dissolved in acid and the remaining material filtered. This approach may be successful in identifying calcium carbonate fillers, for example. This type of protocol depends on the chemical composition of the fillers and needs to be developed for each system.

ASTM D 3171. Resin-matrix composites may be analyzed using ASTM D 3171, "Fiber Content of Resin Matrix Composite by Matrix Digestion." The method employs standard digestion techniques to digest or remove the resin matrix without dissolving the fiber. Method A, a hot nitric acid digestion, and method B, a sulfuric acid/hydrogen peroxide digestion, are commonly used on carbon-fiber composites. Method C is a sodium hydroxide digestion that is designed for aramid-fiber composites. Other variations of the acid digestion procedure use microwave energy and pressure to speed the digestion process. In any of these methods, it is prudent to evaluate a fiber blank when testing a new or different material. Use of the blank will determine the extent that the fiber is attacked during the digestion process.

Hybrid Composites. More complex composites can be difficult to analyze, depending on the specific makeup of the hybrid. Combinations of the methods discussed previously may be useful to determine constituent content. For instance, for a glass-carbon hybrid, one might first perform an acid digestion to determine total fiber content and then burn off the carbon fibers in a muffle furnace to determine glass content.

Microscopic Evaluation. Another method for characterizing constituent content is through "metallographic" cross-sectioning followed by microscopic evaluation. This evaluation may be enhanced by the use of computer-based image analysis techniques. A small section of the composite is cut and then processed through a series of grinding and polishing steps to ensure an optical finish. When performed correctly, there should be no smear or rounding of the various materials, and the entire surface should be in the same plane. Once polished, the fibers, resin, and voids are visually apparent. Sometimes tougheners in two-phase resin systems may be apparent. One can also verify lay-up and ply count. Computerized image analysis may be used to scan the image and sum the areas of each constituent. The advantages of these methods include the ability to verify ply count and lay-up and to discern through-the-thickness variations in resin and void distribution. These methods eliminate the need for hazardous chemicals and thus eliminate the hazardous waste generated by methods such as the acid digestion method. The disadvantage of the method is that the analysis is limited to the single plane of cross-sectioning. The computer-based image analysis tools can require a significant investment in software and hardware. The imaging methods are not standardized, but there are currently efforts in ASTM D-30 and MIL-HDBK-17 to formalize and standardize these methods.

Measuring Voids. Void volume of composites may be calculated if the composite density, cured resin density, fiber density, and resin and fiber content by weight are known. The cured resin and fiber density must be

known with precision, ± 0.001 g/cm^3. These properties are usually available from the materials supplier and should be obtained for the specific lot of material being evaluated. The calculation for void volume is found in ASTM D 2734, “Void Volume of Reinforced Plastics.” Void volume can also be measured directly when using an image analysis approach.

John Moylan, Delsen Testing Laboratories

Density

ASTM D 792. The density of cured composites is usually measured by a water displacement technique. This technique is found in ASTM D 792, “Specific Gravity and Density of Plastics by Displacement.” The test method uses Archimedes' principle to determine the volume of the material. The mass is determined through direct weighing, and density is calculated from mass divided by the volume. The density of metal- matrix composites and ceramic-matrix composites can also be determined with this method. This method works well on materials with relatively smooth surfaces. Air bubbles can bias the measurement, particularly if they accumulate in surface imperfections or voids.

ASTM D 1505. Other techniques for measuring density include a gradient column technique, where specimens are suspended in a column with layers of materials of known densities. The density is determined from the level the specimen is supported in the column. The density within the column is verified by standard density floats. The method is described in ASTM D 1505, “Density of Plastics by the Density-Gradient Technique.” This method is very accurate when performed correctly, but requires skill and practice to obtain optimal results. It is less commonly performed in actual practice.

Helium pycnometry has also been reported as a method for determining composite density. The accuracy of the technique is dependent on the ratio of the volume of sample to the volume of the chamber. This method may not be as accurate as the liquid displacement technique when the liquid displacement test is performed by an experienced operator. The required equipment is relatively expensive and not commonly found in composites laboratories, but may be justified when large quantities of specimens are to be tested without the need of extreme accuracy.

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Coefficient of Thermal Expansion and Coefficient of Moisture Expansion

The dimensional stability of composite parts is primarily a function of the CTE and the CME. The CTE is the slope of the expansion versus temperature curve and is usually expressed in Système International d'Unitès (SI) units of 10^{-6}/K or 10^{-6}/°C, or customary units of 10^{-6}/°F. It is assumed to be linear over the reported range. The CME is the slope of the expansion versus moisture content curve and is usually expressed in units 10^{-6}/% moisture.

Like other composite properties, CTE is highly isotropic in composite materials. Generally, coefficients of linear thermal expansion are measured in the in-plane (x and y) and out-of- plane (z) directions. The out-of-plane CTE is generally much larger than the in-plane CTE. Within the xy plane, the CTE can be expected to vary with the fiber lay-up. Three methods are commonly used to measure CTE in composites: dilatometry, strain gage measurements, and optical measurements.

Dilatometry and its related technique, thermomechanical analysis (TMA), are described in ASTM D 696 and E 831, respectively. In dilatometry, a small composite specimen is placed in a quartz tube with a quartz rod resting on its surface. As the sample is heated, the relative displacement of the tube to the rod is measured. The dilatometer uses a generally larger sample and was originally designed to measure displacement using dial indicators. A linear variable differential transformer can also be used by this method to measure the displacements. Accuracy is attainable down to several parts per million per degree Celsius. Precision between laboratories using the ASTM D 696 method is 1.5 to 2%. The TMA is an automated instrumental approach to the CTE measurement. Either instrument is calibrated with known standards, such as copper. More accurate measurements are needed in some applications (such as spacecraft). In such cases, optical measurements are performed. MIL-HDBK-17 accepts the D 696 method for in- plane CTE and the E 831 method for out-of- plane measurements.

Strain gages may also be used to determine CTE. This technique is generally slow and expensive for making materials property measurements. It is useful for measuring local CTEs on structures. The unknown specimen and a known material, usually quartz, are tested. The strain gages should be as nearly identical as possible. Both the reference material and the unknown specimen are placed together in an oven or temperature chamber. Care must be taken that the temperature is stable and that both the reference and the unknown sample are at precisely the same temperature. The CTE may then be determined from relative change in strain gage output between the two materials. The process is repeated at several temperatures over the range of interest.

Optical measurement techniques fall into two categories, interferometers and optical levers. Both of these techniques lend themselves to very accurate low-level CTE measurements. With care, accuracies to 0.01×10^{-6}/°C have been reported. Interferometer use is covered by ASTM E 289. The method uses interference patterns that relate directly to the wavelength of light used to measure very small changes in dimensions.

The other optical approach is to use an optical lever. The unknown material is placed together with a known material, such as quartz. The specimen is arranged so that the relative movement of the unknown specimen with respect to the known specimen deflects a laser beam, and this deflection is measured. It should be noted that significant edge effects may be present for composites, particularly at very low CTEs, so specimens representative of the actual size in use are sometimes required.

Moisture Expansion. No ASTM standard for CME currently exists. Investigators commonly test two identical specimens together at the same time, measuring dimensional change in one and specimen and weight change (moisture content) in the other. Effects of moisture gradients through the specimens must be considered. It must also be noted that CME may vary with temperature, so CME measurements at more than one temperature may be required. Besides causing swelling, absorbed moisture in a composite can change the T_g of the polymer and affect the mechanical properties. The means of measuring the rate of absorption (moisture diffusivity) and the total moisture content (moisture equilibrium) are discussed in ASTM D 5229/D 5229M, "Test Method for Moisture Absorption Properties and Equilibrium Conditioning of Polymer Matrix Composite Materials." These topics are addressed in the article "Hygrothermal Behavior" in this Volume.

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Glass Transition Temperature

The glass transition of a polymer-matrix composite is a temperature-induced change in the matrix material from the glassy to the rubbery state during heating, or from a rubber to a glass during cooling. A change in matrix stiffness of two to three orders of magnitude can occur during the glass transition, due to the reduction of long-range molecular mobility of the polymer chains. The temperature range over which the glass transition occurs is a function of the molecular architecture and the cross-link density of the polymer chains. The observed glass transition is dependent on the basic test method, on details such as the heating or cooling rate, and on the test frequency, if a dynamic mechanical technique is employed. In addition to the change in stiffness, the glass transition is marked by a change in the heat capacity and a change in the CTE of the material.

The glass transition is frequently characterized by a T_g, but because the transition often occurs over a broad temperature range, the use of a single temperature to characterize it may give rise to some confusion. The experimental technique used to obtain the T_g must be described in detail for the measurement to be meaningful. The method by which T_g is calculated from the data must also be clearly stated. Reported T_g may reflect onset of the glass transition or midpoint temperature, depending on the data reduction method.

The T_g is also affected by environmental conditions, such as absorbed moisture. Upon exposure to high-humidity environments, polymer matrices will absorb environmental moisture and be plasticized by it. This will lower the T_g. Measurement of the T_g in a composite material plasticized by absorbed moisture poses some difficult experimental challenges. Heating the test specimen, as required for the measurement, will drive off at least some of the absorbed moisture, thereby affecting the measured properties.

Due to the decrease in matrix stiffness that occurs at the glass transition and the low strength of these polymer matrices in the rubbery state, the matrix can no longer function as effectively to transfer load to the fibers or suppress fiber buckling above the glass transition. The glass transition temperature is, therefore, frequently used to define the upper-use temperature of a reinforced composite structural material.

A safety margin of 28 °C (50 °F) between the T_g and the material operational limit (MOL) is a commonly used criterion in industry and is a guideline given in MIL-HDBK-17 for epoxy matrices. This should only be used as an initial estimation for a MOL, however. Testing of critical properties at the MOL temperature and long- term aging followed by additional testing are certainly appropriate. Creep behavior, in particular, will be substantially different above and below the T_g.

Several different methods are commonly used to characterize the glass transition in fiber-reinforced materials.

Differential Scanning Calorimetry (DSC). Because the heat capacity of a composite material changes at the glass transition, DSC may be used to determine T_g. The glass transition is detected as a shift in the heat flow versus temperature curve (Fig. 1). Many calorimeters are supplied with software that may be used to calculate T_g. In some resin systems, this change in heat flow at T_g is pronounced; on others it can be difficult to observe. In composite specimens, the resin content in the specimen is small, and the more highly cross-linked the resin, the smaller the change in heat capacity. It is, therefore, sometimes difficult to detect T_g.

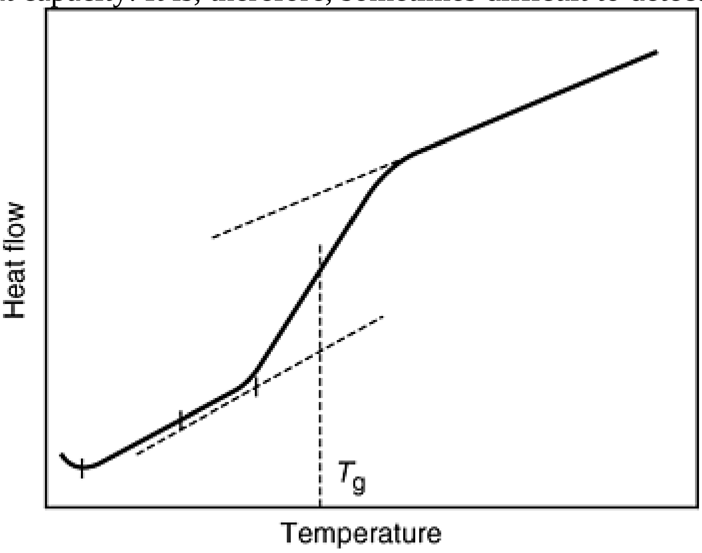

Fig. 1 Heat flow vs. temperature. Glass transition temperature, T_g, is determined by differential scanning calorimetry. Glass transition is marked by a change in heat capacity. Glass transition temperature is characterized as being the midpoint of the transition range. Source: MIL- HDBK-17, Volume 1

Thermomechanical analysis techniques, such as expansion, flexure, or penetration, may also be used to determine T_g. In expansion TMA, the coefficient of linear thermal expansion is measured in the *z*-axis (through the thickness) as a function of temperature. As noted previously, heat capacity undergoes a change during the glass transition. In flexural TMA, a rectangular specimen is loaded in bending, and the dimensional change is measured as a function of temperature. The results of this determination will depend highly on the applied load and specimen geometry, so large laboratory-to-laboratory variation can be expected, unless a very specific protocol is followed. In penetration mode TMA, a sharp probe, similar to that used in a hardness test, is applied to the specimen under constituent load, and the specimen is heated. Near the T_g, the probe will begin to

penetrate the surface of the sample, causing an inflection on the TMA curve. Like flexure TMA, the results depend highly on the applied load and specimen geometry.
Dynamic Mechanical Analysis (DMA). Several types of DMA have been used with composites, including torsion pendulum analysis, other resonant techniques, and forced oscillation measurements in tension, torsion, and shear. These forced measurements are made using a number of DMA instruments manufactured by DuPont, Perkin Elmer, Polymer Laboratory, Rheometrics, TA Instruments, and others. All these DMA techniques produce curves of dynamic storage, loss modulus, and loss tangent as a function of temperature. They reflect the amount of energy dissipated during each cycle of loading and go through a peak value during the glass transition.
The glass transition temperature may be determined from DMA data in several different ways, and this may be a source of differences in the reported values for T_g. The T_g may be determined as the temperature at the onset or the midpoint of the transition based on:

- Storage modulus curve
- Maximum in tan delta
- Maximum in loss modulus

The method used for calculating will produce markedly different values for the same set of DMA data, up to 28 °C (50 °F) difference. The temperature scanning rate and frequency employed will also affect the results.
The lowest DMA value, usually the onset of the observed T_g in the storage modulus curve, will often be the closest estimate of the temperature where a dramatic fall-off in mechanical properties is observed.
Direct Methods. The T_g is also sometimes measured by performing a series of mechanical tests at temperatures near the expected T_g. Matrix-dominated properties, such as ±45 in-plane shear modulus or flexural modulus, are often used. The results are then plotted at 5 °C (10 °F) intervals. The T_g will be apparent as a rapid fall- off of these properties.

Lamina and Laminate Nonmechanical Testing

John Moylan, Delsen Testing Laboratories

Thermal Conductivity, Diffusivity, and Specific Heat

Thermal conductivity, diffusivity, and specific heat are important for predicting heat flow and are used in the design of electronic heat sinks, satellite structural buses, and other applications where prediction of temperature or heat flow is important. Direct thermal conductivity measurement methods are generally made under steady-state conditions. Transient methods actually are determinations of the thermal diffusivity, from which the thermal conductivity may be derived. These are described later in this article. To perform this derivation, specific heat and density must also be known. Specific heat is generally determined by DSC.

Thermal Conductivity

In the steady-state methods, the material is allowed to reach steady-state equilibrium. The test specimen is held in a system with a constant thermal gradient. The temperatures on either side of the specimen are constant, as is the energy to maintain the gradient. On reaching this steady state, the thermal conductivity, λ (W/m · K, or Btu/h · ft ·°F), of a specimen in the thickness direction is determined from the Fourier relation:

$$\lambda = Q/(A\Delta T/L)$$

where Q is heat-flow rate in the metered section (W, or Btu/h), A is the metered section area (m^2, or ft^2) normal to the heat flow, ΔT is the temperature difference (K, or °F) across the specimen, and L is specimen thickness (m, or ft).
Several ASTM test methods are available for steady-state thermal transmission characterizations. The methods are summarized subsequently.

ASTM C 177, known as the guarded hot-plate method, is an absolute determination method covering the measurement of heat flux and associated test conditions for flat-slab specimens. The specimen surfaces are in contact with solid, parallel boundaries held at constant temperatures. This test method is good for low-thermal-conductivity materials and is applicable to a wide variety of specimens and a wide range of environmental conditions. It is most accurate for materials with low conductivity, λ less than 0.5 W/m · K (0.3 Btu/h · ft ·°F). Figure 2 shows the main components of the idealized system: two isothermal cold surface units and a guarded hot plate. The guarded hot plate is composed of the metered area centerpiece and a concentric guard ring. Some apparatuses have a coplanar secondary guard. Sandwiched between these three units is the material to be measured. The measurement, in this case, produces a result that is an average of the two pieces, and therefore, it is important that the two pieces be as identical as possible. A single-sided mode of operation can be used in which the specimen consists of one piece placed on one side of the hot-surface assembly.

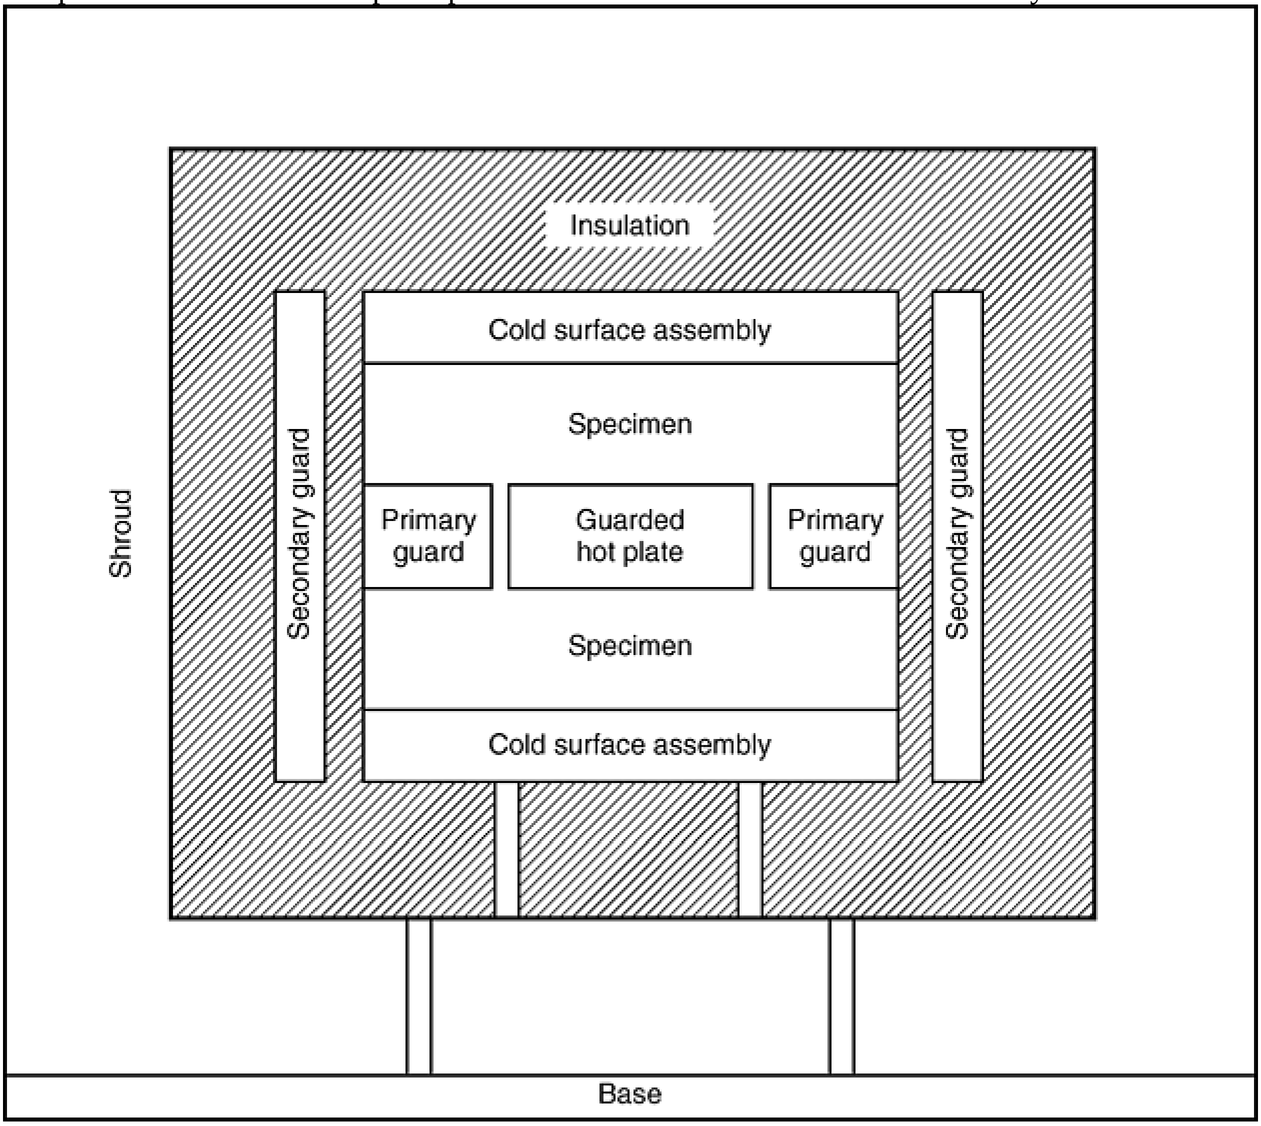

Fig. 2 General arrangement of specimens within a controlled environmental chamber for thermal conductivity measurements using the ASTM C 177 method. This is known as the guarded hot-plate method.

The arrangement of Fig. 2 demands that precautions be exercised concerning heat-flux losses and proper use of the thermal guard ring. Care is necessary for the accurate measurement of temperature differences and the temperature sensor separation. The guarded hot plate provides the power in watts for the measurement and defines the actual test volume, that is, that portion of the specimen that is actually being measured. The function of the primary guard ring is to reduce lateral heat flow within the apparatus.

Steps must be taken to ensure that the heat flows uniformly into the specimen and that there are good thermal contacts at all interfaces. Air gaps must be avoided.

ASTM E 1225, or guarded longitudinal heat- flow technique, is a comparative test method. Hence, reference materials or transfer standards with known thermal conductivities must be used. This test method is for materials with effective conductivities, λ, from approximately 0.2 to 200 W/m · K (0.1 to 115 Btu/h · ft ·°F) over the approximate temperature range of 90 to 1300 K (–300 to 1099 °F). It can be used outside these ranges with decreased accuracy.

The general features of the technique are shown in Fig. 3. A test specimen is inserted under load between two similar specimens of a material of known thermal properties, the meter bars. A temperature gradient is established in the test stack by maintaining the top at an elevated temperature (z_1) and seating the bottom on a heat sink at temperature (z_6). Heat losses are minimized by use of a longitudinal guard having approximately the same temperature gradient. At steady-state equilibrium, the thermal conductivity is derived in terms of the measured temperature gradients in the respective specimens and the thermal conductivity of the reference materials.

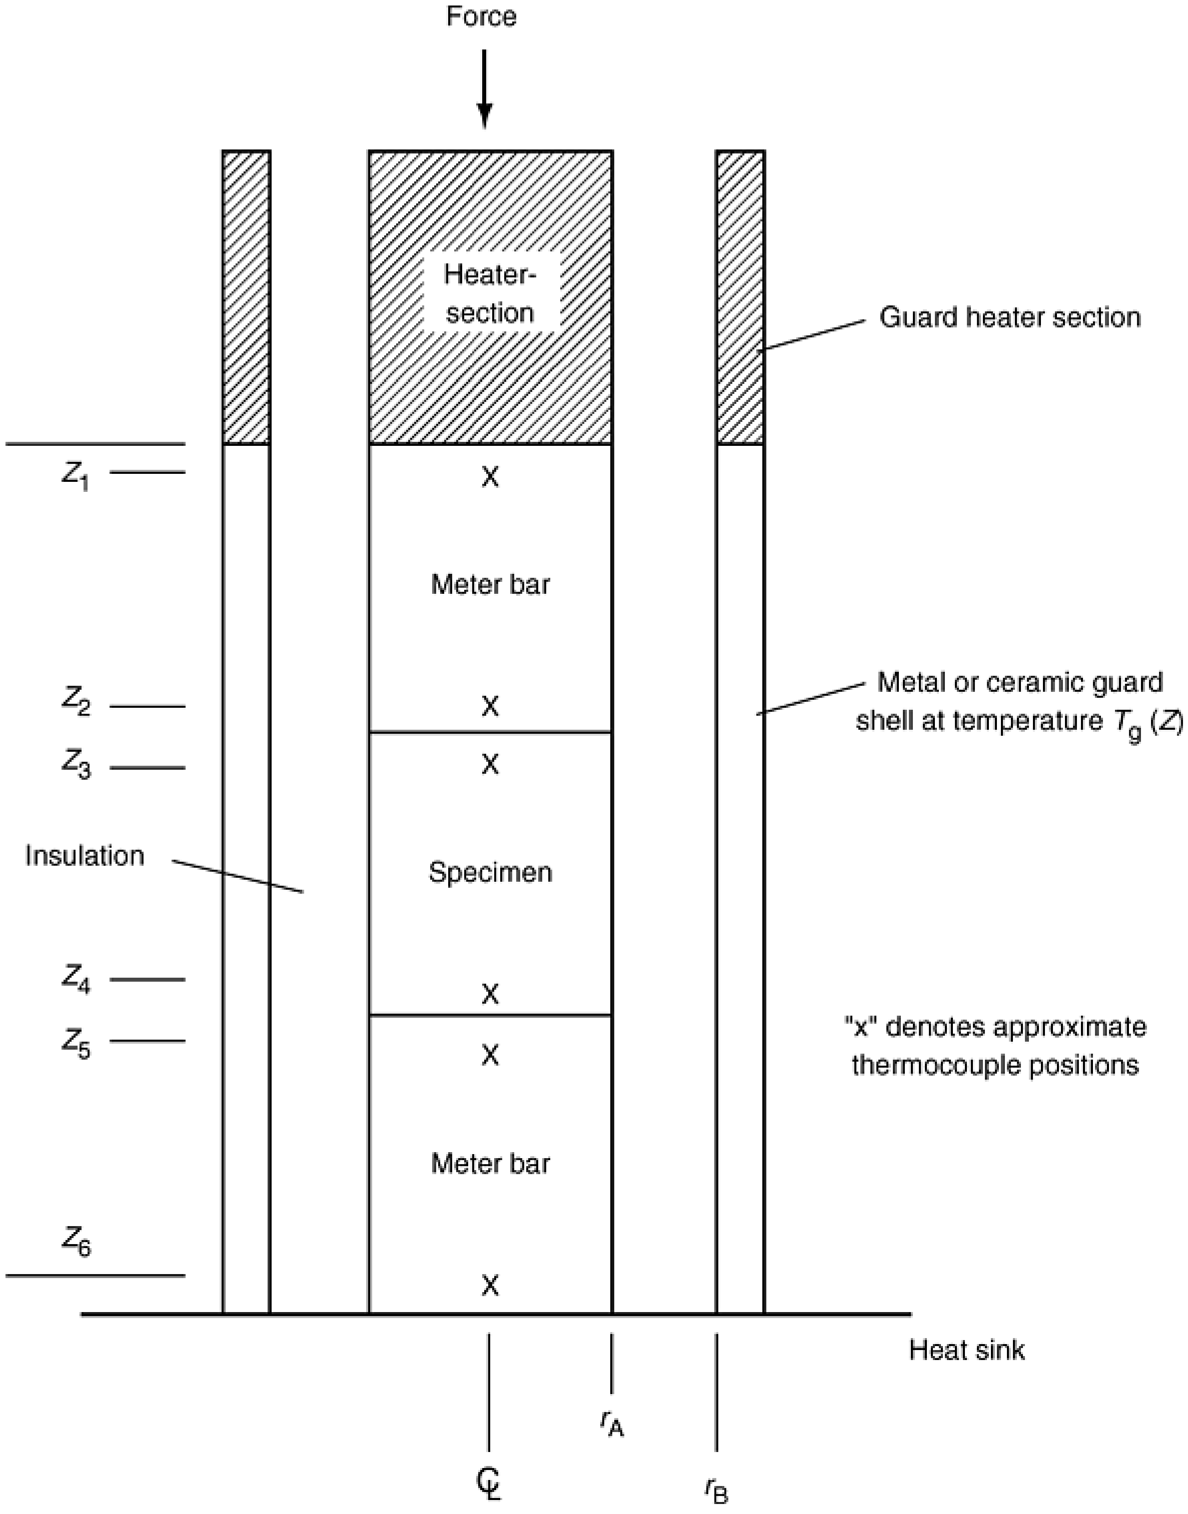

Fig. 3 General arrangement of test specimen and known specimens, the meter bars, in the guarded longitudinal heat flow technique for determining thermal conductivity by the ASTM E 1225 method. z_1 to z_6 are temperatures. For the method known as cut-bar, the specimens are right cylinders with radius r_A

The thermal conductance, the ratio of thermal conductivity to length, of the reference material should match the thermal conductance of the specimen as closely as possible to ensure similarity in temperature gradients and better accuracy. When the meter bars and the specimen are right circular cylinders of equal diameter, the technique is described as the cut-bar method. When the cross-sectional dimensions are larger than the thickness, it is described as the flat-slab comparative method. Essentially any shape can be used, as long as the meter bars and specimen have the same conduction areas.

This test method requires uniform heat transfer at the meter bar to specimen interfaces, which is normally attained by use of an applied axial load in conjunction with a conducting medium at the interfaces. The stack is surrounded by an insulator and enclosed in a guard shell. At steady state, the temperature gradients along the sections are calculated from measured temperatures along the two meter bars and the specimen. This result is a highly idealized situation, because it assumes no heat exchange between the column and insulation and uniform heat transfer at each meter bar/specimen interface. The errors caused by these assumptions are discussed in the ASTM standard.

ASTM C 518 describes the measurement of the steady-state thermal transmission through flat-slab specimens using a heat-flow meter apparatus. This is a comparative, or secondary, method of measurement, because specimens of known thermal transmission properties are required to calibrate the apparatus. The test applies to low-conductivity materials. To meet the requirements of this test, the thermal resistance of the test specimen shall be greater than 0.10 m^2 K/W (0.57 °F · ft^2· h/Btu) in the direction of the heat flow, and edge heat losses shall be controlled using edge insulation and/or a guard heater.

The important features of the heat-flow meter apparatus are two isothermal plate assemblies, one or more heat-flux transducers, and equipment to measure temperature and the output of the heat-flux transducers. Either one or two specimens are used. Three common experimental configurations are depicted in Fig. 4. Equipment to control the environmental conditions is employed when needed.

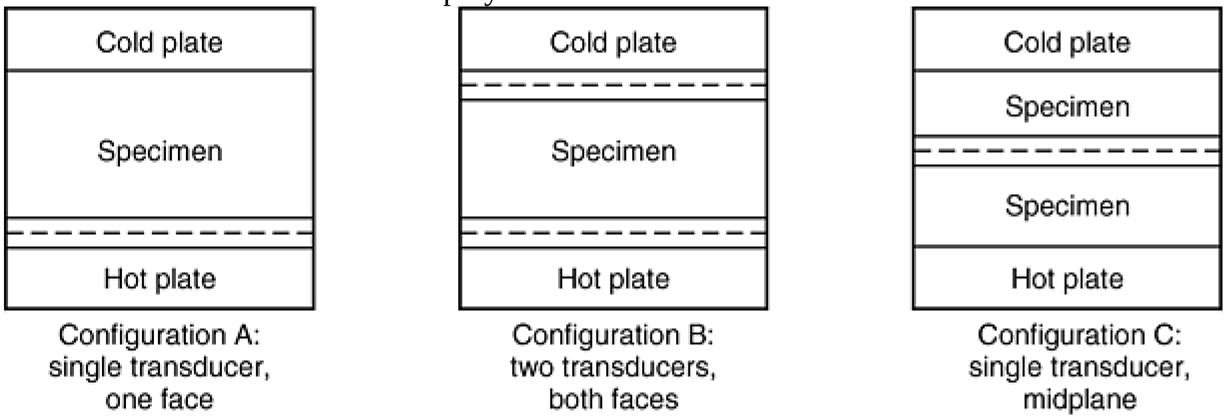

Fig. 4 Typical arrangements for measuring heat flow with heat-flux transducers under the ASTM C 518 method

A heat-flux transducer is a device that produces a voltage output, which is a function of the heat flux passing through it. The various types of heat-flux transducers are described in ASTM C 1046. The gradient type, commonly used in ASTM C 518, consists of a core across which the voltage is measured, normally with a thermopile. Appropriate calibration of the heat- flux transducers with calibration standards and accurate measurement of the plate temperatures and plate separation are required. These procedures are detailed in ASTM C 518.

The experimental procedure is to establish a steady-state, unidirectional heat flow through the test specimen(s) held between the isothermal parallel plates, one hot plate and the other a cold plate. The heat-flow rate, Q, is obtained from the measured voltage output over the heat-flux transducer. The thermal conductivity is calculated knowing Q; the separation between the hot and cold plates, L; the cross-sectional area, A; and the temperature difference across the specimen, ΔT.

The ASTM C 518 method has been used at ambient conditions of 10 to 40 °C (50 to 104 °F), with specimen thickness up to approximately 25 cm (10 in.), and with plate temperatures from–195 to 540 °C (–320 to 1000 °F) at 2.5 cm (1 in.) thickness.
ASTM E 1530 is similar in concept to ASTM C 518, but is modified to accommodate smaller test specimens having a higher thermal conductance. This method is relevant for specimens having a thickness less than 1.2 cm (0.5 in.), with a thermal conductivity in the range of 0.1 to 5 W/m · K (0.05 to 3 Btu/h · ft ·°F).

Specific Heat

The heat capacity is the change in the internal energy of a material per degree temperature change per unit mass of material. The specific heat capacity is the ratio of the heat capacity to that of water. In practice, the specific heat capacity at constant pressure, C_p, is the measured quantity, with values reported in J/kg · K in SI units, or Btu/lb ·°F in customary units.
ASTM E 1269 is the standard test method for measuring the specific heat of polymer-matrix composites. It is based on DSC. This test is generally applicable to thermally stable solids and has a normal operating range from–100 to 600 °C (–150 to 1100 °F). The temperature range may be limited or extended, depending upon the instrumentation and specimen holders used.
A brief summary of the DSC test method is as follows:

1. Empty aluminum pans are placed in the specimen and reference holders. An inert gas atmosphere, such as nitrogen or argon, is typically used as the blanketing atmosphere.
2. An isothermal baseline is recorded at the lower temperature, and the temperature is then increased by adding heat, *Q*(W), in a programmed manner over the range of interest.
3. An isothermal baseline of the difference in energy required to heat the pans is recorded at the higher temperature, as indicated in the lower part of Fig. 5.
4. The procedure is then repeated with a known mass of specimen, *M*, in the specimen pan, and a trace of energy absorbed against time is again recorded.

The data so produced at this point are theoretically sufficient to calculate the specific heat of the specimen, but in practice, a calibration procedure with a standard material is important. Sapphire standards are commonly used.

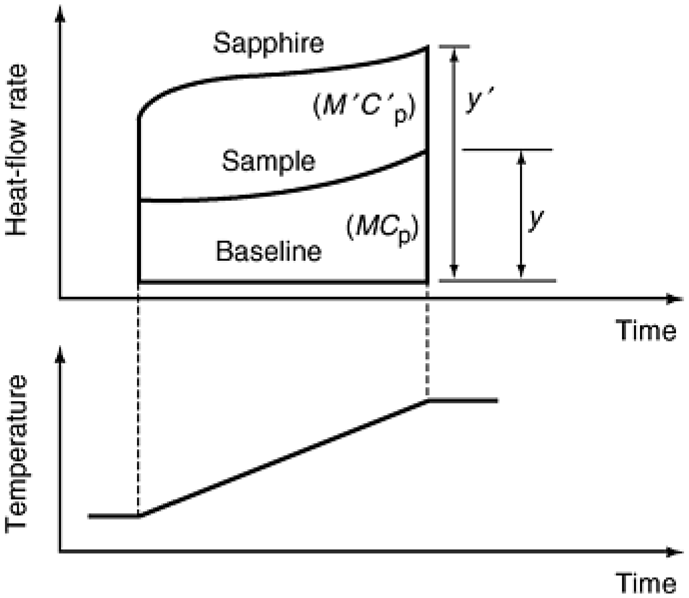

Fig. 5 Determination of specific heat by the ratio method (ASTM E 1269)

A quantitative measurement of energy imparted to a test specimen as a function of temperature must be obtained to determine specific heat. Thus, the instrument used for these measurements must be calibrated in both the heat- flow and temperature modes.
Temperature Mode. Because specific heat is not a quickly changing function of temperature, the temperature mode of the instrument is ordinarily calibrated and checked only occasionally. Temperature calibration is

achieved by observing the melting transition of reference materials. This calibration should be performed over the temperature range to be covered in the specific heat measurement of the unknown specimen. Materials commonly used as DSC temperature calibration standards include tin and indium, but other pure metals may be used.

Heat Flow Mode. Calibration in this mode is achieved through the use of a standard material whose specific heat is well established. The calibration procedure is known as the ratio method. The recommended standard material is synthetic sapphire (α-aluminum oxide).

Notable features of the DSC method are comparatively short test times and milligram specimen sizes. Because such small quantities of specimen material are used, it is essential that specimens be homogeneous and representative. The latter condition may be difficult to achieve if specimens are removed from a polymer-matrix composite panel of large size, due to manufacturing variability from one area of the panel to another. The problem may be addressed by measuring a number of specimens taken from different panel locations and averaging the results.

Thermal Diffusivity

Thermal diffusivity is a thermal response property of a material derived from transient heat-flow conditions. If the density and specific heat are known, the thermal diffusivity, α, may be used to calculate the thermal conductivity of a material from the relationship:

$$\lambda = C_p \alpha \rho$$

where λ is thermal conductivity in W/m · K (Btu/ h · ft ·°F), ρ is density in kg/m^3 (lb/ft^3), C_p is specific heat in J/kg · K (Btu/lb ·°F), and α is thermal diffusivity in m^2/s (ft^2/s).

Two standard test methods are used. ASTM E 1461 is a more-detailed form that has applicability to much wider ranges of materials, applications, and temperatures, with improved accuracy of measurement. ASTM C 714 method applies only to carbon and graphite.

ASTM E 1461, the flash method, exists for the determination of thermal diffusivity of homogeneous, opaque, solid materials. With special precautions, the method can also be used on some transparent and composite materials. Thermal diffusivity values ranging from 0.1 to 1000 × 10^{-6} m^2/s (1 to 10,000 × 10^{-6} ft^2/s) have been measured by this technique, and measurements can be made from about 100 to 2500 K (–280 to 4000 °F). Normally this is done in a vacuum or inert gas environment. The flash method is the most common method reported in the literature for measurement of thermal diffusivity of polymer-matrix composites.

This test method is considered an absolute method of measurement, because no heat-flux reference standards are required. The essential features of the apparatus used in the flash method are the flash source, sample holder and environmental control chamber, temperature response detector, and data collection and analysis system. The flash source may be a laser, a flash lamp, or an electron beam. The usual specimen is a thin, circular disc with a front surface area less than that of the flash beam. The initial temperature of the specimen is controlled by a furnace or cryostat. The detector can be a calibrated thermocouple attached to the rear face of the specimen, an infrared sensor, or an optical pyrometer focused on the rear face and filter which is protected from the flash beam.

To conduct the flash test, the source is pulsed on the front surface of the specimen, and energy is absorbed by the specimen. The resulting rear face temperature rise is recorded. The measured temperature rise curve, Fig. 6, is examined to determine the baseline temperature, the maximum temperature rise, ΔT_{max}, and the time of initiation of the thermal pulse.

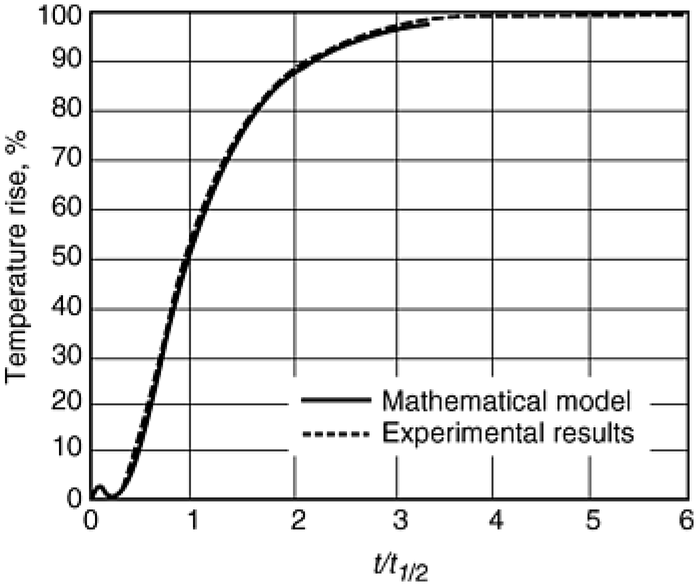

Fig. 6 Time-temperature curve from flash method for determining thermal diffusivity

Thermal diffusivity values are calculated from the specimen thickness, *L*, and the time required for the rear face temperature to reach a certain percentage of its maximum value.

Round-robin test arrangements have shown that a measurement precision of ±5% can be attained for the thermal diffusivity of a variety of materials. Major sources of experimental uncertainty exist:

- *The determination of thickness (L).* This uncertainty is significant, because test specimens are relatively thin, and diffusivity varies with the square of the thickness.
- *The response time of the detector and its associated amplifiers,* which must be no more than 0.1 of the half-time value, $T_{1/2}$. In general, optical instruments have an acceptable response time. Thermocouples tend to be slower and should be carefully checked for response time against a calibrated source or chopped beam.
- *Nonuniform heating of the laser pulse,* which research shows can be a major source of error (>5%). Heat loss correction is required for the data analysis, especially at high temperatures. For temperatures below 400 °C (750 °F), there is a significant nonlinear effect of the infrared detector on the measurements, which requires special corrections.

Advantages of the flash method are the simple specimen geometry, small specimen size, rapidity of measurement, and the ease of using a single apparatus to handle materials having a wide range of thermal diffusivity values. Furthermore, the short measurement time reduces chances of contamination and change of specimen properties due to exposure to high temperatures. The flash method has been extended to two-dimensional heat flow, so that large samples can be measured and the diffusivity in both the axial and radial directions can be measured.

Problems that can arise when applying the flash diffusivity method are partial transparency to the light beam exhibited by a specimen material, and different magnitudes of heat transmission manifested by the components of a multiphase specimen material, such as the reinforcement fiber and matrix of a composite.

The first situation is commonly dealt with by coating the front surface of the specimen with a thin layer of a light-absorbing material, such as graphite. If the second situation exists, the thermal pulse tends to move preferentially through the component phase having the higher thermal diffusivity, with the result that the temperature profile may be nonplanar at the specimen rear surface and depart noticeably from the theoretical model. This effect is sometimes observed, in practice, for composites having a large fraction of high-thermal-conductivity fibers oriented along the heat-flow direction. In this event, the flash method is not applicable.

ASTM C 714. This test method covers the determination of the thermal diffusivity of carbons and graphite to an accuracy of ±5% at temperatures up to 500 °C (900 °F). It requires a circular disk specimen of the order of 1.0 cm (0.4 in.) diameter and 0.5 cm (0.2 in.) thick. The method has the sensitivity to use small samples to analyze very low sulfur contents in graphite and, therefore, is relevant to nuclear reactors where sulfur, even in low concentrations, is a concern.

The method is summarized as follows. A high-intensity, short-duration thermal pulse from a flash lamp is absorbed on the front surface of a specimen, and the rear surface temperature change as a function of time is recorded. Thermal diffusivity is calculated from the specimen thickness and the time required for the temperature of the back surface to rise to one-half of its maximum value. The theoretical considerations and experimental caveats of ASTM E 1461 apply directly to ASTM C 714 and should be consulted.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Introduction

THE USE OF COMPOSITE MATERIALS continues to increase as new performance, reliability, and durability requirements drive structural designs to higher levels of efficiency. Because composite materials inherently require a large number of design variables, the use of analytic models to validate designs is of particular importance. Unfortunately, these analytic models are not yet capable of using lamina (single ply) properties to predict full-scale structural behavior. It is therefore typically necessary to validate all stages of design, from elements to full- scale structure, with both lamina and laminate (two or more plies bonded together) test data.

This article provides very general mechanical testing guidelines for the characterization of lamina and laminate properties. Because of the variety of composite materials currently in use, the test methods discussed in the article may not be appropriate for all material types. Where possible, the limitations of the existing test methods are discussed, but it should be noted that most of the methods discussed here are intended for use on polymer-matrix composites. A more thorough treatment of this topic can be found in Ref 1.

In order to develop and follow a test plan that will produce valuable data, much thought must be given to issues beyond the test methods themselves. The goal of the test program must be to produce data that will represent the structure ultimately being built throughout its performance envelope. To that end, issues such as specimen preparation, environmental conditioning, and instrumentation must all be considered. Brief discussion of some of these items is included in portions of this article, but far more complete treatments can be found in the article “Overview of Testing and Certification” in this Volume and Ref 1.

This article contains lamina and laminate testing guidance for the following general test types:

- Tensile property test methods
- Compressive property test methods
- Shear property test methods
- Flexure property test methods
- Fracture toughness test methods
- Fatigue property test methods

Numerous test methods of varying degrees of standardization are in use in the composite materials industry. This article describes only a select few that have gained industry-wide acceptance; the standards discussed in

this article are listed in Table 1. In general, these methods are ASTM or other industry standards that should be consulted directly in order to judge their appropriateness for a given materials evaluation. Though methods created by the Suppliers of Advanced Composite Materials Association (SACMA) are briefly mentioned, this organization is no longer functioning, and their specifications are not maintained.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Failure Mode Analysis

When selecting and using a particular mechanical strength test method, the importance of obtaining the proper failure mode cannot be overemphasized. While universal definitions of "proper" and "valid" have not been established for most types of tests, careful evaluation of failure modes is critical to all test data analysis. Failure modes must be reported and identified in a consistent manner to enable comparisons of data. Data should be discarded when analysis indicates an unacceptable mode. The reader is advised to be conscientious regarding the documentation of failure modes, and to refer to examples provided within specific test methods where such examples exist.

Careful consideration must be given to the applicability of a given test standard to the material being evaluated. *When a test method consistently results in invalid failure modes for a given material, the testing should be repeated using a different method that is better suited to the material in question.*

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Tensile Property Test Methods

The basic physics of most tensile test methods are very similar: a prismatic coupon with a straight-sided gage section is gripped at the ends and loaded in uniaxial tension. The principal differences between these tensile test coupons are the coupon cross section and the load-introduction method. The cross section of the coupon may be rectangular, round, or tubular; it may be straight-sided for the entire length (a "straight- sided" coupon) or width- or diameter-tapered from the ends into the gage section (often called "dogbone" or "bow-tie" specimens). Straight- sided coupons may use tabbed load application points. This section briefly discusses the most common tensile test methods that have been standardized for fiber-reinforced composite materials. Reference 1 includes a more detailed discussion and briefly reviews several nonstandard methods as well.

By changing the coupon configuration, many of the tensile test methods are able to evaluate different material configurations, including unidirectional laminates, woven materials, and general laminates. However, some coupon/material configuration combinations are less sensitive to specimen preparation and testing variations than others. Perhaps the most dramatic example of this is the unidirectional coupon. Fiber versus load axis misalignment in a 0° unidirectional coupon, which can occur due to either specimen preparation or testing problems or both, can reduce strength as much as 30% due to an initial 1° misalignment. Furthermore, bonded end tabs intended to *minimize* load-introduction problems in high-strength unidirectional materials can actually *cause* premature coupon failure (even in nonunidirectional coupons) if not applied and used properly. Because of these and similar issues, tensile testing is subject to a great deal of "art" in order to obtain legitimate data. Alternatives to problematic tests, such as the unidirectional tensile test, are often available, and careful attention must be paid to the test specification for recommendations. Reference 1 is also an excellent resource for test optimization suggestions.

In-Plane Tension Test Methods

Straight-sided coupon tension tests include:

- ASTM D 3039/D 3039M, “Standard Test Method for Tensile Properties of Polymer- Matrix Composites”
- ISO 527, “Plastics—Determination of Tensile Properties”
- SACMA SRM 4, “Tensile Properties of Oriented Fiber-Resin Composites”
- SACMA SRM 9, “Tensile Properties of Oriented Cross-Plied Fiber-Resin Composites”

ASTM D 3039/D 3039M, originally released in 1971 and updated several times since then, is the original standard test method for straight- sided rectangular coupons. It is still the most commonly used in-plane tension method. ISO 527 parts 4 and 5 and the two SACMA tensile test methods, SRM 4 and SRM 9, are substantially based on ASTM D 3039 and as a result, are quite similar. Care should be taken, however, not to substitute one method for another, because subtle differences between them do exist. In general, the ASTM standard offers better control of testing details that may cause variability, as discussed subsequently. For this reason, it is the preferred method.

In each of the previous test methods, a tensile stress is applied to the specimen through a mechanical shear interface at the ends of the coupon, normally by either wedge or hydraulic grips. The material response is measured in the gage section of the coupon by either strain gages or extensometers, subsequently determining the elastic material properties.

If used, end tabs are intended to distribute the load from the grips into the specimen with a minimum of stress concentration. A schematic example of an appropriate failure mode of a multidirectional laminate using a tabbed tension coupon is shown in Fig. 1. Because the straight- sided specimen provides no geometric stress-concentrated region, such as would be found in a specimen with a reduced-width gage section, failure often occurs at or near the ends of the tabs or grips. While this failure mode is not necessarily invalid, care must be taken when evaluating the data to guard against unrealistically low strengths resulting from poorly performing tabs or overly aggressive gripping.

Fig. 1 Typical tension failure of multidirectional laminate using a tabbed coupon

Design of end tabs remains somewhat of an art, and an improperly designed tab interface will produce low coupon strengths. For this reason, a standard tab design has not been mandated by ASTM, although unbeveled 90° tabs are preferred. Recent comparisons confirm that the success of a tab design is more dependent on the use of a sufficiently ductile adhesive than on the tab angle. An unbeveled tab applied with a ductile adhesive will outperform a tapered tab that has been applied with an insufficiently ductile adhesive. Therefore, adhesive selection is most critical to bonded tab use. Furthermore, the use of a softer tab material is usually preferred when testing high-modulus materials (such as fiberglass tabs on a graphite-reinforced specimen).

The simplest way to avoid bonded tab problems is to not use them. Many laminates (mostly nonunidirectional) can be successfully tested without tabs, or with friction rather than bonded tabs. Flame-sprayed unserrated grips have also been successfully used in tensile testing without tabs.

Other important factors that affect tension testing results include control of specimen preparation, specimen design tolerances, control of conditioning and moisture content variability, control of test machine-induced misalignment and bending, consistent measurement of thickness, appropriate selection of transducers and calibration of instrumentation, documentation and description of failure modes, definition of elastic property calculation details, and data reporting guidelines. These factors are described in detail by ASTM D 3039/D 3039M.

Limitations of the straight-sided coupon tensile methods are described subsequently.

Bonded Tabs. The stress field near the termination of a bonded tab is significantly three-dimensional, and critical stresses tend to peak at this location. Much research has been done on minimizing peak stresses, but it is impossible to make general recommendations that are appropriate for all materials and configurations. Furthermore, improperly designed tabs can significantly degrade results. As a result, tabless or tabbed

configurations that use unbonded tabs are becoming more popular, when the resulting failure mode is appropriate.

Specimen Design. There are, particularly within ASTM D 3039, a large number of coupon design options included in the standard, which are needed to cover the wide range of materials systems and lay-up configurations within the scope of the test method. Great care should be taken to ensure that an appropriate geometry is chosen for the material being tested.

Specimen Preparation. Specimen preparation plays a crucial role in test results. While this is true for most composite mechanical tests, it is particularly important for unidirectional tests, and unidirectional tension tests are no exception. Fiber alignment, control of coupon taper, and specimen machining (while maintaining alignment) are the most critical steps of specimen preparation. For very low strain-to-failure materials systems or test configurations, like the 90° unidirectional test, flatness is also particularly important. Edge machining techniques (avoiding machining-induced damage) and edge surface finishes are also particularly critical to strength results from the 90° unidirectional test.

Unidirectional Testing. All the elements that make tensile testing subject to error are exacerbated in the unidirectional case, particularly in the 0° direction. This has led to the increased use of a much less sensitive $[90/0]_{ns}$-type laminate coupon (also known as the “crossply” coupon) from which unidirectional properties can be easily derived (Ref 2). Properly tested crossply coupons often produce results equivalent to the best attainable unidirectional data. While unidirectional testing is still performed, and in certain cases may be preferred or required, a straight- sided, tabless, $[90/0]_{ns}$-type coupon is now generally believed to be the lowest cost, most reliable configuration for lamina tensile testing of unidirectional materials. This straight-sided tabless configuration also works equally well for nonunidirectional material forms and for other general laminates. Another advantage is that, unlike with 0° unidirectional specimens, $[90/0]_{ns}$- type coupon failures do not usually mask indicators of improper testing/specimen preparation practices.

Width tapered coupon tension tests are standardized in ASTM D 638, “Standard Test Method for Tensile Properties of Plastics.” The test, developed for and limited to use with plastics, uses a flat, width-tapered tensile coupon with a straight-sided gage section. Several geometries are allowed, depending on the material being tested. Figure 2 shows a schematic of one general configuration. Despite its heritage, this coupon has also been evaluated and applied to composite materials. The coupon taper is accomplished by a large cylindrical radius between the wide gripping area at each end and the narrower gage section, resulting in a shape that justifies the nickname of the “dogbone” coupon. The taper makes the specimen particularly unsuited for testing of 0° unidirectional materials, because only about half of the gripped fibers are continuous throughout the gage section. This usually results in failure by splitting at the radius, due to inability of the matrix to shear the load from terminated fibers into the gage section.

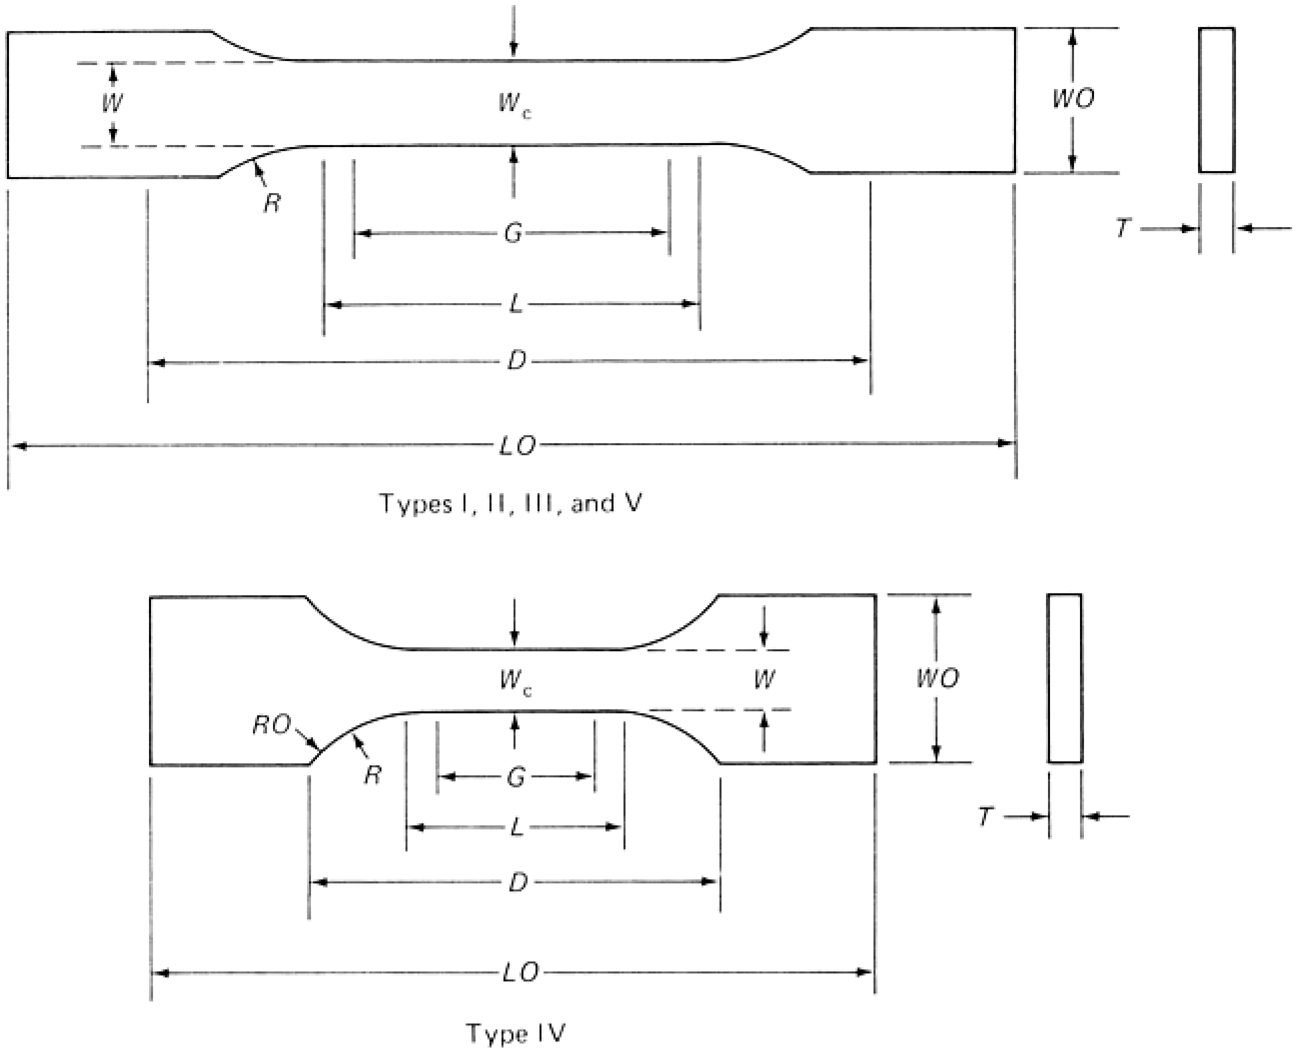

Fig. 2 Schematic of typical ASTM D 638 test specimen geometry. *W*, width; W_c, width at center; *WO*, width overall; *T*, thickness; *R*, radius at fillet; *RO*, outer radius; *G*, gage length; *L*, length; *LO*, length overall; *D*, distance between grips

While the ASTM D 638 coupon configuration has been successfully used for fabric-reinforced composites and with general nonunidirectional laminates, some materials systems remain sensitive to the stress concentration at the radius. For its intended use with plastics, the coupon is molded to shape. Likewise, discontinuous fiber composites can be molded to the required geometry. To ensure valid results, care must be taken that the molding flow does not create preferentially oriented fibers. For laminated materials the coupon must be machined, ground, or routed to shape. The coupon also has the drawback of having a relatively small gage volume and is poorly suited for characterization of coarse weaves with repeating units larger than the gage width of 6.4 to 13 mm (0.25 to 0.50 in.). The standardized procedure, due to the intended scope, does not adequately cover the testing parameters required for advanced composites.

Limitations of the ASTM D 638 method are described in the following paragraphs.

Standardization. While the ASTM D 638 test is standardized, it was not developed for advanced composites and is primarily applicable to relatively low-modulus, unreinforced materials, or low-reinforcement volume materials incorporating randomly oriented fibers.

Specimen Preparation. Special care is required to machine the taper into a laminated coupon.

Stress State. The radius transition region can dominate the failure mode and result in reduced strength results. The width-tapered coupon is not suitable for unidirectional laminates, and is limited to fabrics or nonunidirectional laminates when gage section failures can be attained.

Limited Gage Section Volume. The limited gage width makes it unsuitable for coarse fabrics.

The sandwich beam test is standardized as ASTM C 393, “Standard Test Method for Flexural Properties of Flat Sandwich Constructions.” While primarily intended as a flexural test for sandwich core shear evaluation, the scope also allows use for determination of facing tensile strength. While this use is not well documented within

the test method, it has been used for tensile testing of composite materials, particularly for 90° properties of unidirectional materials, or for fiber-dominated testing in extreme nonambient environments. This test specimen is claimed by some to be less susceptible to handling and specimen preparation damage than D 3039-type 90° specimens, resulting in higher strengths and less test-induced variation.
In order to assure failure in the tensile facesheet, the compression facesheet is often manufactured from the same material, but at twice the thickness as the tensile facesheet.
Limitations of the ASTM C 393 method are described subsequently.
Cost. Specimen fabrication is relatively expensive.
Stress State. The effect on the stress state of the sandwich core has not been studied in tension and could be a concern.
Standardization. While this test technically is standardized, its practical application and limitations are not well studied or documented.
Environmental Conditioning. Conditioning is problematic because of the difficulty of assuring tensile facesheet moisture equilibrium due to the moisture protection offered by the compression facesheet and the core. The extended conditioning times required also often cause adhesive breakdown prior to testing.

Out-of-Plane Tension Test Methods

ASTM D 6415, "Standard Test Method for Measuring the Curved Beam Strength of a Fiber- Reinforced Polymer-Matrix Composite," is currently the only published standard for out-of- plane tensile testing specifically relating to composites, though modifications to ASTM C 297, C 633 and D 2095 are also often employed. These methods are not discussed here, and the reader is referred to Ref 1 and the test standards for more information.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Compressive Property Test Methods

The compression response of composite materials has been the subject of research efforts and test programs since the early 1960s. Even with this long-term study, there exist numerous methods to test composites in compression and no consensus on a single most-recommended test method to use. Compression tests are conducted on composite materials, using appropriate instrumentation, to determine compressive modulus, Poisson's ratio, ultimate compressive strength or strain-at-failure. These properties are determined through the use of test fixturing that is typically designed to be as simple to use and fabricate as possible, to minimize stress concentrations, to minimize specimen volume, and to introduce a uniform state of uniaxial stress in the specimen test section.
Compression testing is inherently influenced by test fixturing. Sufficient restraint must be provided by fixturing to inhibit undesirable failure modes, such as end brooming and column buckling. However, if excessive restraint is used, the resulting failure strengths may be artificially high. For this reason, consensus on the preferred test method has not been reached, and there are significant differences of opinion on the "proper" way to perform compression testing for a given material form. Selection of a compressive test method depends on

the material being tested, the test environment, and the goals of the testing program. The quality of the test results can often be judged by the coefficients of variation in strength and modulus and the failure modes of the test specimens.

The measured compression strength for a single material system has been shown to differ when determined by different test methods. Variation in results can usually be attributed to one of the following parameters: fabrication practices, control of fiber alignment, improper coupon machining and specimen preparation, improper placement of coupons in test fixtures or fixtures in testing machines, and improper use of test fixtures.

The numerous in-plane compression test methods available can be broadly classified into three groups: (1) those that introduce load into the specimen test section through shear; (2) those that introduce load into the specimen test section through end-loading; and (3) those that introduce load into the specimen test section through a combination of end-loading and shear.

In-plane compression test methods can be further classified as having a supported or unsupported test section. An unsupported test section is defined as one inherently free from global buckling, with the faces of the specimen in the test section remaining unrestrained throughout the test. A supported test section is one with support on the specimen faces in the test section provided by the test fixture or ancillary equipment. All of the test methods discussed in this section require specimens with unsupported test sections, with the exception of ASTM D 5467, the sandwich beam method. A more complete discussion of compression test methodology and a description of test methods not covered here can be found in Ref 3, 4, 5, 6, and 7.

In-Plane Compressive Test Methods

In-plane compressive test methods are standardized as:

- ASTM D 5467, “Standard Test Method for Compressive Properties of Unidirectional Polymer Matrix Composite Materials Using a Sandwich Beam”
- ASTM D 3410, “Standard Test Method For Compressive Properties of Polymer-Matrix Composite Materials with Unsupported Gage Section by Shear Loading”
- ASTM C 393, “Standard Test Method For Flexural Properties of Sandwich Constructions”
- ASTM D 695, “Standard Test Method for Compressive Properties of Rigid Plastics”
- SACMA SRM 1, “Compressive Properties of Oriented Fiber-Resin Composites”
- SACMA SRM 6, “Compressive Properties of Oriented Cross-Plied Fiber-Resin Composites”

The in-plane compression test methods described in this section can be used to generate the ultimate compression strength, strain-at-failure, longitudinal modulus, and Poisson's ratio of [0], [90], and orthotropic coupons, over a typical thickness range of approximately 1 to 6 mm (0.040 to 0.200 in.) With the exception of ASTM D 5467 (sandwich beam method), all of the test methods discussed subsequently will also accommodate $[0/90]_{ns}$-style laminates. Testing of these laminates and performing subsequent data reduction has become a popular means for eliminating specimen and fixture-related sensitivities associated with unidirectional specimens. A discussion on the use of [0/90] laminates for determining lamina properties and associated data-reduction methods can be found in Ref 2 and within SACMA method SRM 6. (Note again that SACMA methods are no longer maintained and should be used with care.) Test methods for specimen thicknesses greater than those covered by the test methods discussed here exist, but have not been standardized, and additional information on test methods for laminates thicker than 10 mm (0.400 in.) can be found in MIL-HDBK- 17 (Ref 8).

Limitations of in-plane compression testing are described subsequently.

Test Method Sensitivity. It has been shown that different test methods do not measure the same compression strength for a single material system. Such differences can be attributed to the effects of specimen alignment, specimen geometry, and fixtures. For example, the variation in test results between the two procedures in ASTM D 3410 and the one procedure in ASTM D 5467 can be found in Ref 9.

Material and Specimen Preparation. Compression modulus and especially compression strength are sensitive to poor material fabrication practices, damage induced by improper coupon machining, and poor fiber alignment. Great care should be taken to minimize all these sources of error.

ASTM D 3410/D 3410M, “Compressive Properties of Polymer-Matrix Composite Materials with Unsupported Gage Section by Shear Loading.” Two compression procedures are published by ASTM in test method D 3410

and have historically been called the Celanese (D 3410 procedure A) and the Illinois Institute of Technology Research Institute (IITRI) (D 3410 procedure B). The Celanese and IITRI procedures, as with many other published procedures, originally carried the names of the organizations under which the procedure was developed. The Celanese and IITRI procedures address the use of tabbed or untabbed rectangular coupons and the transfer of load into the specimen through shear via wedge-type grips.

General limitations of the ASTM D 3410 method are described herein.

Material Form. The test is limited to continuous-fiber or discontinuous-fiber reinforced composites for which the test direction is parallel to one of the principal material directions.

Test Fixture Characteristics. Although both procedures A and B transmit load to the specimen via tapered wedge grips, the wedges in procedure A are conical and the wedges in procedure B are rectangular. The conical wedges from procedure A are known to be prone to cone-to- cone seating problems (Ref 9). The rectangular wedge grip design used in procedure B was employed to eliminate this wedge-seating problem. In addition to these differences, the fixture used for procedure A is much smaller in size and weight than the fixture used for procedure B. (However, significantly smaller modified fixtures for procedure B have been developed and used with good success. The Wyoming Modified IITRI compression test fixture weighs roughly 25% of the ASTM D 3410 procedure B fixture but is essentially identical in function. It is limited to specimens of 13 mm (0.5 in.) or less in width and a thickness range of approximately ±2.5 mm (±0.10 in.) (per wedge set.) Fixture modifications to the Procedure A geometry are also available that alleviate the cone-to-cone seating problems with the specification-defined fixture (Ref 7, 10, and 11).

A fixture characteristic that can have a significant effect on test results is the surface finish of the mating surfaces of the wedge grip assembly. Because these surfaces undergo sliding contact, they must be polished, lubricated, and free of nicks and other surface damage.

Strain Measuring Devices. While extensometers are not ruled out, practical considerations make the use of strain gages essentially required. Back-to-back gages are required for procedures A and B, although the standard relaxes this requirement for large numbers of test specimens.

ASTM D 3410, procedure A requires a test fixture that consists of a pair of matched conical wedge grips that are seated in a cylindrical housing (Fig. 3). The test specimen used in this fixture is a tabbed coupon of rectangular cross section. The specimen dimensions are nominally 140 mm (5.5 in.) long and 6 mm (0.25 in.) wide. The total thickness of specimen plus tabs is variable, but is toleranced to only ±0.05 mm (±0.002 in.) for a given wedge geometry. After placing the specimen in the test fixture, a compressive load is applied to the ends of the fixture in a standard testing machine. The load applied to the fixture is transferred from the wedge grips to the specimen tabs and then to the specimen through shear. The complex stress state in the tabbed region of the specimen changes to uniaxial compression in the specimen test section. Compression strength is determined from load at failure, while modulus and strain-at-failure are determined when strain gages are employed.

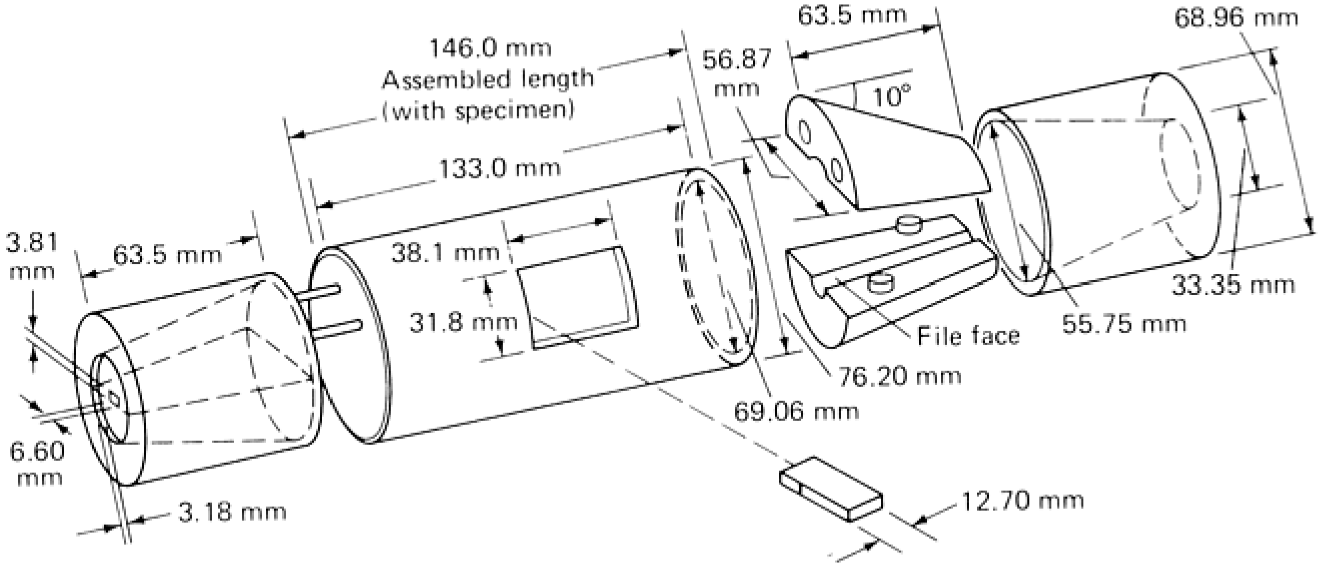

Fig. 3 Exploded view of compression test fixture (ASTM D 3410, method A)

Limitations of ASTM D 3410, Procedure A. In general, this test method is highly susceptible to testing irregularities because of the problems discussed subsequently. Because of this, and because the addition to the standard of the more forgiving procedure B, procedure A has become a rarely used method.

Specimen Dimensions. Due to the conical geometry of the wedge grips in this test method, a given set of wedges will accommodate only a single specimen thickness. The total specimen thickness tolerance for a given wedge set is only ±0.05 (±0.002 in). This limitation and restrictive tolerance requires surface grinding of specimens to final thickness, as well as maintaining enough wedge sets to accommodate multiple specimen thicknesses.

Fixture Seating. The fixture design for the test method makes it susceptible to cone-to-cone seating problems on the conical wedge grips, as mentioned previously.

Material Form. The fixed gage length and width of this specimen make it inappropriate for fabric-based materials with unit cell sizes larger than the smaller specimen dimension.

Tabbing and Tolerances. The data resulting from this test method have been shown to be sensitive to the flatness and parallelism of the tabs, so care must be taken to ensure that the specimen tolerance requirements are met. This usually requires precision grinding of the tab surfaces after bonding them to the specimen. The fixture for this procedure requires tight manufacturing, assembly, and installation tolerances.

ASTM D 3410, Procedure B. The fixture design, specimen configuration, and loading principal for this test procedure are based on the same concepts as procedure A described previously. The fixture for this test method was designed primarily to eliminate the seating problems associated with the conical wedge grips in procedure A (Ref 9). In place of conical wedge grips, the fixture for this test method consists of a pair of matching rectangular wedge grips seated in a rectangular housing (Fig. 4). The fixture for this method is much larger and heavier than for procedure A. The test specimen used is typically tabbed, with a rectangular cross section having recommended dimensions of 140 to 155 mm (5.5 to 6.0 in.) long, 10 to 25 mm (0.50 to 1.0 in.) wide, and with a 10 to 25 mm (0.5 to 1.0 in.) gage length. Specimens tested with this procedure have a minimum required thickness, specified as a function of gage length, material modulus, and expected material strength, with an absolute minimum thickness of 1 mm (0.040 in.). As with the procedure A, the load that is applied to the fixture is transferred from the wedge grips to the specimen tabs through shear, and from the tabs to the test specimen through shear. The complex stress state in the tabbed region of the specimen changes to uniaxial compression in the specimen test section. Compression strength is determined from load at failure, while modulus and strain-at-failure are determined when strain gages or extensometers are employed.

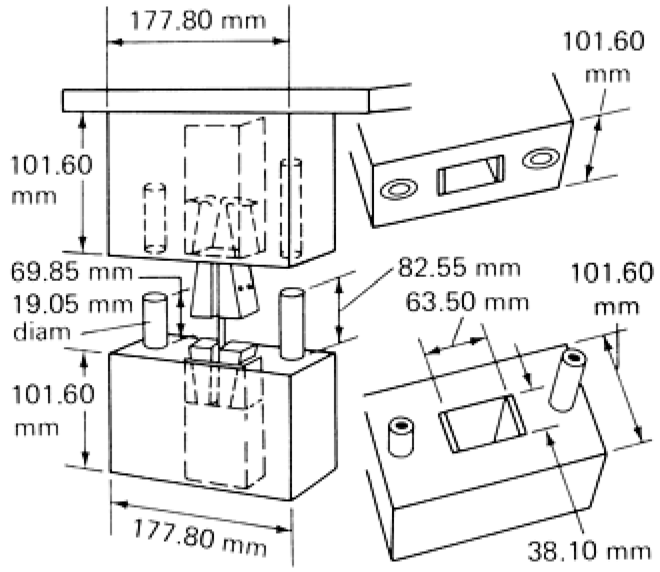

Fig. 4 Schematic of compression test fixture with pyramidal wedges (ASTM D 3410, method B)

Limitations of ASTM D 3410, Procedure B. The data resulting from this test method have been shown to be sensitive to the flatness and parallelism of the tabs, so care should be taken to ensure that the specimen tolerance requirements are met. This often requires precision grinding of the tab surfaces after bonding them to the specimen. The fixture for this procedure requires tight manufacturing, assembly, and installation tolerances.

ASTM D 5467, “Compressive Properties of Unidirectional Polymer Matrix Composites Using a Sandwich Beam.” This method uses a honeycomb-core sandwich beam that is loaded in four-point bending, placing the upper facesheet in compression (Fig. 5). The upper sheet is loaded in compression and is usually a six-ply unidirectional laminate. The lower facesheet is typically the same material, but twice as thick in order to drive failure into the compressive facesheet. The two facesheets are separated by and bonded to a deep honeycomb core (usually aluminum). Failure of the compressive facesheet enables measurement of compression strength, compression modulus, and strain-at-failure if strain gages or extensometers are employed.

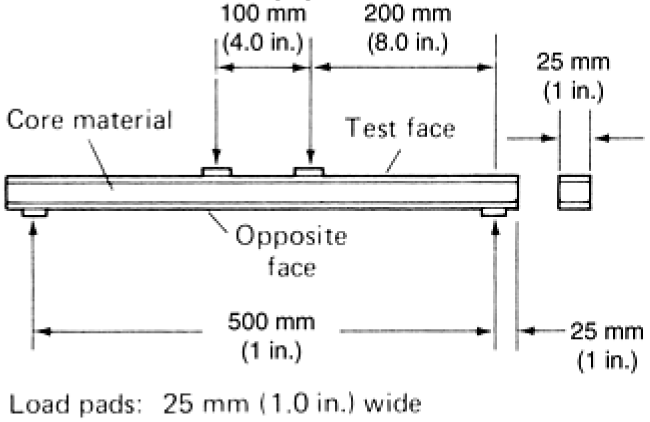

Fig. 5 Schematic of typical longitudinal sandwich beam compression specimen (ASTM D 5467)

Limitations of the ASTM D 5467 method are described subsequently.

Material Form. This test procedure is limited to unidirectional material only.

Specimen Complexity. The specimen is much larger, and specimen preparation is more complex and expensive than for the two procedures in ASTM D 3410.

Compression Strength. Compression strength for unidirectional materials are typically higher (10 to 15%) than for the two procedures in ASTM D 3410. This is believed to be attributable to the one-sided support provided by the core material in the test specimen.

Poisson's Ratio. The validity of Poisson's ratio from this method has been questioned, due to anticlastic bending.

ASTM C 393, “Flexural Properties of Flat Sandwich Constructions.” ASTM C 393 is one of a series designed to test sandwich constructions, and covers the determination of the properties of flat, sandwich constructions subjected to flatwise flexure in the same manner as ASTM D 5467. ASTM C 393 expands on the properties measured by ASTM D 5467, and provides methodology to determine the flexural and shear stiffness of the entire sandwich, the shear modulus and shear strength of the core, or the compressive or tensile strength of the facesheets.

There are no limitations on the core or skin materials for this test method. The specimen is rectangular in cross section, and the core, facesheet, and span geometries are designed to achieve the desired failure mode according to the material property being measured. While not widely used for the determination of composite materials properties, this test method does allow for the design of a test specimen not covered by ASTM D 5467. Caution should be exercised in using this test for composite materials properties, because the equations for determining the material properties may not be applicable for some specimen geometries or core-facesheet combinations.

The use of this test method to determine the tensile properties of [90°] laminates is covered in MIL-HDBK-17 (Ref 12).

Limitations of the ASTM C 393 method are described in the following paragraphs.

Material Form. This test method is not limited in the material form of the core material or facesheet material. Equations for determining the material properties may not be applicable for some specimen geometries or core-facesheet combinations.

Specimen Geometry. This test method is limited to rectangular sandwich constructions, and the core, facesheet, and span geometries are allowed to vary in order to achieve the desired failure mode according to the material property being measured.

ASTM D 695, “Standard Test Method for Compressive Properties of Rigid Plastics.” This method was developed by ASTM Committee D-20 for compression testing of unreinforced and reinforced rigid plastics. Two types of specimens can be used for this method. The first is typically used for unreinforced plastics and is

in the form of a right cylinder or prism whose length is twice its principal diameter or width. Preferred specimen sizes are 12.7 by 12.7 by 25.4 mm (0.50 by 0.50 by 1.0 in.) for a prism and 12.7 mm diam by 25.4 mm (0.50 in. diam by 1.0 in.) for a cylinder. Smaller diameter rods or tubes may also be tested, provided they are of sufficient length to allow a specimen slenderness ratio of 11:1 to 16:1. The specimen is tested by placing it between the hardened-steel faces of a compression tool and loading it to failure.

The second test specimen in the standard is documented as intended for “reinforced plastics, including high-strength composites and highly orthotropic laminates” less than 6.4 mm (0.125 in.) thick. It uses a flat, untabbed specimen with a reduced width test section, as shown in Fig. 6. Two I-shaped support plates with longitudinal grooves are clamped to the faces of the specimen and are slightly shorter than the specimen. (See Fig. 7, which illustrates the same fixture, but a different specimen geometry.) After positioning the specimen between the support plates, a compressive load is applied to the end of the specimen until failure to determine ultimate compression strength. An extensometer may also be mounted to the specimen edge to determine compression modulus.

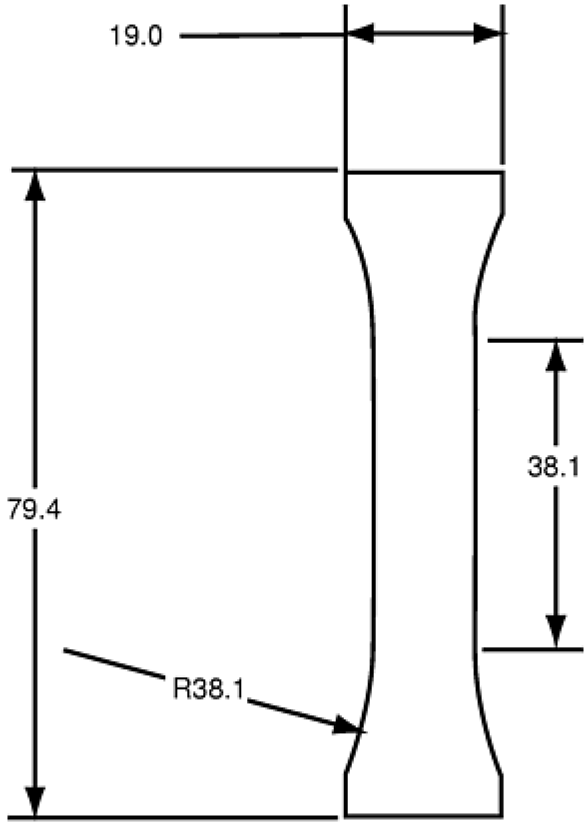

Fig. 6 ASTM D 695 specimen for thin materials. Dimensions in millimeters

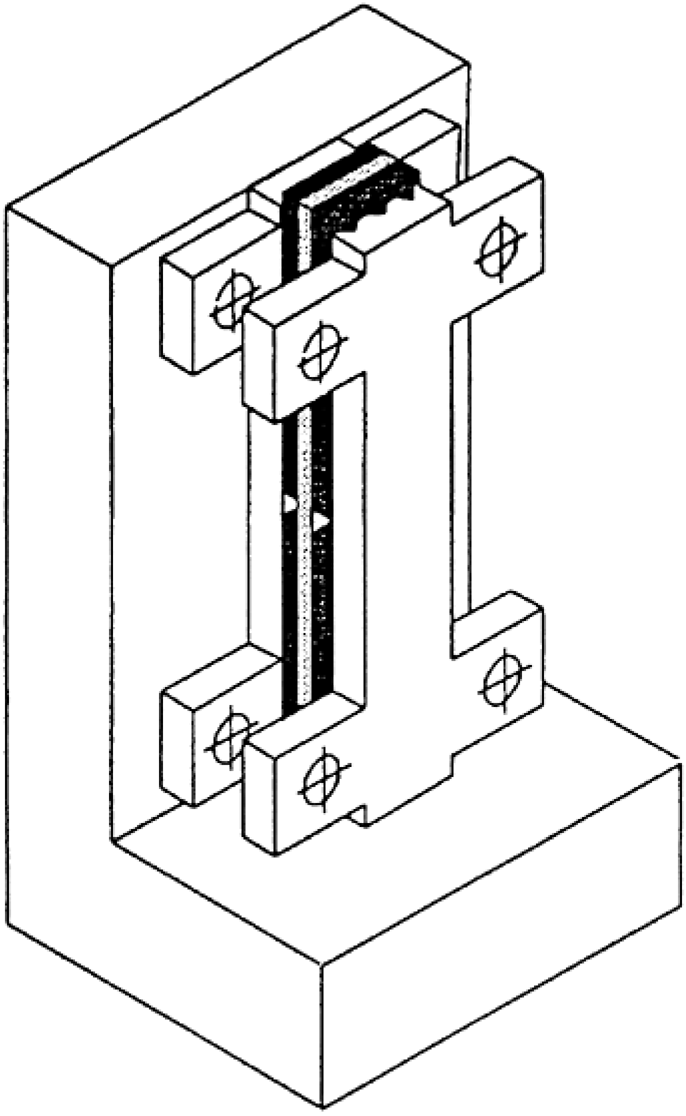

Fig. 7 Schematic of SACMA SRM 1 test fixture and strength specimen

The dogbone specimen geometry has been evaluated with mixed results for its use with fiber-reinforced composites (Ref 9). Results indicate that while the shaped specimen works for some forms of fiber-reinforced composites, it is not appropriate for use with other relatively high modulus materials. In an attempt to modify this portion of the test method for use with high- modulus composites, a straight-sided, tabbed coupon has been developed to measure strength, and a similar specimen without tabs has been developed to measure modulus. In addition, an L-shaped base to support the fixture-specimen assembly has also been added to the test method. This method is often referred to as the "modified" ASTM D 695 method and is well represented by the SACMA SRM 1 method discussed subsequently.

Limitations of the ASTM D 695 Method. The published scope of this document states it is limited to unreinforced and reinforced rigid plastics, including high-modulus composites. Round-robin testing conducted by Committee D- 30 found this method unacceptable for the measurement of strength of high-modulus composites (Ref 9).

SACMA SRM 1, "Compressive Properties of Oriented Fiber-Resin Composites." A variation on the ASTM D 695 test method for continuous high-modulus fiber composites has been developed and documented by SACMA as SRM 1. While essentially retaining the simple fixturing of the ASTM D 695 method, the variation uses straight-sided tabbed specimens for compression strength and an untabbed specimen for the measurement of modulus. An L-shaped base supports the fixture-specimen assembly. Both specimens are 80 mm (3.18 in.) long, 6.4 mm (0.5 in.) wide, and 1 to 3 mm (0.040 to 0.120 in.) thick. A schematic of the strength specimen installed in the fixture is shown as Fig. 7. The unsupported test section in this method is the shortest test section of any test method of this class and measures only 4.8 mm (0.188 in.) long. This may contribute to the higher values of compression strength typically measured with this method than from ASTM D 3410 procedures A and B.

Limitations of the SACMA SRM 1 method are described subsequently.

General. SACMA is no longer in existence, and its methods are not currently maintained. Therefore, referencing this specification should be done with care. Separate strength and modulus specimens are required for this test method. The short gage length and narrow width of the strength specimen result in a small test section volume.

Material Form. The material form is limited to polymer-matrix composites reinforced with oriented, continuous, high-modulus (>21 GPa, or 3×10^6 psi), fibers, and made primarily of prepreg or similar product forms. This test method is applicable to fabric-based materials only when the unit cell size of the coupon weave/ braid is smaller than the 4.8 mm (0.188 in.) gage length of the coupon.

Compression Strength. Measured compression strengths from this test method are typically higher than for the methods in ASTM D 3410. This is believed to be due to the short and narrow gage length of this test specimen, and to the effect this geometry has in suppressing failure mechanisms that are present in longer, unsupported gage lengths such as in ASTM D 3410 procedures A and B.

This test method has been successfully used for strength measurement of unidirectional carbon-reinforced composites. However, one must be very careful to follow proper specimen preparation procedures, tabbing procedures, fixture/ specimen alignment practices, and fixture loading practices, many of which have not been standardized or documented in SACMA SRM 1R-94 and are factors that will affect the results from this test method.

Strain-at-failure is not available because the gage region of the strength specimen is not large enough for a strain gage, and the modulus specimen geometry is not suitable for loading to failure. Consequently, stress-strain response, including monitoring of coupon bending strains as commonly done to assess proper gage section loading, cannot be observed over most of the actual curve.

SACMA SRM 6, “Compressive Properties of Oriented Cross-Plied Fiber-Resin Composites.” This test method is identical to SACMA SRM 1R, with the exception that it is limited in material form to cross-plied laminates. This limitation is applied because the method is intended for the determination of unidirectional compression strength by applying a back-out factor to the strength determined from the cross-plied laminate. A method for backing out unidirectional properties is included in the standard and in MIL-HDBK-17 (Ref 2), although the two methods are slightly different, with the SACMA method using a greater degree of approximation.

Limitations of the SACMA SRM 6 method are the same as those listed previously for SACMA SRM 1. In addition, the use of the back-out factor in this test method assumes a linear elastic response of the material to which it is being applied. Also, the test is limited to cross- plied versions of the materials previously referenced in SACMA SRM 1.

Through-Thickness Compressive Tests

Because through-thickness compression data is rarely required, there are no standardized or widely accepted test methods to determine compression strength, modulus, or Poisson's ratio of composite laminates in this direction. These data have been reported to a limited extent in the literature, (Ref 13, 14), and in general, simple rectilinear specimens cut from thick-section laminates have been used to obtain these properties.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Shear Property Test Methods

Shear testing of composite materials has proven to be one of the most difficult areas of mechanical property testing in which to define a rigorously correct test, especially in the out-of- plane direction. A number of test methods have been devised, only some of which are described herein. Many of these methods were originally developed for materials other than continuous fiber-reinforced composites, such as metal, plastic, wood, or adhesive. Several of the methods are not yet fully standardized for composite materials, and none of the methods is without deficiency or limitation, though some are clearly more desirable than others.

While there is general agreement regarding the accuracy of shear modulus measurements (for properly conducted tests), determination of shear strength is far more problematic. The presence of edge effects, material coupling effects, nonlinear behavior of the matrix or the fiber-matrix interface, imperfect stress distributions, or the presence of normal stresses make shear strength determination from existing shear test methods highly questionable. Due to this uncertainty, shear strength data to be used for structural applications must be reviewed on a case- by-case basis.

A growing body of experience with composite shear testing, both published and unpublished, has led to a greater understanding of the strengths and weaknesses of each test method. The following conclusions have been offered by ASTM Committee D-30 (Ref 15). These philosophies are being included in existing and future ASTM standard shear test methods:

- There are no known standard (or nonstandard) test methods that are capable of producing a perfectly pure shear stress condition to failure for every materials system, although some test methods can come acceptably close on specific materials systems, as judged by the end user for a given engineering purpose.
- The strengths resulting from test methods that do not consistently produce a reasonable approximation of pure shear, or that do not fail via a shear failure mode, should not be termed “shear strength.”
- Because ultimate strength values from existing shear tests are no longer believed able to provide an adequate criterion for comparison of materials systems, the addition of an offset strength is now recommended (0.2% offset, unless otherwise specified).

With the highly nonlinear stress-strain behavior of many filamentary composites, and especially with high-elongation materials systems, it is common to terminate a shear test prior to actual coupon failure. ASTM D-30 currently recommends ending shear tests at 5% shear strain if failure has not previously occurred. The rationale for this includes the following general statements, which are covered in more detail in MIL- HDBK-17 (Ref 16):

- *Practical use in structural laminates:* Shear strains in fiber-reinforced structures of 5% is a practical upper bound, even with the most ductile fibers available.
- *Limitations of common shear test methods:* Realignment, or scissoring, of fibers during both the ±45° tensile shear and the V- notched beam shear tests (ASTM D 3518 and D 5379, respectively) makes data questionable past 5% shear strain.
- *Strain gage instrumentation limitations:* Strain gages are typically limited to about 6% shear strain, making this a practical limit for shear strain measurement.
- *Laminate restrictions:* While several of the shear test methods discussed herein are capable of determining a substantial portion of a laminate stress-strain curve and, with it, a shear modulus, there is no standard test method that has been shown to adequately determine the ultimate shear strength of a multidirectional laminate.

In-Plane Shear Tests

In-plane shear tests are standardized as:

- ASTM D 3518/D 3518M, “Standard Practice for In-Plane Shear Response of Polymer-Matrix Composite Materials by Tensile Test of a ±45° Laminate”
- SACMA SRM 7, “In-Plane Shear Stress- Strain Properties of Oriented Fiber-Resin Composites”
- ASTM D 5379, “Standard Test Method for Shear Properties of Composite Materials by the V-Notched Beam Method”
- ASTM D 4255, “Standard Guide for Testing In-Plane Shear Properties of Composite Laminates”

ASTM D 3518/D 3518M, “Standard Practice for In-Plane Shear Response of Polymer- Matrix Composite Materials by Tensile Test of a ±45° Laminate.” This test uses a modified ASTM D 3039 tensile test coupon with a lay-up of $[\pm 45]_{ns}$ to measure in-plane shear properties. The in-plane shear stress in this coupon can be shown to be a simple function of the average applied tensile stress, allowing for straightforward calculation of the shear response of the material. This test method uses a simple test coupon, requires no fixturing, and measurement of strain can be performed using either extensometers or strain gages.
The 1994 release of the standard now contains many features missing in previous versions and should therefore be preferred over any older version. The SACMA version is a restricted subset of the ASTM standard. This fact, together with the unmaintained nature of SACMA specifications, should discourage the use of the SACMA SRM 7 method.
Limitations of the ASTM D 3518 method are described in the following paragraphs.
Material and Laminate Form. The material and laminate form is limited to fully balanced and symmetric ±45° materials. As discussed previously, the stacking sequence, ply count, and ply thickness have a direct effect on coupon strength, making it important to follow the recommendations of the specification.

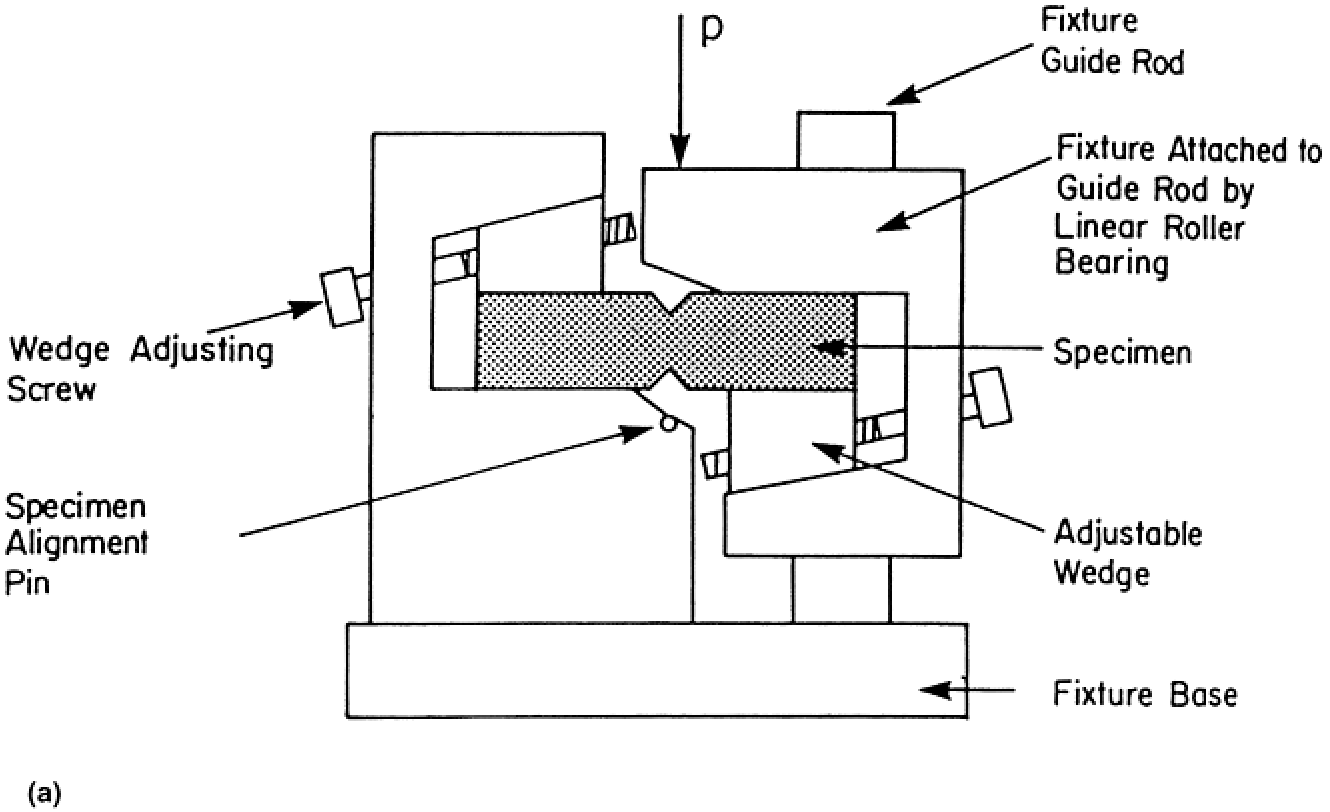
Inhomogeneous Materials. The material is assumed homogeneous with respect to the size of the test section. Material forms with features that are relatively coarse with respect to the test section width, such as woven or braided textiles with a coarse repeating pattern, require a larger specimen width than is currently standardized.

Impurity of Stress State. The material in the gage section is not in a state of pure in-plane shear, because an in-plane normal stress component is present throughout the gage section, and a complex stress field exists near the free edges. Although the coupon is believed to provide reliable initial material response and can establish shear stress-strain response well into the nonlinear region, the calculated shear stress at failure does not represent the material strength. This is why the ASTM standard terminates the test at 5% shear strain.

Effects of Large Deformation. The extreme fiber scissoring that can occur in this specimen in ductile coupons changes the fiber orientation progressively with increasing strain, conflicting with the fiber orientation assumptions used in the calculation of results. This is a second reason why the test is terminated at 5% shear strain.

ASTM D 5379/D 5379-93, "Test Method for Shear Properties of Composite Materials by the V-Notched Beam Method." The V- notched beam shear test is often called the Iosipescu shear test, after one of its originators (Ref 17, 18, and 19). The original concept was developed for metals testing in the late 1950s and early 1960s (Ref 20, 21, and 22) and was refined and modified for fiber-reinforced composites during the early 1980s, which ultimately led to the release of the current ASTM standard (Ref 23, 24, 25, and 26).

In this method (Fig. 8), a material coupon in the form of a rectangular flat strip with symmetrical, centrally located V-notches is loaded in a mechanical testing machine by the fixture shown in Fig. 8(a). Either in-plane or out-of-plane shear properties may be evaluated, depending upon the orientation of the material coordinate system relative to the loading axis. When testing specimens of relatively thin cross section (generally less than 2.5 mm, or 0.10 in., thick), tabs are recommended. Tabs are bonded to either end of the specimen, away from the test area, to provide increased stability in the load introduction regions.



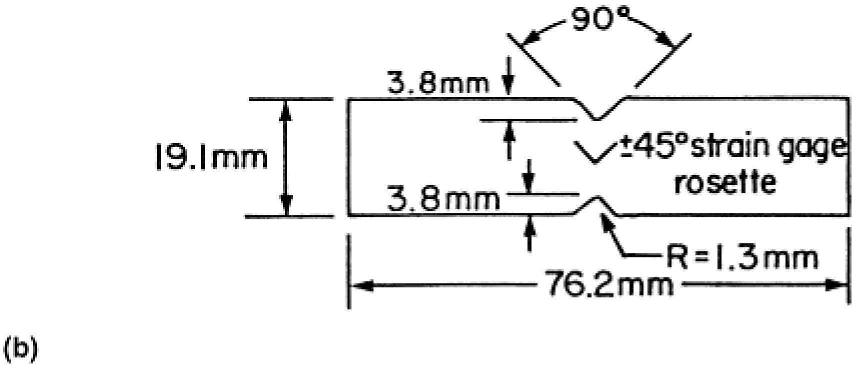


Fig. 8 Iosipescu V-notched beam shear test (ASTM D 5379). (a) Testing configuration. (b) Specimen

The specimen is inserted into the fixture with the notch located along the line-of-action of loading. The upper head of the fixture is attached to and driven downward by the cross head of the testing machine. The resulting relative displacement between the two fixture halves introduces the load into the specimen and develops a shear plane between the notches. By placing two strain gage elements, oriented at ±45° to the loading axis and centered between the notches, the shear response of the material can be measured. Further details about the mechanics of the specimen can be found in MIL-HDBK-17 (Ref 27).

Limitations of the ASTM D 5379 method are described subsequently.

Inhomogeneous Materials. The material is assumed homogeneous with respect to the size of the test section. Materials that have relatively coarse features with respect to the test section dimensions, such as fabrics using large filament count tows (12K or more) or certain braided structures, should not be tested with this method.

Uniformity of Strain Field. The calculations assume a uniform shear strain state between the notches. The actual degree of uniformity varies with the level of material orthotropy and the direction of loading. A new strain gage grid configuration has recently been developed especially for use with this test method. The active grid on this gage extends from notch-to-notch and provides an improved estimation of the average strain response. Especially when using conventional strain gages, the most accurate measurements of in-plane shear modulus for unidirectional materials have been shown to result from the $[0/90]_{ns}$ specimen.

Load Eccentricity. Twisting of the specimen during loading can occur, affecting strength results and especially elastic modulus measurement. It is recommended that at least one specimen of each sample be tested with back-to-back rosettes to evaluate the degree of twist. The use of tabs can often alleviate twisting problems associated with thin specimens.
Determination of Failure. Failure is not always obvious in certain materials or configurations. The test specification gives guidance in this area.
Instrumentation. Strain gages are required.
ASTM D 4255-83, "Guide for Testing for In-Plane Shear Properties of Composite Laminates." This test standard is one of the more expensive and complex shear methods currently standardized. It has also historically been subject to relatively high scatter, especially between laboratories. ASTM Committee D-30 is currently considering a revision that is intended to remove the most significant sources of that scatter.
The standard contains two methods: a two-rail method and a three-rail method shown schematically in Fig. 9 using specimens measuring 76 × 152 mm (3.0 × 6.0 in.) and 137 × 152 mm (5.375 × 6.0 in.), respectively. Each specimen type is loaded in bearing using steel fixturing and fasteners 12.7 mm (0.5 in.) in diameter. The two-rail configuration pulls each longitudinal edge of the specimen in opposite directions, creating a shear plane along the longitudinal centerline of the specimen. The three-rail configuration loads the outer two longitudinal edges of the specimen and the centerline of the specimen in opposite directions, creating two shear planes. In both cases, strain gages are typically used to measure applied shear strain.

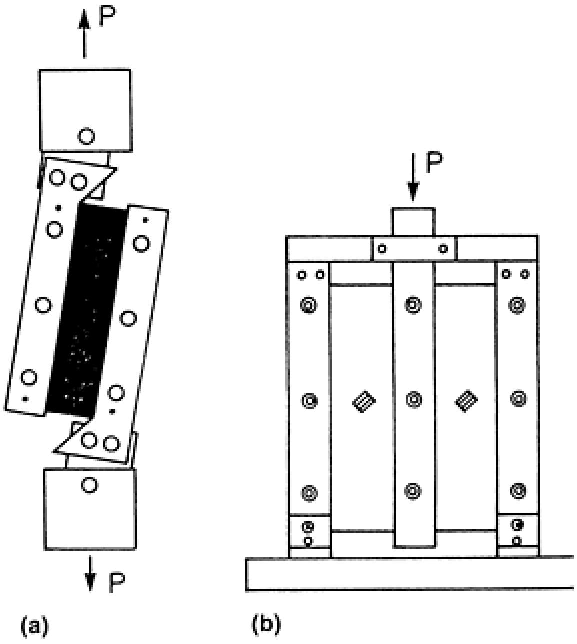

Fig. 9 Rail shear test (ASTM D 4255). (a) Two-rail configuration. (b) Three-rail configuration

Because the shear stress state is not uniform through the coupon, and because failures are often noted to begin outside the center of gage section (such as at the restrained corners of the plate), this test as currently standardized does not always produce reliable shear strength data (Ref 28). The three-rail test has a purer state of stress (Ref 29), although it requires a larger specimen size of approximately 150 × 150 mm (6 × 6 in.).
Limitations of the ASTM D 4255-83 method are described subsequently.
Specimen Size. Both versions require larger specimens than other shear tests.
Instrumentation. Strain gages are required.
Stress State. The stress state is known to be nonuniform, and the failure mode is typically influenced by nonshear failures starting outside of the gage section.
Data Scatter. High data scatter from round- robin tests casts doubt upon the reliability of the current version.

Out-of-Plane Shear Tests

Out-of-plane shear tests are standardized as:

- ASTM D 2344-84, “Standard Test Method for Apparent Interlaminar Shear Strength of Parallel Fiber Composites by Short-Beam Method”
- SACMA SRM 8R-94, “Apparent Interlaminar Shear Strength of Oriented Fiber-Resin Composites by the Short-Beam Method”
- ASTM D 5379, “Standard Test Method for Shear Properties of Composite Materials by the V-Notched Beam Method”

ASTM D 2344, “Standard Test Method for Apparent Interlaminar Shear Strength of Parallel-Fiber Composites by Short-Beam Method.” ASTM Test D 2344, commonly known as the short-beam shear (SBS) test, attempts to quantify the interlaminar (out-of- plane) shear strength of parallel-fiber-reinforced composites. The specimen for this test is a short, relatively deep beam cut from a flat laminate. The specimen is mounted as a simply supported beam and loaded at the midpoint of the span of the specimen. The intent is to minimize bending stresses while maximizing out-of-plane shear stresses by using a short, deep “beam.” However, the contact stresses induced at the load points greatly interfere with the strain distribution, both through the depth of the beam and axially along the length of the beam. The resulting failure is rarely, if ever, a true pure shear failure, but instead results from the complex stress state present in the specimen (Ref 30).

Despite its significant limitations, this test has commonly been used to develop design allowables for structural design criteria. This practice is not recommended. The ASTM D 5379 V- notch shear method discussed previously is the much-preferred choice. The short-beam shear test should only be used for qualitative testing, such as materials process development and control. As a quality control test, testing of laminate configurations other than unidirectional is common and acceptable, although they are currently nonstandard. A revision to the ASTM method is currently underway to allow the standard SBS testing of balanced and symmetric laminates.

A related (but unmaintained and less-preferable) method is SACMA SRM 8R-94.

Limitations of the ASTM D 2344 method are described in the following paragraphs.

Stress State. The stress state is known to be significantly disruptive and three-dimensional. The resultant strengths are a poor estimation of the out-of-plane shear strength.

Failure Mode. The failure mode is often multimode.

No Modulus/Material Response. Instrumentation of this specimen is not practical; therefore modulus and stress-strain data cannot be obtained.

ASTM D 5379, “Standard Test Method for Shear Properties of Composite Materials by the V-Notched Beam Method” (as applied for out-of-plane shear testing). This test method and the specimen geometry are described for the section “In-Plane Shear Tests” in this article. When testing for out-of-plane shear properties, the orientation of the fibers in the laminate is changed so as to cause a shearing action in the desired transverse plane. This test method is the only acceptable out-of-plane shear test available. The out-of-plane testing of laminates with fibers off-axis to the test direction, such as three-dimensional textiles, is subject to the same restrictions and limitations that are discussed in the section on in-plane testing.

ASTM D 3846-79, “Test Method for In- Plane Shear Strength of Reinforced Plastics.” ASTM test method D 3846, despite the title, is *not* normally used as an in-plane shear strength test, but is in fact an out-of-plane shear strength test and as such is covered in this section.

This test is primarily intended for use on randomly dispersed fiber-reinforced thermosetting sheet plastics as a substitute to the short-beam shear test method ASTM D 2344 described previously. The test consists of a doubly notched specimen loaded in compression in a supporting jig as shown in Fig. 10. (The fixture is the same as is used in the ASTM D 695 compression test.) Failure occurs in out-of-plane shear in the plane of the specimen between the two notches. While this specimen can be (and has been) used for testing continuous-fiber laminated-reinforced plastics, it is not recommended for use on advanced composite laminates. The notches, which are machined into the specimen to force failure of the laminate in shear, have been shown to negatively influence the stress distribution in the coupon (Ref 31). As a result, a nonuniform, multiaxial stress state exists in the gage section, making a true strength calculation suspect at best.

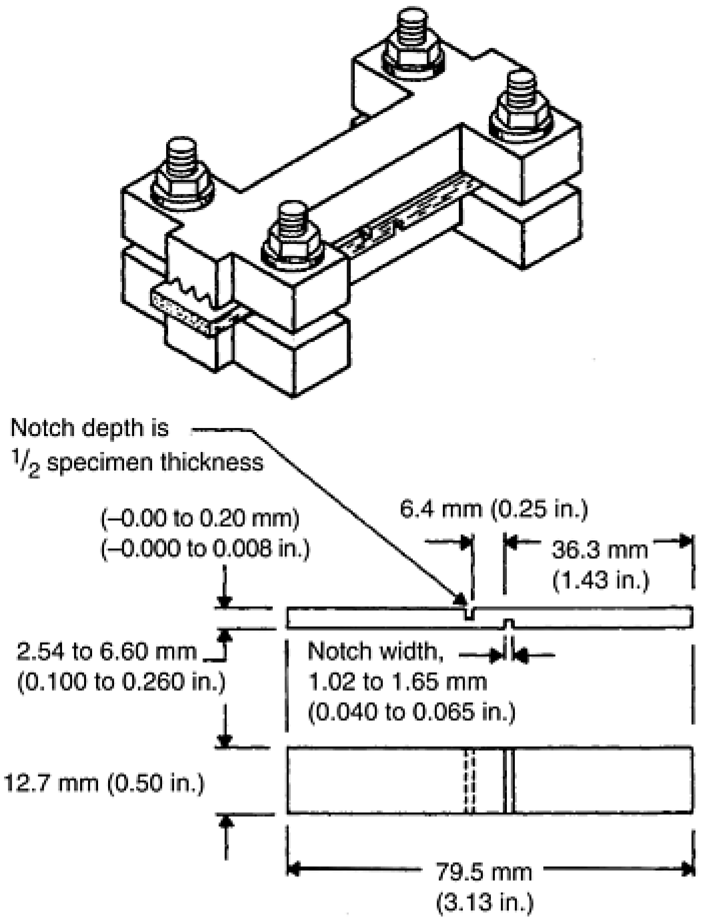

Fig. 10 Schematic of ASTM D 3846 test specimen and fixture

Limitations of the ASTM D 3846 method are described herein.

Stress State. A highly three-dimensional, nonuniform stress state in the gage section causes strength values from this test to be unusually poor estimations of the true out-of-plane shear strength.

No Modulus/Material Response. Instrumentation of this specimen is not practical; therefore modulus and stress-strain data cannot be obtained.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Flexure Property Test Methods

There is considerable debate concerning the validity of flexural testing of fiber-reinforced composite materials. Measured flexural properties are often highly dependent on stacking sequence, as is illustrated by the fact that for highly orthotropic laminates, the maximum stress of a flexure specimen may not occur in the outermost fibers. In these cases, assumptions based on homogeneous beam theory that enable simple data analysis do not hold, and more detailed analysis based on laminated beam theory must be applied. Other aspects of flexure testing that may have significant influence on the accuracy of the properties measured include interactions with the loading surface geometry, end forces developed by large support span-to-specimen depth ratios, and shear deflections that result from low span-to-depth ratios. Because of the complexity of some of these effects, it is difficult to make broad recommendations that apply to the majority of candidate materials. It is for these

reasons that laminate flexure testing should be used primarily for quality assurance and materials specification purposes.

ASTM D 790, "Standard Test Methods for Flexural Properties of Unreinforced and Reinforced Plastics and Electrical Insulating Materials." This specification was originally written for plastics, but has since been modified and approved for composites. It includes provisions for measuring maximum fiber stress, flexural strength, and flexural modulus. The basic test method consists of simply supporting a straight-sided, rectangular cross-section specimen on two supports symmetrically placed about the transverse centerline and loading in flexure with a third point placed on the transverse centerline. The specification includes two procedures that differ only by the applied strain rate. Procedure A is used primarily for measurement of flexural modulus and uses an outer fiber strain rate of 0.01 mm/mm/minute. Procedure B is restricted to measurement of flexural strength only and uses a strain rate ten times greater than procedure A (0.20 mm/mm/minute).

The span-to-depth ratio recommended by the specification depends upon the material stiffness and depth. Typical ratios are from 16:1 to 40:1, although some highly anisotropic composites require ratios of up to 60 to 1 in order to more accurately measure flexural modulus.

While many of the properties measured by this standard are subject to inaccuracies due to the complex stress states induced, particularly for highly anisotropic materials, the test method is useful for comparison purposes, provided all tests are performed using the same specimen geometry, span, and loading point arrangement. The reader is encouraged to read the specification carefully for guidance in performing this test and to critically review the data obtained.

Limitations of the ASTM D 790 method are described subsequently.

Highly Orthotropic Material Stress Distribution. The test method may not induce the maximum stress in the outer fibers of highly orthotropic laminates, making the calculations for maximum fiber stress inaccurate.

Maximum Fiber Strain Limitation. The method is only valid for materials that fail below 5% fiber strain.

Absolute Properties Are Often Not Measured. Due to the complex stress state that is often induced in this test, it should generally be used only as a quality assurance test rather than a source of absolute properties.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Fracture Toughness Test Methods

Fracture in structural solids is usually initiated by some crack or notch-like flaw, which induces high stresses in its immediate vicinity. The development of fracture mechanics has gained wide acceptance in metals, but because of the anisotropy of composite materials and the vast range of material behaviors represented in composites, their fracture behavior is still relatively poorly understood. A reasonable introduction to the basics of fracture mechanics can be found in MIL-HDBK-17 (Ref 32).

Fracture testing can be categorized into three types, based upon the manner in which crack tip stresses are developed. These three "modes" are defined by the relative displacement of the upper and lower crack surfaces with respect to each other. These modes are shown in Fig. 11. The primary property measured in fracture testing is the strain energy release rate, which is defined as the reduction in strain energy (or increase in potential energy) due to an infinitesimal self- similar extension of a crack. Catastrophic propagation of the crack will occur when this rate reaches a critical value, often referred to as the material toughness. Various test methods have been devised to measure the toughness of a given material in each of the three loading modes. However, though considerable work has been done in this area, as well as attempts to create methods for developing *R*-curves for modeling stable delamination growth as a result of both increasing static load and cyclic loading, only one test method (for mode I behavior) has been standardized. The following section describes only the standardized method for mode I testing, and the reader is referred to Ref 32 for information regarding several nonstandard methods.

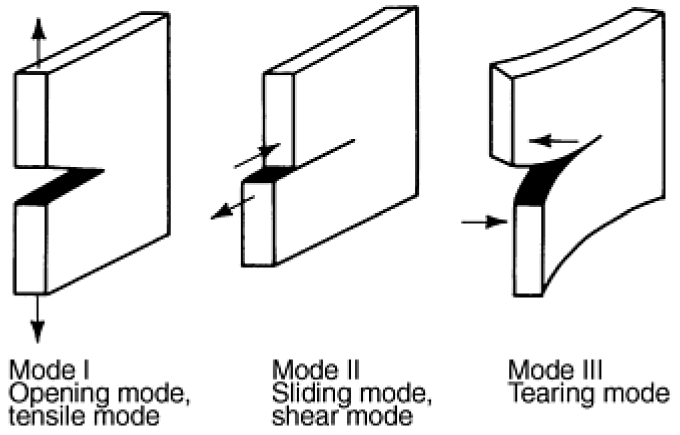

Fig. 11 Basic modes of crack extension

Mode I test methods are standardized as ASTM D 5528, "Standard Test Methods for Mode I Interlaminar Fracture Toughness of Unidirectional Fiber-Reinforced Polymer-Matrix Composites." The test, commonly referred to as a double-cantilever beam test, is shown schematically in Fig. 12. The specimen measures 125 mm (5 in.) long, 20 to 25 mm (0.8 to 1 in.) wide, and 3 to 5 mm (0.12 to 0.20 in.) thick and uses a nonbondable film insert placed at the specimen midplane during panel manufacture to create an initial crack length of approximately 63 mm (2.5 in.). The applied load, P, to the two arms, the corresponding displacement, δ, and typical load- displacement traces obtained are shown in Fig. 12(c). The numbers on these traces indicate results for various delamination lengths and are obtained as the delamination progresses. Various procedures for data reduction, other details, and restriction on specimen dimensions to avoid geometric nonlinearities are documented in the standard.

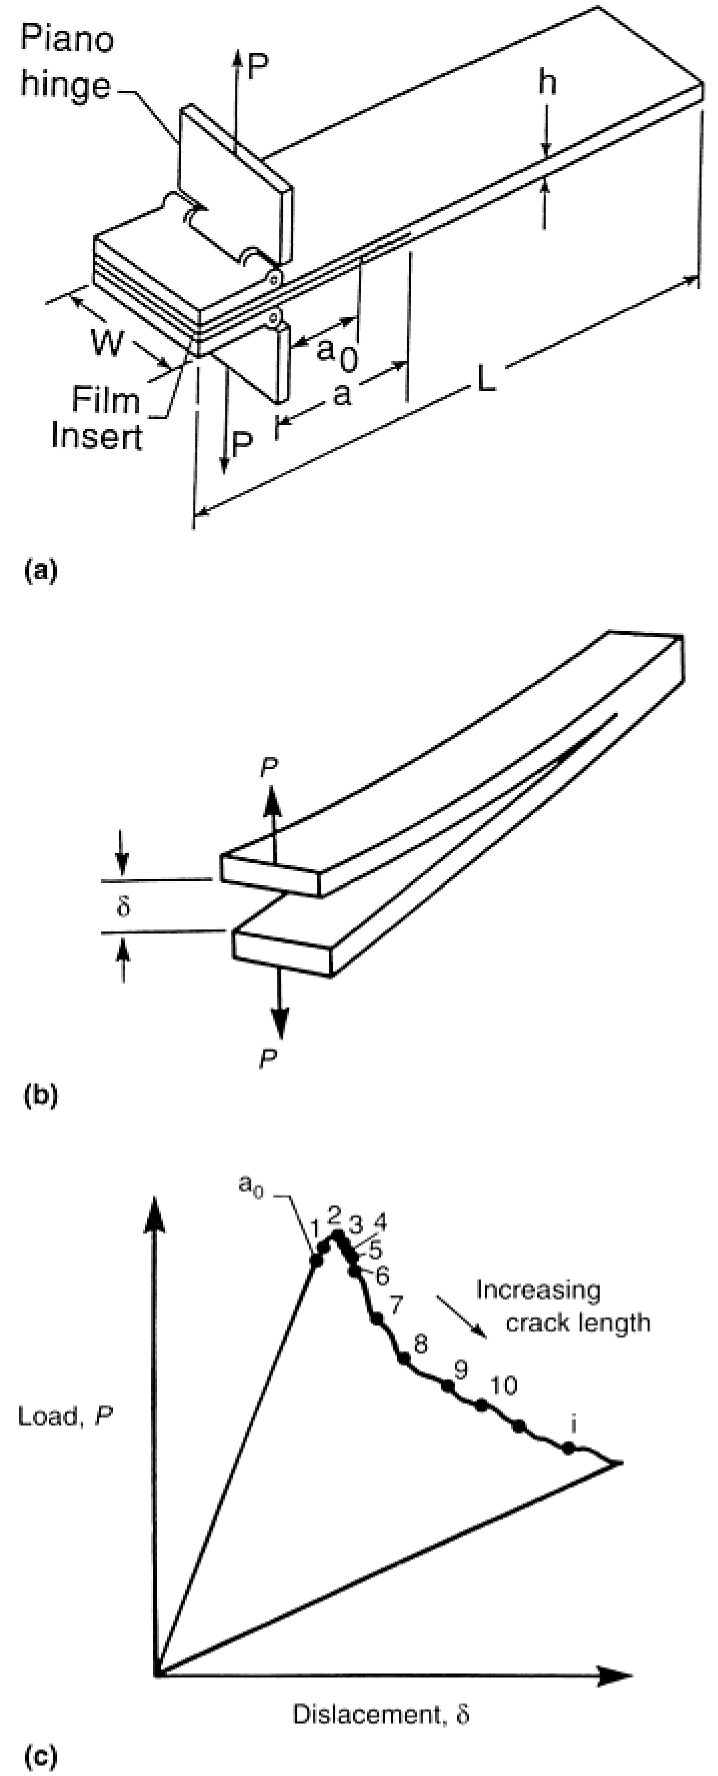

Fig. 12 Double-cantilever beam test (ASTM D 5528). (a) Specimen geometry. (b) Definition of crack- opening displacement. (c) Load-displacement trace during crack growth. a_0, initial crack growth

Toughness values may vary depending on the tendency of the delamination to grow out-of- plane. For this reason, testing of nonunidirectional laminates is prohibited. However, some unidirectional laminates may allow

considerable fiber bridging across the delamination plane. These bridging fibers may increase the measured toughness for all data past the initial crack, and the toughness value for initiation should therefore be identified separately from those at later stages of delamination growth.

In materials not strongly influenced by fiber bridging, a competing mechanism may dominate. When the delamination starts to grow from the insert, the initial toughness may be higher than that measured for subsequent growth. Data analysis in these cases requires that the initial toughness be disregarded as artificially high and that subsequent data be used instead.

Limitations of the ASTM D 5528 mode I method are described subsequently.

Material. Testing should be limited to unidirectional materials or at least laminates in which the delamination grows between two unidirectional plies aligned with the crack growth direction.

Failure Mode. Fiber bridging and artificially high initial toughness values (depending on the material being tested) require close attention to failure modes for proper interpretation of the data. Furthermore, propagation of the delamination front that "wanders" off the specimen midplane may result in high scatter.

Crack Growth Monitoring. Monitoring of the crack tip for growth is often difficult and requires great care. Observance of both sides of the specimen is important, because delamination fronts can grow asymmetrically. Application of a thin white film on each side of the specimen is often helpful, but great care should be taken to minimize the thickness of this film and to create as uniform a film surface as possible.

Lamina and Laminate Mechanical Testing

Rod Wishart, Integrated Technologies, Inc. (Intec)

Fatigue Property Test Methods

Static lamina test data is often used to predict the properties of application-specific laminate materials by the use of lamination theory. However, there are not yet well-established methods for doing the same for fatigue properties. For this reason, fatigue design properties for a given structural application usually must be generated using laminates representative of that structure. Furthermore, expansion of coupon data using element and structural component specimens in a "building-block" approach is often required. Because of the design-specific nature of most fatigue testing, there are very few standardized test methods for fatigue characterization of composite materials. The methods that do exist are tension-tension methods that do not consider compression loading. This is primarily due to the fact that most fatigue driven structures are tension- critical, and that the buckling-sensitive nature of compression fatigue testing makes most tests specific to an application and inappropriate for standardization.

Fatigue testing is usually performed using a constant-amplitude oscillatory stress or strain applied about some mean load. Other fatigue tests called "spectrum" or "block-spectrum" tests are not constant amplitude and are designed to reflect the full spectrum of loads that a structure might experience during a representative service cycle. (For example, the service cycle of an aircraft structure typically extends from takeoff to landing.) Because of the application-specific nature of spectrum testing, it is not discussed here.

Coupon-level fatigue testing is most often used to establish the characteristic curve of a laminate, relating the maximum applied oscillatory stress (S) or strain (ϵ) to the number of cycles to failure (N). These curves are called "stress-life" (S-N) or "strain-life" (ϵ-N) curves, respectively. The applied stress or strain is usually expressed as a percentage of the static material strength or failure strain.

In defining a fatigue test series, several variables must be considered, and all must be defined with regard to the intended use of the structure being evaluated. They include the following:

- *Upper cycle count limit, or "runout:"* Because it is possible to set the maximum oscillatory load low enough to cycle a specimen essentially forever without failing, a runout should be defined as a stop point to prevent the unnecessary time and expense of running a specimen longer than is appropriate for the application. At runout the residual strength of the specimen may be measured statically to determine property degradation compared to uncycled baseline specimens.
- *R-ratio:* This is the ratio of the minimum to the maximum applied stress or strain. For example, a tension-tension fatigue test with oscillatory stresses of 10 to 100 kN (2,250 to 22,500 lbf) has an ***R***-ratio of 0.1. A reverse- loaded (tension-compression) test with oscillatory stresses of 50 kN to–50 kN (11,240 to–11,240 lbf) has an ***R***-ratio of–1.0. Therefore, tension-tension tests have positive ***R***-ratios between zero and 1, while compression-compression test ***R***-ratios are positive and greater than 1.
- *Frequency:* Although most materials are generally insensitive to frequency, it is good practice to generate a given *S-N* curve using the same frequency for each specimen. Of particular concern is ensuring that the frequency used is not so fast that unacceptable heating of the specimen occurs. Each laminate has its own characteristics regarding frequency dependent heating. A general guideline is to limit frequency induced heating to 10 °C (20 °F) above ambient.
- *Waveform:* Most fatigue tests apply load using a sinusoidal waveform.

ASTM D 3479 "Standard Test Method for Tension-Tension Fatigue of Polymer-Matrix Composite Materials." The ASTM D 3479 test method uses the specimen geometry defined by ASTM D 3039 and provides for development of *S-N* curves as well as the characterization of damage growth, such as microcracking, delamination, or fiber damage due to fatigue cycling. Because of the gradual damage growth usually typical of fatigue testing, it is especially important to minimize the critical issues affecting test results for straight-sided tension testing, including tabbing, specimen machining, and grip alignment. (See the section "In-Plane Tension Test Methods" in this article.)

Element and Subcomponent Testing

Lawrence A. Gintert, Concurrent Technologies Corporation

Introduction

STRUCTURAL TEST SPECIMENS designed to characterize composite material behavior for failure modes not addressed in flat coupon specimens are known as *elements* (for smaller, more standard specimen configurations) and *subcomponents* (for nonstandard and typically larger specimens). Materials data can be used to design tests for structural elements and subcomponents tailored to represent the actual structural components being studied experimentally. These tests are used for allowable verification and for fulfillment of structural-integrity requirements specific to the materials and geometry of the component under consideration. These tests are necessary because the behavior of composites is not adequately characterized using two-dimensional coupon testing as in homogeneous or isotropic materials, especially in areas of structural joints and complex geometry.

It is assumed that the reader is familiar with the general structural behavior of composite materials and has been introduced to the “building- block” approach to composite materials certification discussed in the previous articles in this Section (see, in particular, the article “Overview of Testing and Certification”). This discussion focuses on experimental characterization of composite structures at the element and subcomponent level of complexity of the building-block approach described in *Composite Materials,* MIL-HDBK-17. The elements discussed characterize laminates, bolted and bonded joints, and damage tolerance behavior that is needed for design of composite structures, while subcomponents characterize structural behavior unique to specific design features of the full-scale structure. General discussion on analysis and design of bolted and bonded joints can be found in MIL- HDBK-17, Volume 3, Section 5, while damage tolerance is covered in Volume 3, Section 6.2.4. A complete description of the building-block methodology is provided in MIL-HDBK-17, Volume 1.

This article begins with an overview of why structural element and subcomponent testing are conducted, including a discussion on the different types of failure modes in composites. An overview of the testing methodology, fixturing, instrumentation, and data reporting is provided, followed by a description of various standard elements used to characterize composite materials for the various failure modes. Simple structural-element testing under in-plane unidirectional, multidirectional, and combined loading as well as out-of-plane loading are discussed. Simple bolted joints and bonded joints are discussed as well as data correlation with analytical predictions. Some of the standard testing methods are briefly discussed, and a list of ASTM testing standards applicable at the element level of testing for both polymer-matrix composites and metal-matrix composites is also included. Examples of subcomponent test specimens are also provided. The article ends with a brief discussion on durability and damage tolerance testing. Testing used to characterize damage applies to typical composite structures, assuming common design practices are employed such that damage incurred is typical of relatively balanced laminates of reasonable quality and integrity. This testing, known as compression after impact (CAI) testing, is used widely in the aerospace industry to gage damage tolerance potential of composite materials. It is discussed as being applicable to solid laminates as well as sandwich construction laminates.

The methodology provided herein is generally applicable to composites designed with standard composite practice employed, such as material buildup for mechanical fastening, adequate fastener edge distance, and fastener pitch. Refer to MIL-HDBK-17 for a more thorough discussion regarding composite design practice and certification guidelines.

Element and Subcomponent Testing

Lawrence A. Gintert, Concurrent Technologies Corporation

Test Methodology and Considerations

The purpose of element and subcomponent testing is to characterize failure modes not addressed in lower-level testing. These failure modes are typically those that are influenced by stresses applied in the weakest direction of the composite materials being used, normally through the thickness for layered composites. The results of this testing are correlated with analysis to verify strength methodology as it applies to failure modes and magnitudes. Subcomponent tests usually represent a full-sized or scale-model segment of the real structure being evaluated.

Testing and analysis of composite joints and other elements are essential for establishing the structural integrity of composite structures and ensuring their reliability. Due to the inherent weakness of composite materials in the through- thickness direction, any joint in a composite structure is a potential failure site. Without proper design a joint can act as a damage initiation point, which can lead to a loss in structural strength and eventual failure of the component. Two types of joints in common use are mechanically fastened joints and adhesively bonded joints. The guidelines discussed subsequently from MIL-HDBK-17 define test types, laminates, environments, and replication that are needed for sound joint design.

For mechanically bolted joints, tests are recommended that characterize the joint for various failure modes: bearing, notched tension/compression, bearing/by-pass, shear-out, and fastener pull-through. Test matrices are provided in MIL-HDBK-17. A straightforward test method to determine material bearing strength is provided. The bearing strength measured by this test is the upper bound value that can be achieved in a realistic structural joint. The test is useful for qualification purposes or for material-to-material comparisons. A detailed analysis of the stress distribution around a fastener hole is available in MIL-HDBK-17, Volume 3, Section 5.3. Discussion on both theoretical and empirical approaches to the stress analysis of bolted joints in composite materials can be found in Ref 1.

For bonded joints, two types of tests are described. The first type determines adhesive properties that are needed in design. These tests provide adhesive stiffness and strength properties needed for analysis and design methods of MIL- HDBK-17, Volume 3, Section 5.2. The second type is used to verify specific designs. Examples of such tests are shown.

Failure Modes. An important consideration in element and subcomponent testing and analysis is the selection of the type of test method, with due attention to the failure mode that is likely to result with a specific design in a particular composite system. The various failure modes for bolted joints described subsequently provide an example of how this needs to be considered.

The occurrence of a particular failure mode is dependent primarily on joint geometry and laminate configuration or lay-up. Composite bolted joints may fail in various modes, as shown in Fig. 1. The likelihood of a particular failure mode is influenced by bolt diameter (D), laminate width (w), edge distance (e), and thickness (t). The type of fastener used can also influence the occurrence of a particular failure mode. Net section tension-compression failures occur when the bolt diameter is a sufficiently large fraction of the strip width. This fraction is about one- quarter or more for near-isotropic lay-ups in graphite/epoxy systems. It is characterized by failure of the plies in the primary load direction. Cleavage failures occur because of the proximity of the end of the specimen. This type of failure often initiates at the end of the specimen rather than adjacent to the fastener. In some instances, the bolt head may be pulled out through the laminate after the bolt is bent and deformed. This mode is frequently associated with countersunk fasteners and is highly dependent on

the particular fastener used. Finally, it is important to note that for any given geometry, the failure mode may vary as a function of lay-up and stacking sequence or laminate configuration.

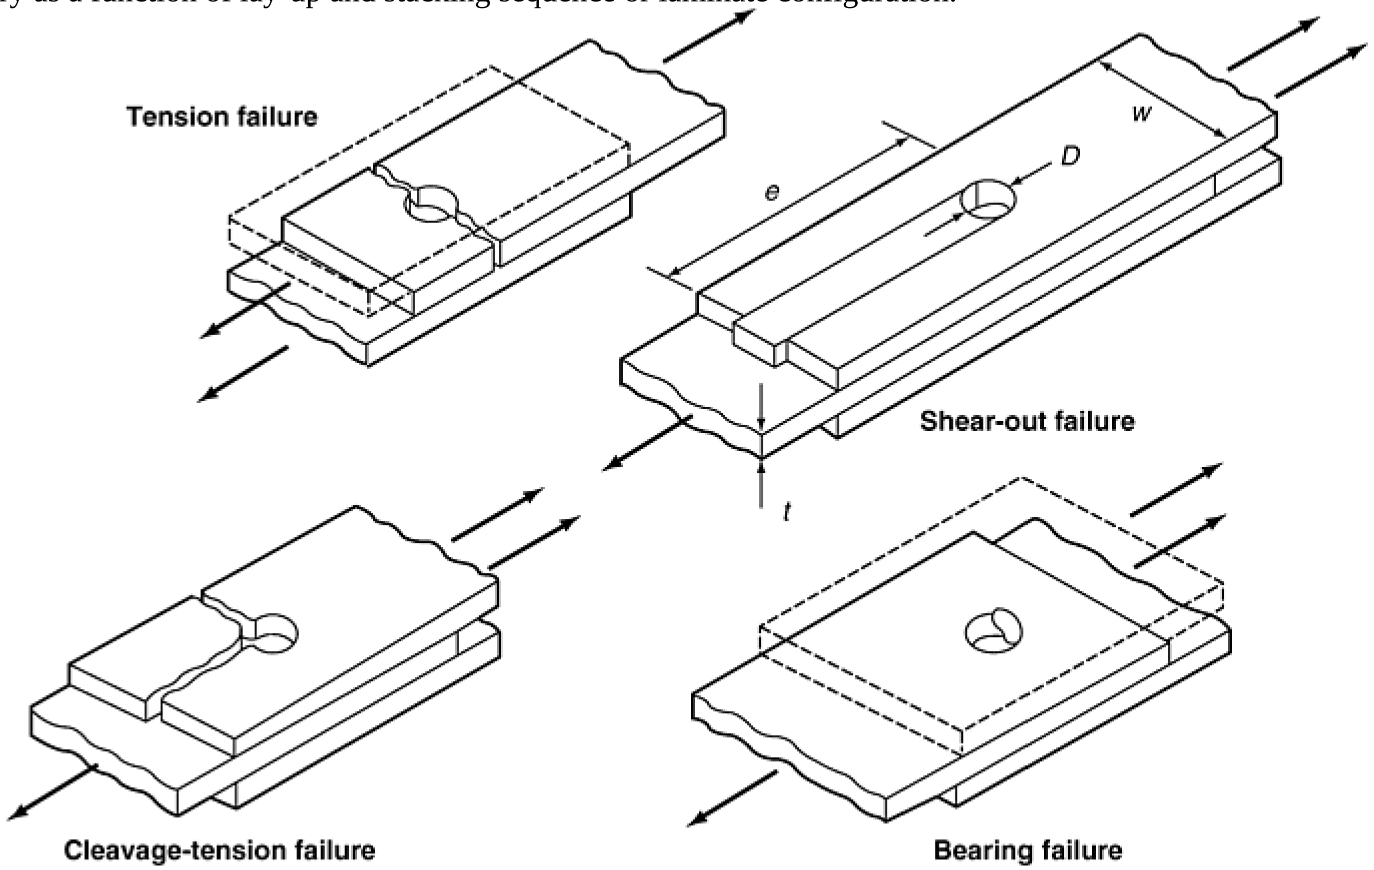

Fig. 1 Typical failure modes for bolted joints in advanced composites

In order to design against the different failure modes and the interactions between them, the capability of the composite material has to be determined by tests. These are described in MIL- HDBK-17 to provide guidance as to amount of testing that would be typical, but not necessarily the minimum. These properties may be different for each distinct laminate, fastener type, and environmental condition. The properties also change depending on ply orientations (or typically the percentage of 0°, 90°, or ±45° direction plies) in the laminate. The number of laminates to be tested is governed by analysis capability and degree of confidence in extrapolation from test results.

The shear-out mode of failure is usually avoided in design by providing sufficient edge distance between the holes and at the free edge, and by using a balanced laminate configuration. Shear-out critical joints sometimes cannot be avoided, especially in rework situations. In those situations, a test program must be undertaken to establish the materials properties for this failure mode. (See MIL-HDBK-17, Section 7.2.8 for further discussion.)

Net tension-compression and shear-out strengths are a strong function of laminate configuration, joint geometry, and hole size, but are only marginally dependent on fastener type, joint configuration, or environment. On the other hand, bearing and fastener pull-through strengths are greatly influenced by the type of fastener used and its characteristics, such as clamp effects, bolt stiffness, head and tail areas, countersinking, and so on. The laminate lay-up and stacking sequence do not affect bearing or pull-through strengths significantly unless extreme lay-ups are used, the extreme being defined as a laminate having highly concentrated plies or plies in only two directions.

Fixturing. Load introduction and support structures (i.e., fixturing) must be carefully designed to simulate those of the real structure, yet must not fail before the element or subcomponent does. Jigs and fixtures for subelements are usually custom-designed, while many standard fixtures for elements are governed somewhat by the standards for those test configurations. The test fixture should fully support the specimen against buckling in compression between tabs and might need to provide floating support features in order to avoid interference or unwanted load paths. Loading should represent design static or durability (fatigue) load cases based on the internal loading calculated for the particular structural segment, and therefore, the fixturing or load introduction apparatus would need to easily withstand this loading. Boundary conditions should also be

representative of those provided by the surrounding structure, mandating a consideration of relative stiffness for the fixturing. Data to be recorded should be understood and planned for during fixture design so that instrumentation can be located in an effective manner that is easily accessed for inspection and troubleshooting. Anticipated strains and deflections at critical points in the structure should be considered as well.

Instrumentation. Instrumentation may be as simple as that shown in Fig. 2 for tensile elements, but will usually include a number of back-to-back biaxial strain gages used to measure the material and element behavior under more complex loading conditions. It may also include extensometers and deflection gages, especially if the test objectives include measurement of deformation or buckling of critical elements.

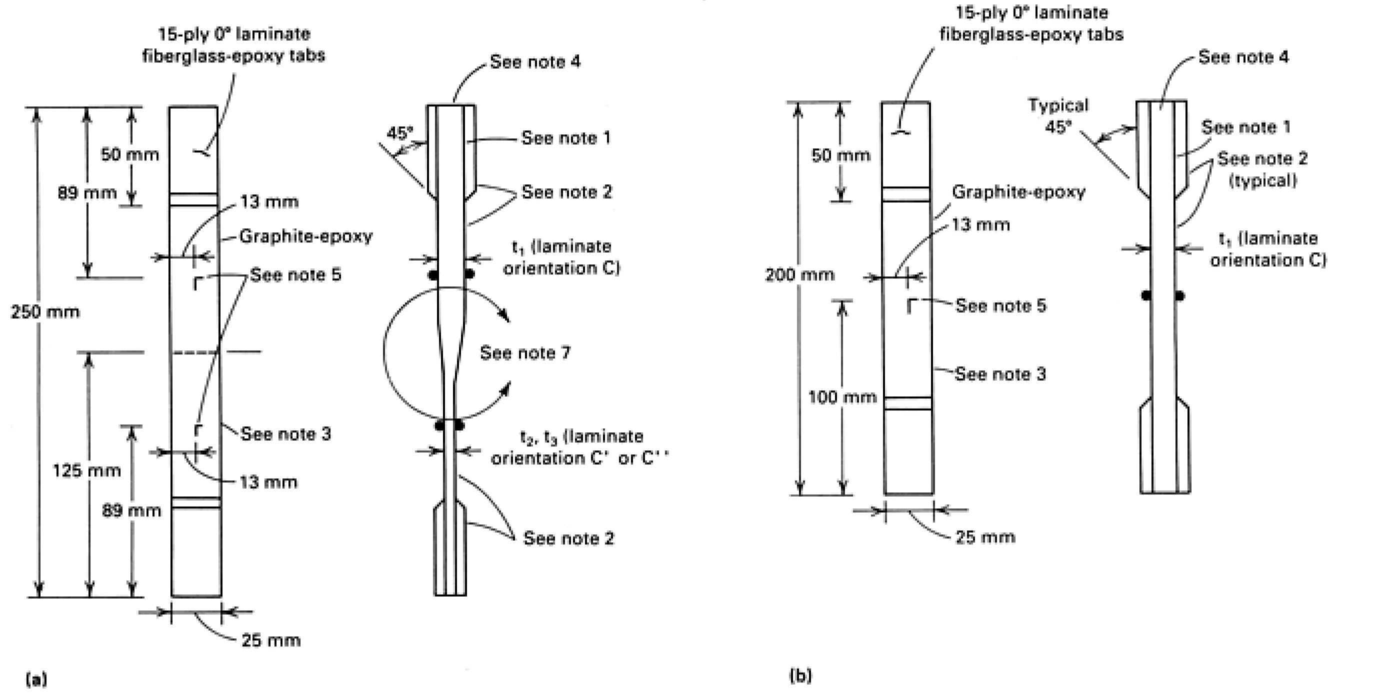

Fig. 2 Longitudinal or transverse tensile static and fatigue specimens. (a) Ply drop-off specimen. (b) Plain specimen. (1) Bond glass-epoxy tabs with an epoxy film adhesive. (2) Specimen thickness shall not vary more than ±0.13 mm (0.005 in.) from nominal. (3) Specimen longitudinal edges shall be parallel to 0.13 mm (0.005 in.). (4) Top end and bottom end surfaces shall be flat and parallel to 0.25 mm (0.010 in.). (5) Strain gages shall be micromeasurements EA 03-250BF-350 or equivalent, located as shown. (6) Testing shall be in accordance with ASTM D 3039 (Ref 2). (7) Location of ply drop-off

Instrumentation is usually greater for static than for fatigue testing, and to some extent, the static test results will influence the location and type of instrumentation to be used in the fatigue testing. Certainly the highest stress (strain) and deflection areas observed in the static test need to be monitored at least periodically, if not continuously, in fatigue testing. For surviving subcomponents, added instrumentation may be desirable for static residual-strength testing so that an accurate comparison can be made with the original static strength. Special instrumentation may be required for subcomponents that exhibit elastic buckling before reaching design ultimate load. Back-to-back biaxial gages or three-gage rosettes are preferred for nonbuckling compression testing, but are a necessity for compression buckling testing. A divergence of the strain readings of the back-to-back compression gages of more than ±10% from the mean strain usually indicates buckling.

Loading and recording equipment should be of a type that allows continuous reading, such that constant monotonically increasing loading rates, or deflection or strain rates, at critical points can be maintained to failure. Preliminary instrumentation static checkout runs should not exceed 20% of predicted design ultimate failure load. For fatigue loading of subcomponents, the temperature increases of the structure at high- strain areas should be monitored; if increases exceed 3 °C (5 °F), either the temperature or the fatigue-loading rate should be reduced.

For a monotonically increasing load, strain, or deflection-controlled static test, the important properties to measure at critical points are load- strain and load-deflection behavior to failure. Also, the failure mode, location, and type should be recorded photographically.

Data Analysis and Reporting. Materials property data should be collected, reduced, and analyzed, as well as simple element mechanical- behavior data. Load versus strain and load versus deflection data from static tests should be tabulated and continuous plots of their behavior curves recorded to failure. This data may represent not only materials properties, but also important element behavior under loading, such as linearity range, deformation at elastic limit, and load versus deformation behavior beyond the elastic range to failure. Failure modes and their classification and relation to materials behavior become even more important than in coupons because they more closely resemble selected discrete areas of failure in the subcomponent test. Failure modes should be analyzed visually and microscopically, and selected critical failure surface areas should be studied with cross-sectional photomicrographs to determine the character, cause, and progression of the fracture at the microstructure level that leads to the macrostructural failure causing the subcomponent structural failure. Such study of the microstructure can provide information on materials, processing, or design defects that might cause premature failure. Accurate analytical prediction of failure load and mechanical behavior of structural elements is also more important than at the coupon level, because the element behavior may represent a discrete part of the subcomponent and lead to the development of analytical methodology for the subcomponent. Laminate lay-ups that have too many plies of the same orientation laid up together can also cause premature failure under certain loading conditions, such as hot/wet compression, which can be identified along with the microfailure mode.

Key points on the load-strain or load-deflection curves should be tabulated. These might be the end of linearity, any points of sudden load, strain, or deflection changes, and the initial straight-line slope, which gives the elastic-range structural stiffness. Recorded experimental data will need to be reported in detail, along with explanations of what data were obtained and how, when, and where. In addition, the data should be compared with analytical predictions of stresses, strains, and deflections at various points along the load path, and the predicted and actual failure load and mode should be compared. Once the body of the report is complete, conclusions can be drawn and the meaning and importance of the test results detailed. These will include such things as whether the structure performed in the manner for which it was designed, along with discussion of the meaning of any discrepancies in behavior. The concluding remarks should also state whether the testing met its scope of work and whether the test results satisfied the test plan objectives.

Element and Subcomponent Testing

Lawrence A. Gintert, Concurrent Technologies Corporation

Standard Elements

Standard elements are those that characterize the general behavior of materials systems under in-plane loading, normal and bending loading, and at joints. Data from these standard element tests are useful to the designer for applications using the materials system in areas where this type of loading is expected, such that structural sizing may be established using the data and analytical techniques correlated with the testing results. This approach enables the design to proceed with structural substantiation by analysis correlated with these results, provided that the same critical parameters, such as material orientations, ply sequencing, edge distances, processing parameters, and general sound design practice are employed. Out-of-plane loading conditions and areas of nonstandard geometry must be considered separately, using subcomponent or full-scale testing.

Environmental effects are typically addressed as part of the standard element testing because it is more economical to do at this level, but is only useful for addressing the failure modes characterized by those test methods.
Various test methods for solid laminates, sandwich laminates, and joints are discussed subsequently. Table 1 provides a list of ASTM testing standards applicable to composites at the element level of the building-block approach.

In-Plane Loaded Elements

In many respects, simple element testing under uniaxial tension and compression loading resembles coupon testing. However, the specimens are usually larger and occasionally contain discontinuities such as holes, notches (slots), ply drop-offs or joggles. These elements typically have more instrumentation than do simple coupons, and more effort is required to provide adequate design of the load introduction and test fixtures, because few standard methods are available at the element level. In this case, adequate design means that the load introduction and test fixture configuration will allow the specimen to be loaded to the required stress (or strain) level at failure. Such design will also allow an acceptable failure mode to occur; that is, one that is expected in the full-sized structure (component and subcomponent).

Different types of elements are discussed subsequently. Note that for each type of element and subcomponent, adequate material must be incorporated into the grips or load introduction tabs in order to develop the loading such that the appropriate failure mode is experienced at specimen failure. For more information regarding the design of tabs and grips see MIL-HDBK-17, Volume 1, Section 7.

Tension-Loaded Elements. Although much information on tension-loaded coupons is given in ASTM D 3039 (Ref 2) that may be useful in design and testing of tension elements, additional work on load-introduction tabs, consideration of discontinuities, and added instrumentation are usually necessary. In the laminate evaluation longitudinal-tension specimens with and without a thickness discontinuity illustrated in Fig. 2, the discontinuity is a ply drop-off, but it could have been a center hole or a combination of both.

Effects of such discontinuities are covered in Ref 3 and 4. Small reductions in static compression strength and no reduction in fatigue strength are observed in these ply drop-off tests.

Compression-Loaded Elements. A typical compression-loaded element with ply drop-off defects is shown in Fig. 3. The clamped platen- supported fixture for these specimens is shown in Fig. 4. Load introduction is by bearing on the ends of the specimen, which is machined flat and parallel to within 0.025 mm (0.001 in.). The test set-up, which can be used in compression loading for both the static and fatigue test conditions, is shown in Fig. 5.

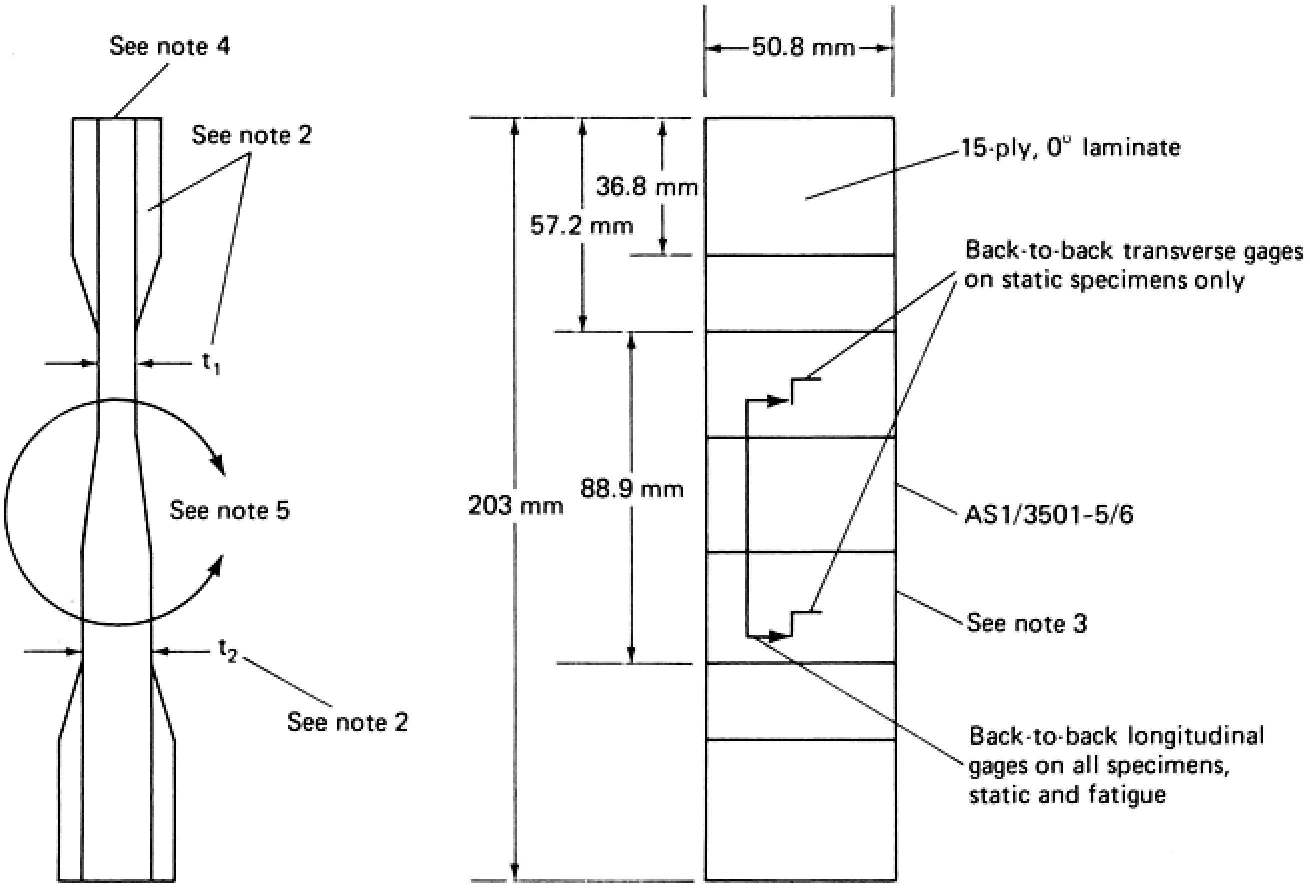

Fig. 3 Static and fatigue ply drop-off test specimen. (1) Bond fiberglass-epoxy tabs with epoxy film adhesive. (2) Specimen thickness shall not vary more than ±0.13 mm (0.005 in.). (3) Specimen longitudinal edges shall be parallel to 0.13 mm (0.005 in.). (4) Top end and bottom end surfaces shall be flat and parallel to 0.025 mm (0.001 in.). (5) Location of ply drop-off

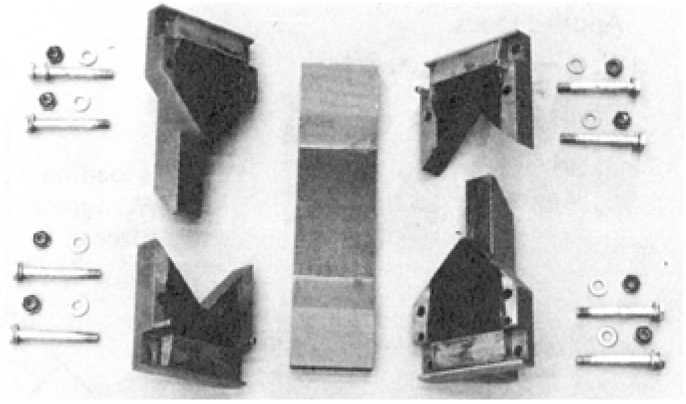

Fig. 4 Support fixture for compression static and fatigue testing

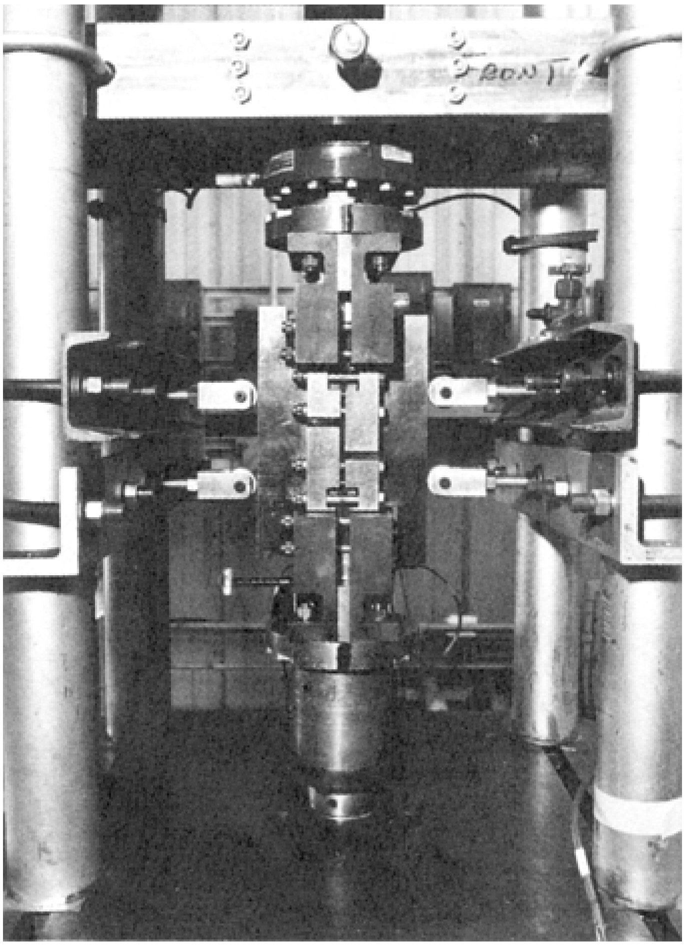

Fig. 5 Machine set-up for compression static and fatigue testing

Because load introduction in these compression specimens is primarily by end bearing on the specimen and the tab, the bonded-area quality is not as critical as before. However, grinding the ends flat and parallel to ≤0.025 mm (≤0.001 in.) is critical, and both ends of every specimen should be inspected on a surface plate after machining. Those that do not meet this requirement should be rejected and reground, because nonuniform bearing can cause premature failure of the end-pad bonds.

Combined Load Elements. Combined in- plane loaded composite materials test elements and methodology can be as simple as the rail- shear test detailed in ASTM D 4255 (Ref 5) for obtaining shear stress-strain curves to failure of simple, unnotched, unidirectional, or multidirectional laminates. A picture frame test set-up shown in Fig. 6 is used for testing notched and unnotched multidirectional laminates in shear. With proper instrumentation (strain gages or deflectometers), this gives a shear stress-strain curve to failure. More complex testing includes biaxially loaded notched or unnotched multidirectional laminates. Such tests are usually combinations of compression and compression or tension and compression loading, each at 90° to the other.

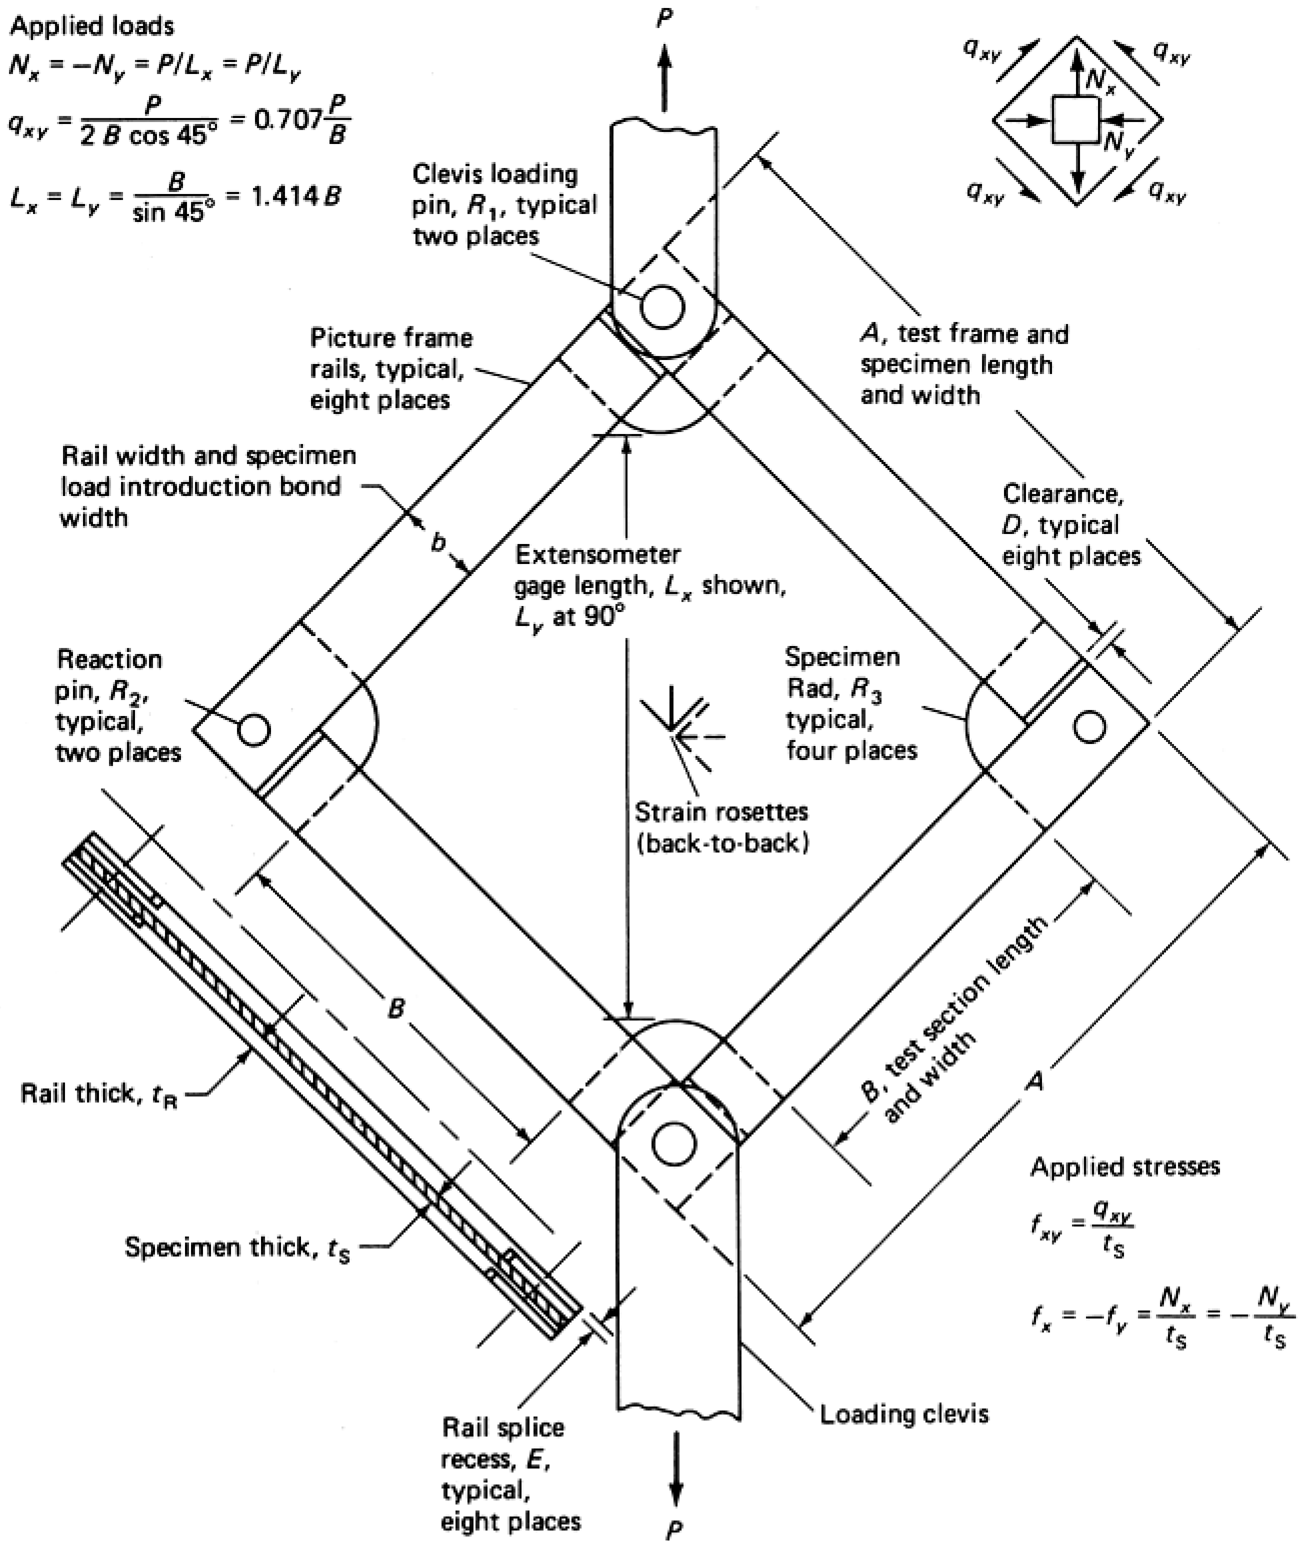

Fig. 6 Picture frame test set-up and specimen

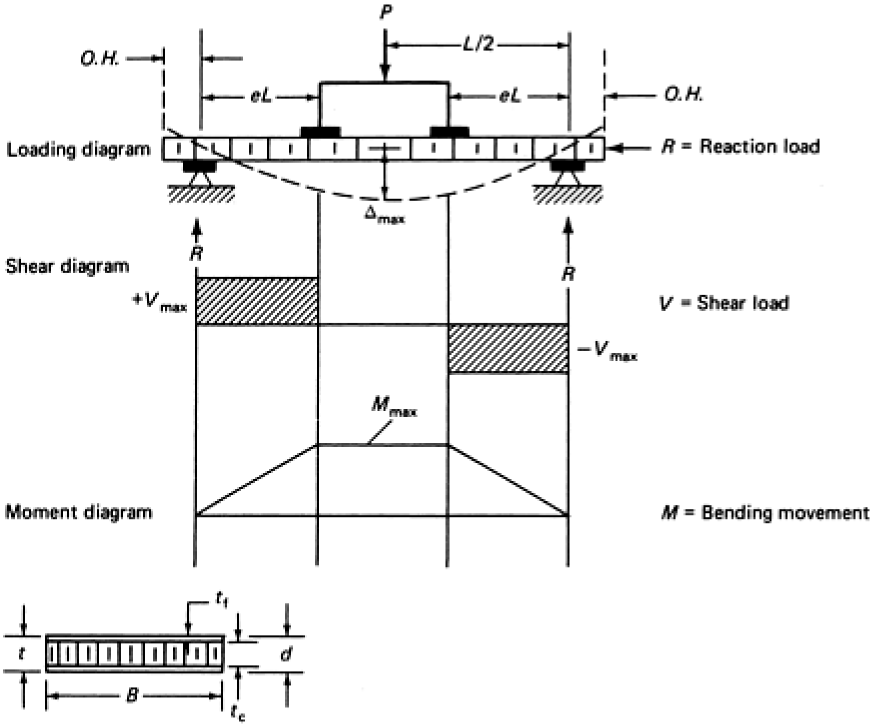
Normal and Bending Loaded Elements

At the element level, these tests include bending of beams, transverse shear, transverse tension (or peel), and transverse compression (core compression in sandwich laminates). These beams may be solid laminates, stiffened sections (blade, hat, I), or sandwich beams with composite faces. Beam technology, in general, is well documented. Simple sandwich beams are discussed in Ref 6 and 7.

Testing composite and sandwich beam elements differs from testing isotropic material (metal) beam elements in that shear stresses (or strains) and deformations must be taken into consideration when designing, testing, and analyzing them. In addition, load and support-point softness should be considered in load introduction, as

should the requirement for load pads to prevent local crushing, especially in sandwich beams with honeycomb or foam cores that are relatively weak in flatwise compression strength.

Long Beam Flexure. A four-point loaded simple sandwich beam element is shown in Fig. 7, with the applicable equations for calculating maximum face stress, core shear stress/bondline shear stress, and core shear modulus. Such elements may be tested according to ASTM C 393 and are used to measure core or face properties or to perform quality assurance testing, and are tested as structural elements representing larger beam-bending sandwich structures. For relatively long spans, the testing is sometimes referred to as “long beam flexural” testing. The same testing method, however, may be used to characterize transverse shear properties by shortening the span such that a panel shear failure mode is experienced as discussed subsequently. Generally, the sandwich flatwise tension strength and the flatwise compression strength and modulus are required for complete analysis, in addition to similar sandwich core shear and facesheet properties. This is because of the need for face-wrinkling analysis plus intercellular- buckling analysis of honeycomb core sandwich specimens on the compression face (Ref 6). In addition, the core flatwise compression strength is used to calculate the load/support pad area necessary for use in testing the beam. Once the properties of all the sandwich constituents are known, the maximum load at failure can be calculated, and then the load pad size can be calculated.



Formulas

- Bending stress in faces

$$F_b = \frac{M_{max} y}{I_f}$$

- Shear stress in core

$$f_s = \frac{V_{max}}{A_c} k$$

- Maximum deflection

$$\Delta_{max} = \frac{PL^3}{48D}(3e - 4e^3) + \frac{VeL}{A_c G_c} k$$

- Shear modulus calculation

$$G_c = \frac{\left(\frac{P}{\Delta}\right) eL}{B(t + t_c)\left[1 - \left(\frac{P}{\Delta}\right)\frac{L^3(3e - 4e^3)}{48D}\right]}$$

Equations

$$A_c = B\frac{(t + t_c)}{2} = Bd, \text{ shear area}$$

$$D = \frac{E_f I_f}{(1 - \mu^2)}$$

$$I_f = \frac{B(t - t_c)}{4}\left(\frac{t + t_c}{2}\right)^2 = \frac{1}{2}B t_f d^2, \text{ moment of inertia of faces about neutral axis}$$

B	Width of faces
t_f	Face thickness
t_c	Core thickness
d	Distance between centroids of faces, $(t + t_c)/2$
μ	Poisson's ratio of face material
E_f	Modulus of elasticity of face material
(P/Δ)	Initial straight line slope of load deflection curve
t	Total sandwich thickness
$y = t/2$	Distance from neutral axis to outer surface of one face
$R = P/2$	
P	Total applied load
$V = P/2$	
$M = PeL/2$	
O.H.	Overhang
k	Correction factor
e	A decimal fraction with the limits $0 < e \leq 0.5$

Fig. 7 Sandwich beam four-point load test

Panel Shear. The same four-point loading set- up is shown in Fig. 8, using a shorter span ratio such that a transverse shear failure occurs. This testing (also according to ASTM C 393) is used to characterize core shear properties for sandwich laminates and may require testing with the core material in specific orientations if the materials properties vary relative to the orientation, as with honeycomb core, for example.

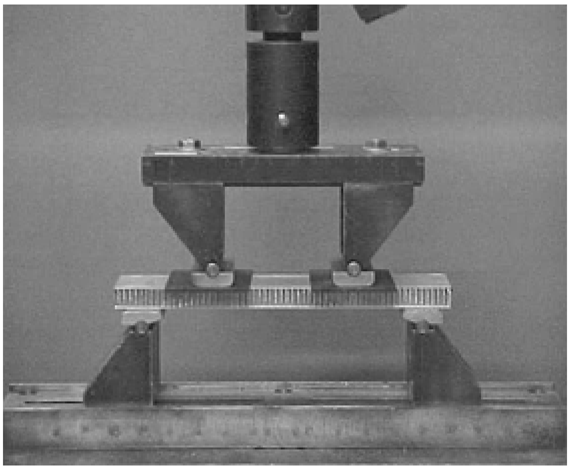


Fig. 8 Sandwich panel shear test set-up

Transverse Tension. The transverse tension strength of composites is one of the most important properties to characterize for sound design, because it is inherently the weakest direction for the material. While there are numerous approaches to characterize these properties, an example of one approach to this type of testing is provided in Fig. 9, showing a set-up for climbing drum peel testing in accordance with ASTM D 1781. This test literally peels one of the facesheets away from the core to establish the bond strength between the constituent materials. Other methods include flatwise tension of rectangular specimens and angle specimens with a precise bend radius, which is tested such that the radius is subjected to interlaminar tension stresses by pulling the legs of the specimen apart so that the radius tries to open.

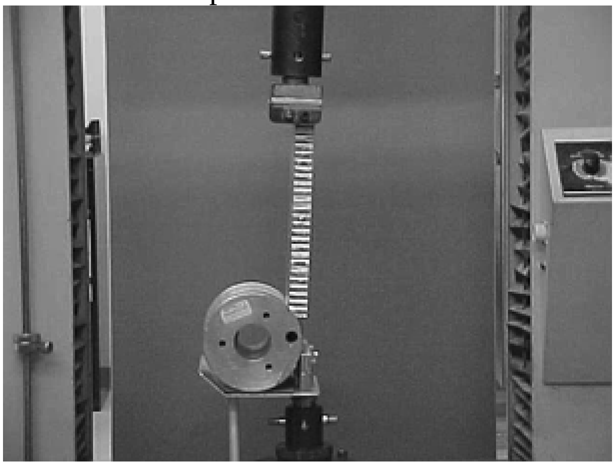

Fig. 9 Climbing drum peel testing for sandwich composites

Transverse Compression. The transverse compression test is generally conducted in accordance with ASTM C 365 in order to determine the core compression strength of a core material used in sandwich laminates. This strength may then be used in design to determine the required footprint to support a direct bearing load on a sandwich panel. It may also be used to establish allowable bending loads for a curved sandwich shell where kick loads tend to crush the core.

Joint Elements

The joint elements discussed in this section include mechanically fastened (or bolted) and bonded joint configurations used in the tests described in Ref 8 and 9. The various failure modes for bolted joints discussed earlier in this section will not be repeated here, but the testing used to characterize these failure modes is briefly covered. The bolted-joint discussion includes an example of analytical correlation of predicted strength values generated using an aerospace-approved method of analysis for bolted joints in composites. It should be noted that for composites, a joint that is both bonded and bolted would generally perform structurally superior to one that is either bonded or bolted. The bolt helps prevent a peel-type failure of the bond, and the bond reduces the tendency of the bolted joint to shear out. Testing of a bonded-bolted joint may be considered as a nonstandard joint and thereby tested as a subcomponent.

Material Bearing Strength. A simplified test introduces the bearing load in a double-shear configuration. In actual applications, load transfer in a single-shear configuration is more commonplace, resulting in larger stress concentrations in the thickness direction and lowering the realizable bearing strength. These single-shear tests are discussed later in this section. In other words, the bearing strength values measured in the double-shear test cannot be applied to single- shear joints. The double-shear arrangement is shown in Fig. 10.

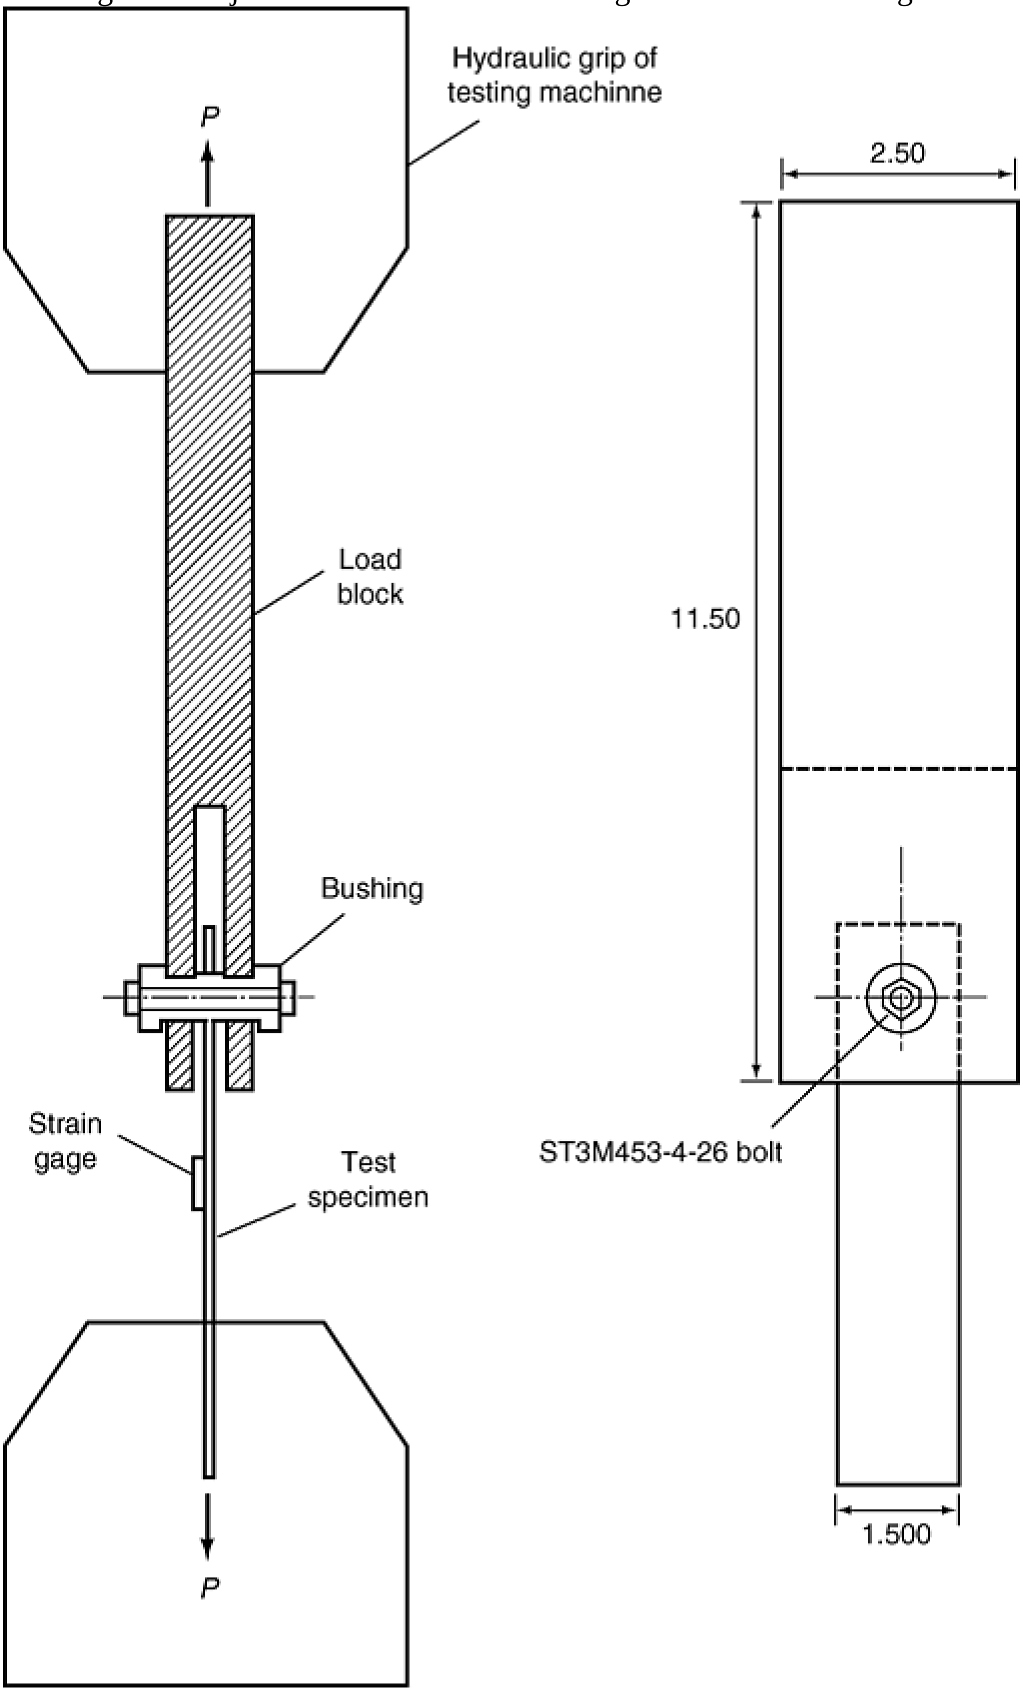

Fig. 10 Material bearing strength testing. Dimensions in inches

Only a tensile loading condition is proposed for evaluating bearing failures. Under compression, the larger edge distance (*e*>> 3*D*) should only minimally influence the bearing stress at failure, unless a shear-out mode of failure is possible (e.g., a laminate with a large percent of 0° plies).

Both final bearing failure and bearing deformation are needed for materials characterization purposes. Therefore, it is recommended that the bearing stress variation as a function of hole deformation be documented, and that bearing stress values corresponding to the proportional limit, yield bearing (see MIL-HDBK-17, Volume 1, Section 7.2.1), and ultimate failure are recorded.

In summary, bearing strength, as measured by the double-shear test, is considered a materials property for relative evaluation and design. In realistic structural joints, factors like geometry, fastener type, and load eccentricity will significantly influence the realizable fraction of the bearing strength measured in the proposed test. Bearing strength tests more appropriate in design of joints are discussed later in this section as well as in MIL-HDBK-17, Volume 1, Section 7.2.5.

Single-Shear Bearing Strength of Joints. This section describes single-shear test specimens required to obtain bearing strength of single-lap joints. The resulting test data can be applicable either for the selection and screening of fasteners, the design of bolted joints, or both. If the actual joint configuration is double-shear, the test specimen and procedure described previously would be more appropriate.

Bearing strength is a function of joint geometry and stiffness of the members and the fastener. It should be noted that for a 0/±45/90 family of laminates with 20 to 40% of 0° plies and 40 to 60% of ±45° plies, the bearing strength is essentially constant. In addition, fastener characteristics such as clamp-up force and head and tail configuration have a significant effect. However, for a specific laminate family, a specific fastener, and equal-thickness lamina- joining members, the parameter with the greatest influence is *t/D*. This was recognized by the aircraft designers, and all the bearing data for metals is presented in MIL-HDBK-5 (Ref 10) in terms of the *t/D* parameter, Fig. 11. The slope of this nondimensional curve is the bearing strength, which decreases with increased *t/D* until, for sufficiently thick laminates, shear failure occurs in the bolt. The data generated using the recommended test specimens, procedures, and test matrices will produce equivalent data for composite joints.

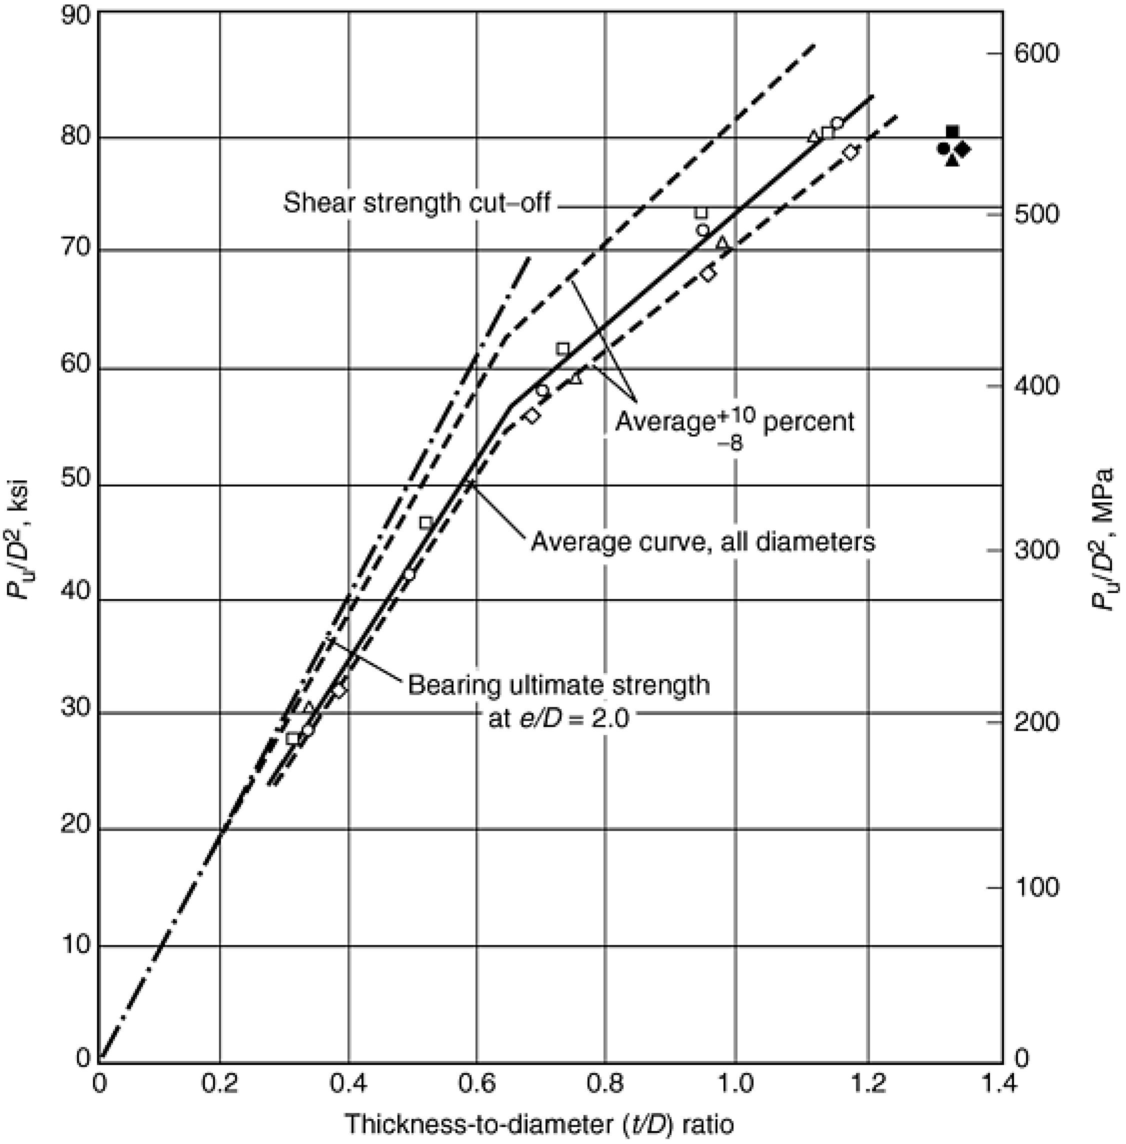

Fig. 11 Average ultimate-load analysis. P_u, ultimate load; *D*, diameter; *t*, thickness; *e*, edge distance

In the design process, there may be instances where the joint configuration may not correspond to the test configurations recommended here, that is, unequal-joining members, gaps, solid shims, or fuel sealing provisions. These effects on bearing strengths should be evaluated by modifying the specimen geometry as needed. The test procedures presented here are still applicable.

Recommended composite-to-composite and composite-to-metal bearing specimen geometry are shown in Fig. 12 and 13. Both are single-lap geometry. Although it is generally more difficult to test than the double-lap configuration, the single-lap test configuration is more representative of most critical aircraft bolted-joint applications. The single-lap induces both bending and shear loads on the fastener, while the double-lap induces mostly shear loads.

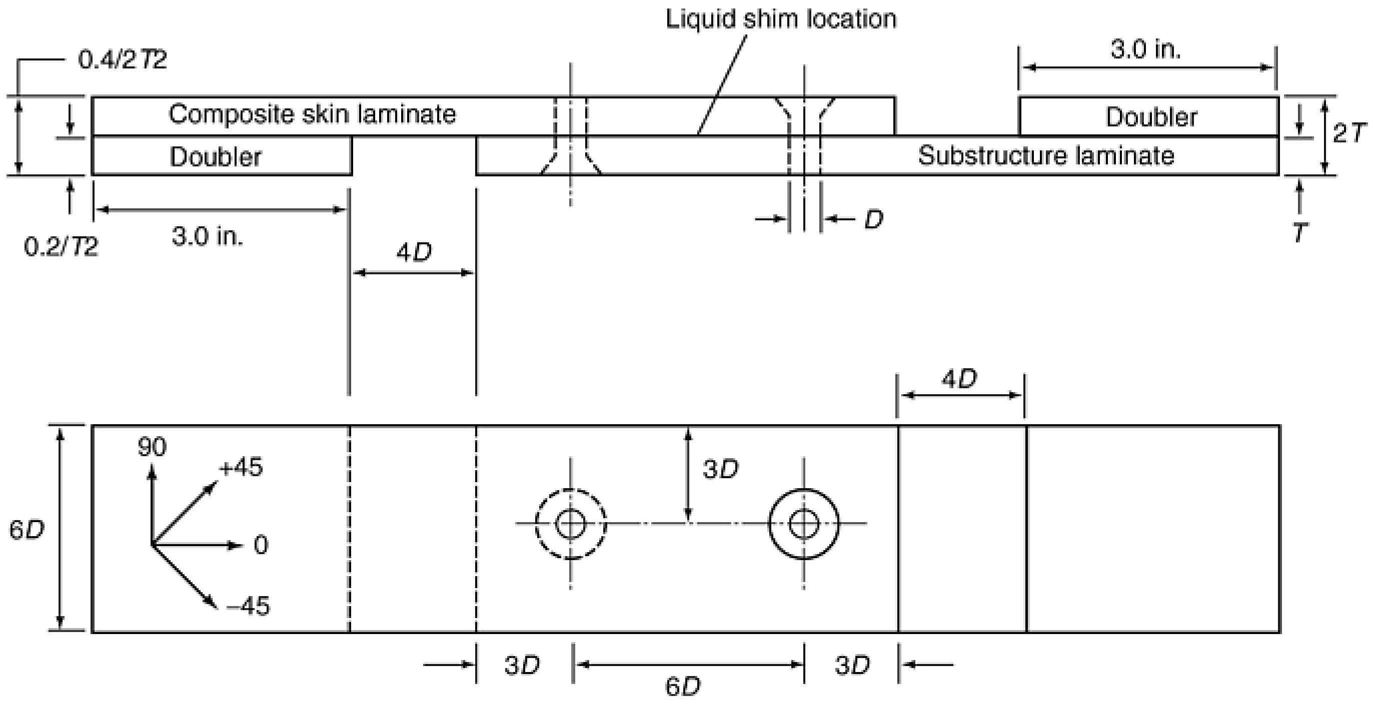

Fig. 12 Composite-to-composite joint configuration

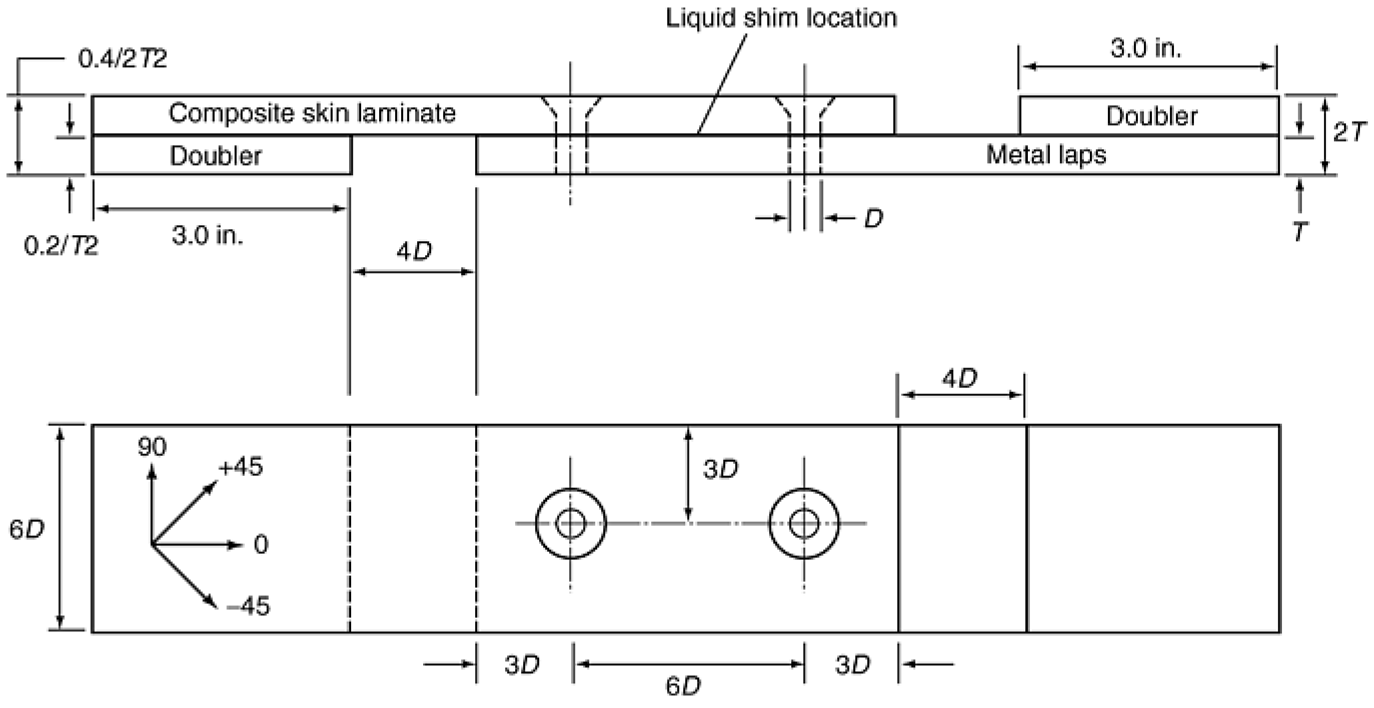

Fig. 13 Composite-to-metal joint configuration

The joint configurations shown in Fig. 12 and 13 may be used to generate both design and fastener screening data. In some cases, the fastener supplier and/or the requester may want to evaluate fastener behavior in a single-fastener configuration. The recommended single-fastener joint configuration is shown in Fig. 14. This is the same specimen specified in MIL-STD-1312- X (Ref 11).

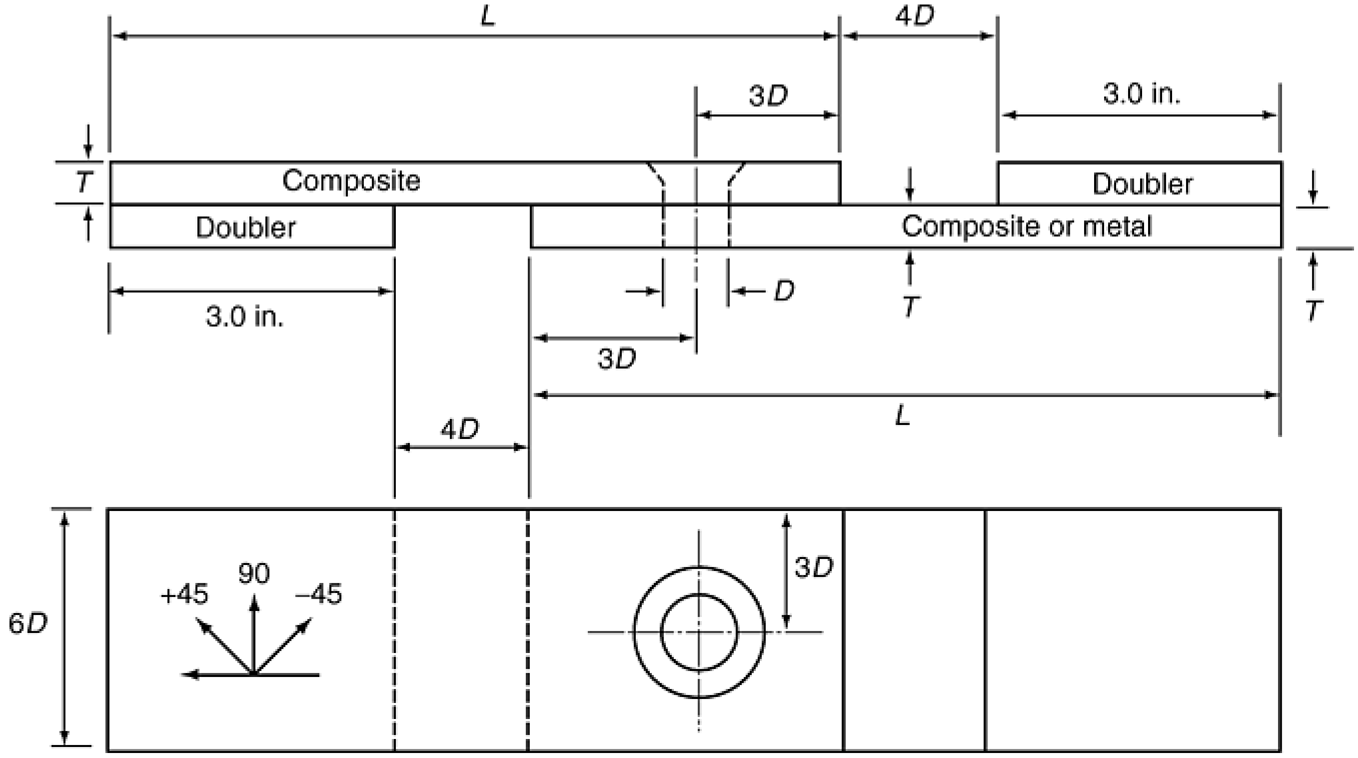

Fig. 14 Single-fastener lap joint

It should be recognized that this joint configuration might be subject to high bending due to the load eccentricity transmitted through the bolt. Increasing the stiffness of the two laps, through increased thickness or material stiffness, can reduce the bending. It should also be noted that the single-fastener joint is generally not representative of multifastener joint applications (e.g., joint rotation, deflection). Therefore, it should be used mostly for fastener screening purposes.

When tested, the specimen geometry shown in Fig. 12 and 13 are intended to result in composite bearing failures (as opposed to tension or cleavage failures). Fastener pull-throughs and fastener failures, though not acceptable as a measure of composite bearing strength, do provide a measure of joint strength for a particular fastener type.

The metal tongue and doubler dimensions (Fig. 12 and 13) are specified to align the load path along the interface between the two laps. The doublers and the tongue shall be bonded to the composite bearing specimens prior to loading, or prior to specimen conditioning for environmental hot/wet tests. Fiberglass-epoxy can be substituted for metal doublers.

Pull-Through Strength. The test specimen configuration to determine pull-through strength is shown in Fig. 15, 16, and 17. It may be used for composite joints fastened by bolt/nuts, pin/ collars, or comparable fastening devices. Pull- through is defined as the load level at which the composite specimen being tested can no longer support an increase in load. The test procedures are provided in MIL-HDBK-17, Volume 1, Section 7.2.9.

Bolted-Joint Element and Analysis Correlation. The bolted-joint structural element shown in Fig. 18 represents a static and fatigue specimen that was used to evaluate joints for aircraft wing structures. The joint was designed to fail at 1.58 MN/m (9000 lbf/in.). The grip tabs on the graphite-epoxy composite end represent an effective bonded area of 3.03×10^3 mm^2 (4.70 $in.^2$). At 15 MPa (2 ksi), the bonded area allowable used above the joint will be safe for at least 1.65 MN/m (9400 lbf/in.). The steel ends were tied directly with screws to the load plate on the test machine.

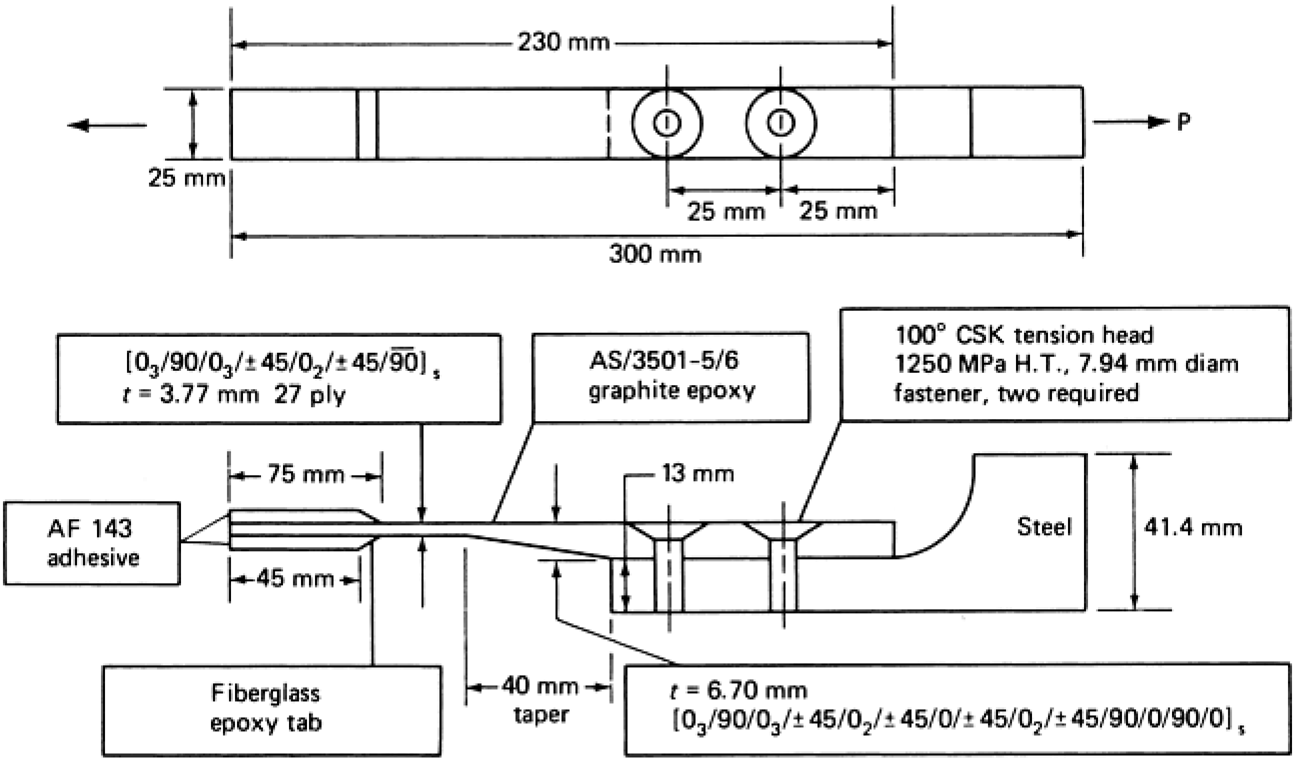

Fig. 18 Bolted-joint test specimen

Failure of the specimen was designed to be gross thin-section tension (away from the joint), thick-section bolt bearing, or both. Stress in the thin, unnotched, gross composite area (outside the joint buildup) is 418 MPa (60.6 ksi) at design failure, whereas the unnotched stress allowable is 1048 MPa (152 ksi).

Using properties given in Ref 12, the bolted joint of Fig. 18 was analyzed with a bolted-joint stress field model (BJSFM) computer program at a net area through the first hole (from the taper) in a load-net area analysis summarized in Fig. 19. The tension test data are slightly above the analytical bearing-failure values predicted by BJSFM. When the net tension analysis is compared with the test failure, a stress-concentration factor of approximately 2 is observed for this joint. Although the most obvious specimen failure was net tension through the first bolt hole, subsequent inspection of the failed specimens showed the onset of bearing failure that correlates to a reasonable degree with the BJSFM- predicted bearing (yield) failure. A finite element analysis of this joint, assuming that half the load is taken by each of the two fasteners, accurately predicted the failure load and mode as net tension through the first hole from the thickness taper. Therefore, both modes of failure, net tension through the first hole from the taper and bolt bearing at the same location, are applicable.

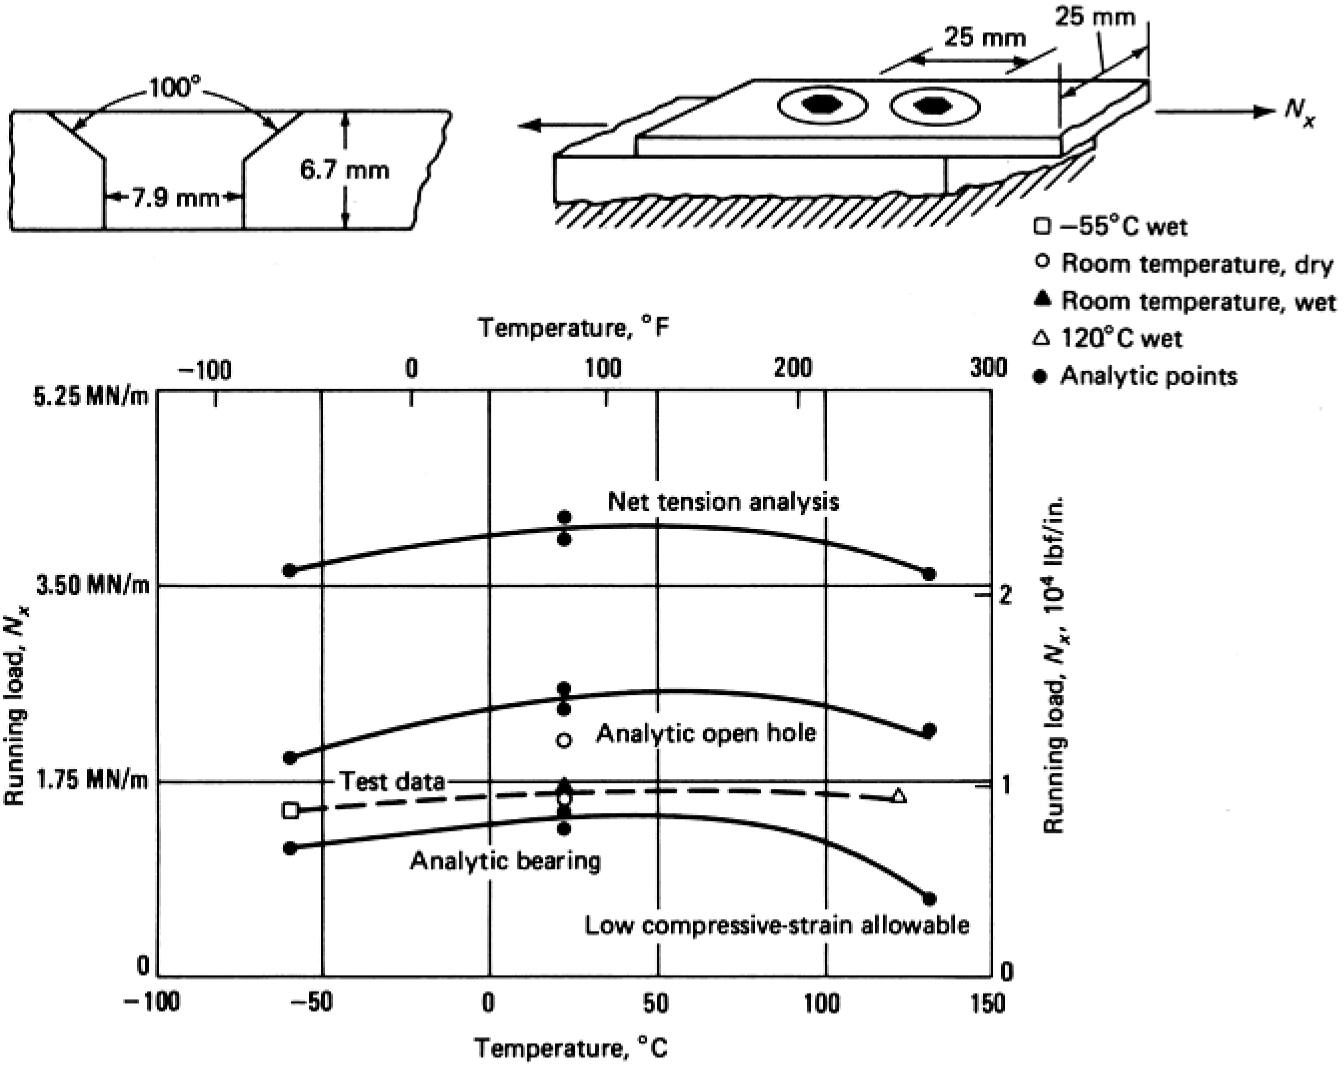

Fig. 19 Correlation of bolt-bearing data and analytical models

Bonded Joints. In principle, bonded joints are structurally more efficient than those that are mechanically fastened. Bonded joints eliminate hole drilling for fastener installation, resulting in a structure without notches that cause stress concentrations. Composite structures can have bonded joints fabricated by three different processes: secondary bonding, co-bonding, and co- curing. Secondary bonding uses a layer of adhesive to bond two precured composite parts (see the article "Secondary Adhesive Bonding of Polymer-Matrix Composites" in this Volume). Thus, this type is most similar to metal bonded joints in structural behavior and fabrication method. Co-curing is a process wherein two parts are simultaneously cured. The interface between the two parts may or may not have an adhesive layer. In the co-bonding process, one of the detail parts is precured, with the mating part being cured simultaneously with the adhesive. Surface preparation is a critical step in any bonded joints and must be clearly defined before any bonding is performed. This is particularly important in secondary and co-bonding processes. More detail on bonded joint fabrication is given in MIL-HDBK-17, Volume 3, Section 2.9.

The type of bonded joints addressed in this section are secondarily bonded and co-bonded. For these types of joints, knowledge of mechanical properties, particularly stiffness of the adhesive, is a design imperative. Well-designed adhesive joints in aircraft structures are not critical in the adhesive layer, but in the adherends, whether they be metal or composites, but this does not obviate the need to know the strength capability of the adhesive in shear and tension. The composite adherends are, in most cases, well-constructed laminates with sufficient number of plies in the principal load directions, ensuring that the failure mode is fiber-dominated. The adhesives are formulated to be much more ductile than the resins used as matrices in composites, because they are not required to provide support to fibers, particularly under compression loading, thus steering the joint failure to the adherends. The fibers also constrain the resin so that the behavior of the matrix is also more brittle than the resin by itself. This may shift the composite bonded-joint failure to a transverse, through-the-thickness, tension failure of the composite laminate.

Two distinct types of tests are needed to characterize the behavior of a bonded joint and obtain sufficient mechanical data to perform structural analysis: shear properties and tensile properties. It is assumed that the mechanical properties of the composite adherends are known. For simplicity and standardization goals, the tests to determine adhesive properties make use of metal adherends. The results of these tests provide properties of adhesive for design and analysis, comparative data, and surface preparation effectiveness, but in no way represent the strength of a composite structural bonded joint. This is obtained by testing specimen configurations with composite and/or honeycomb adherends, which are more application-representative.

Adhesive Characterization. Adhesive strength and stiffness data is required if successful bonded joints are to be designed. Because the behavior of the adhesive is elastic-plastic, it is not sufficient to characterize the adhesive by ultimate strength and initial tangent modulus. The data that are needed include stress-strain curves in shear and tension at the service temperature and humidity environments. The test methods currently favored by the industry to obtain these data are the thick adherend test pioneered by Krieger (Ref 13 and 14) for the shear properties, and the tensile strength by means of bar and rod specimen described by ASTM D 2095 (Ref 15). None of the tests are completely satisfactory, for various reasons. These test methods are more thoroughly discussed in MIL-HDBK-17, Volume 3, Section 7.3.

Moisture-conditioning of adhesive specimens to equilibrium (uniform moisture content of the entire bondline) before wet testing requires prohibitive duration times—several years. This is because of low values of moisture diffusivity of common adhesives and the use of test specimens with moisture-impervious metal adherends, for which water can only enter the adhesive through exposed bondline edges. Fortunately, adhesive failures usually initiate at bond edges, due either to shear stress peaking or to peel (tensile) stresses. Thus, as long as a reasonable depth of adhesive near the edges has approached the desired equilibrium moisture level, test results will be representative of a fully equilibrated bondline. The common practice of exposing test specimens to the required relative humidity at reasonably high temperatures (71 to 82 °C, or 160 to 180 °F, for epoxies) for 1000 hours (42 days) achieves this goal. An alternative method to determine the effect of absorbed moisture on adhesives is to perform tension and compression testing on cast adhesive neat-resin specimens. Because, in this case, the entire specimen is exposed, the times to reach equilibrium are significantly less.

Characterization of adhesive shear properties by the thick adherend test method is accomplished using the KGR-1 extensometer, which is attached to a specimen of geometry shown in Fig. 20. Because of the KGR-1 design and use of aluminum adherends, the test method is limited to150 °C (300 °F).

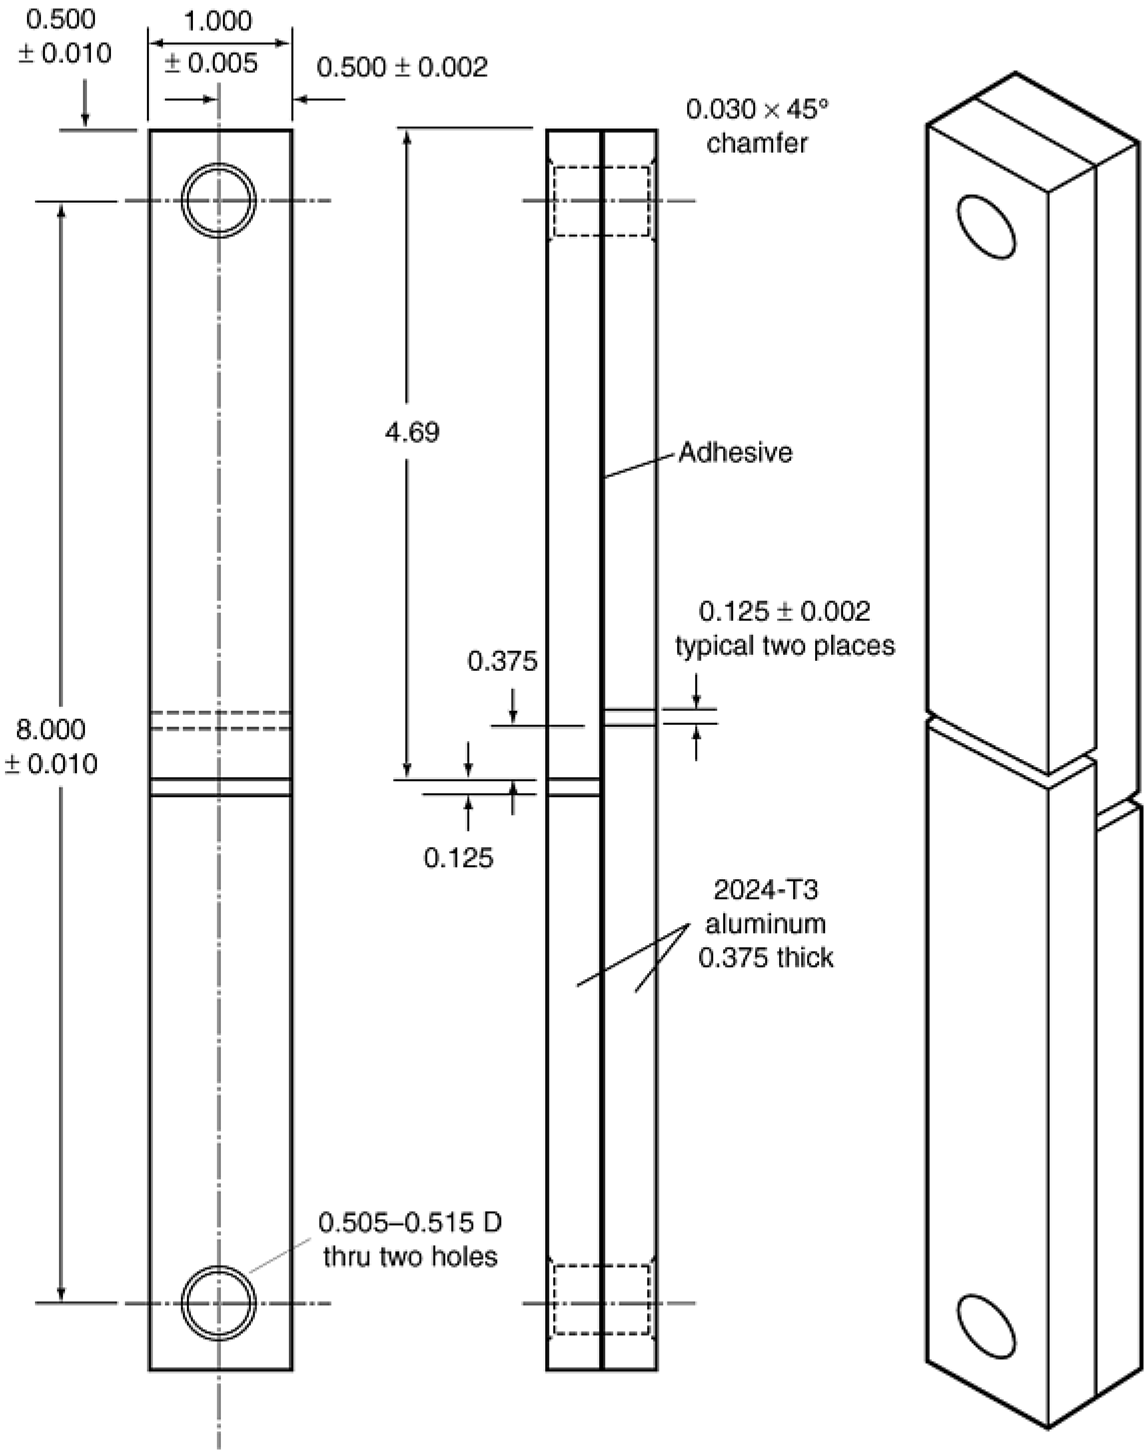

Fig. 20 Thick adherend specimen for characterizing the shear properties of adhesives. Dimensions in inches

An alternate method to obtain shear strength and stiffness is by use of a tubular specimen loaded in torsion. The basis of the test is a narrow, annular ring of adhesive subjected to uniform shear loads around the circumference. Because the thickness of the tube is small compared to its radius, the shear stress across it is considered constant. Although the test provides pure shear distribution, the test apparatus is complex and specialized testing know-how is required, which have led to disuse of this test method. A test method using the tubular specimen is ASTM E 229 (Ref 16). It uses narrow but large-diameter adherend tubes and measures angle of twist by an Amsler mirror extensometer. Details of the test are described in the standard.

Tensile strength of the adhesive can be obtained by the ASTM D 2095 method, Fig. 21 (Ref 15). Either bar or rod specimen can be used in this test method. The design of the specimens and specimen preparation is described in ASTM D 2094 (Ref 17). The tensile strengths obtained by this test method should be used with caution, because the test specimen is susceptible to peel- initiated failure at the specimen edges. The adhesive failure strength can be used in an approximate peel analysis, as proposed in Ref 18. Because good bonded-joint

design practice minimizes peel stresses, the exact knowledge of tensile strength capability is not that critical. An independent measurement of the Young's modulus of the adhesive is needed, because the adhesive often does not obey laws of isotropic material and thus cannot be derived from shear modulus measurement.

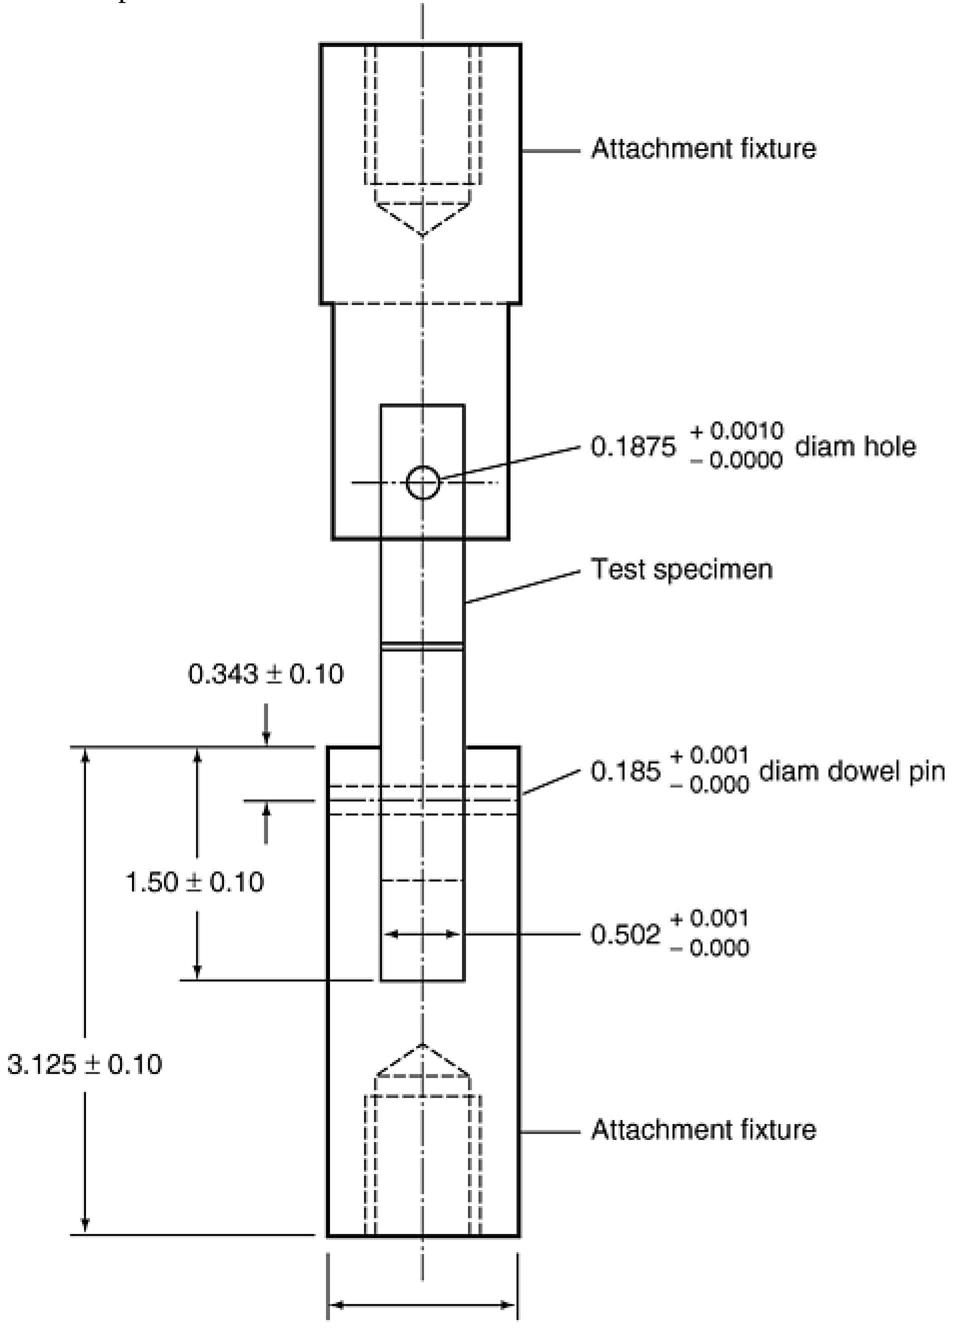

Fig. 21 Test specimens and attachment fixtures for characterizing adhesive tensile strength

Tests for adhesive properties should be performed at room temperature, ambient conditions, and at low- and high-use temperature extremes, as discussed in MIL-HDBK-17, Volume 1, Section 2.2.8. The replication should be a minimum of five at each test condition.

Bonded-Joint Elements. Tests of bonded- joint configurations representative of actual joints must be tested to validate the structural integrity of the joint. Because these specimens quickly become point-design oriented, it is difficult to standardize. Thus the discussion will be limited to the simplest specimens that contain the important parameters of the bonded composite joint. A more complete discussion may be found in MIL-HDBK-17, Volume 3, Section 7.

Single-overlap specimens are similar to those described in the previous section. However, because single-overlap specimens induce additional peel stresses due to bending, the length of the joint must be longer to minimize that effect. This effectively eliminates usefulness of single- step specimens to determine strength

property of realistic joints. Single-step single-overlap joints, however, are used for comparison between different adhesives and for quality control. The simplest, 25 mm (1 in.) wide, multistep or scarfed specimen has been developed to assure integrity of bonded repairs using "wet" lay-up for composite panels. This specimen, shown in Fig. 22, is referenced in a preliminary European Aircraft Industry Standard prEN 6066 (Ref 19). This standard also defines types of failures that are possible with such a specimen (Fig. 23).

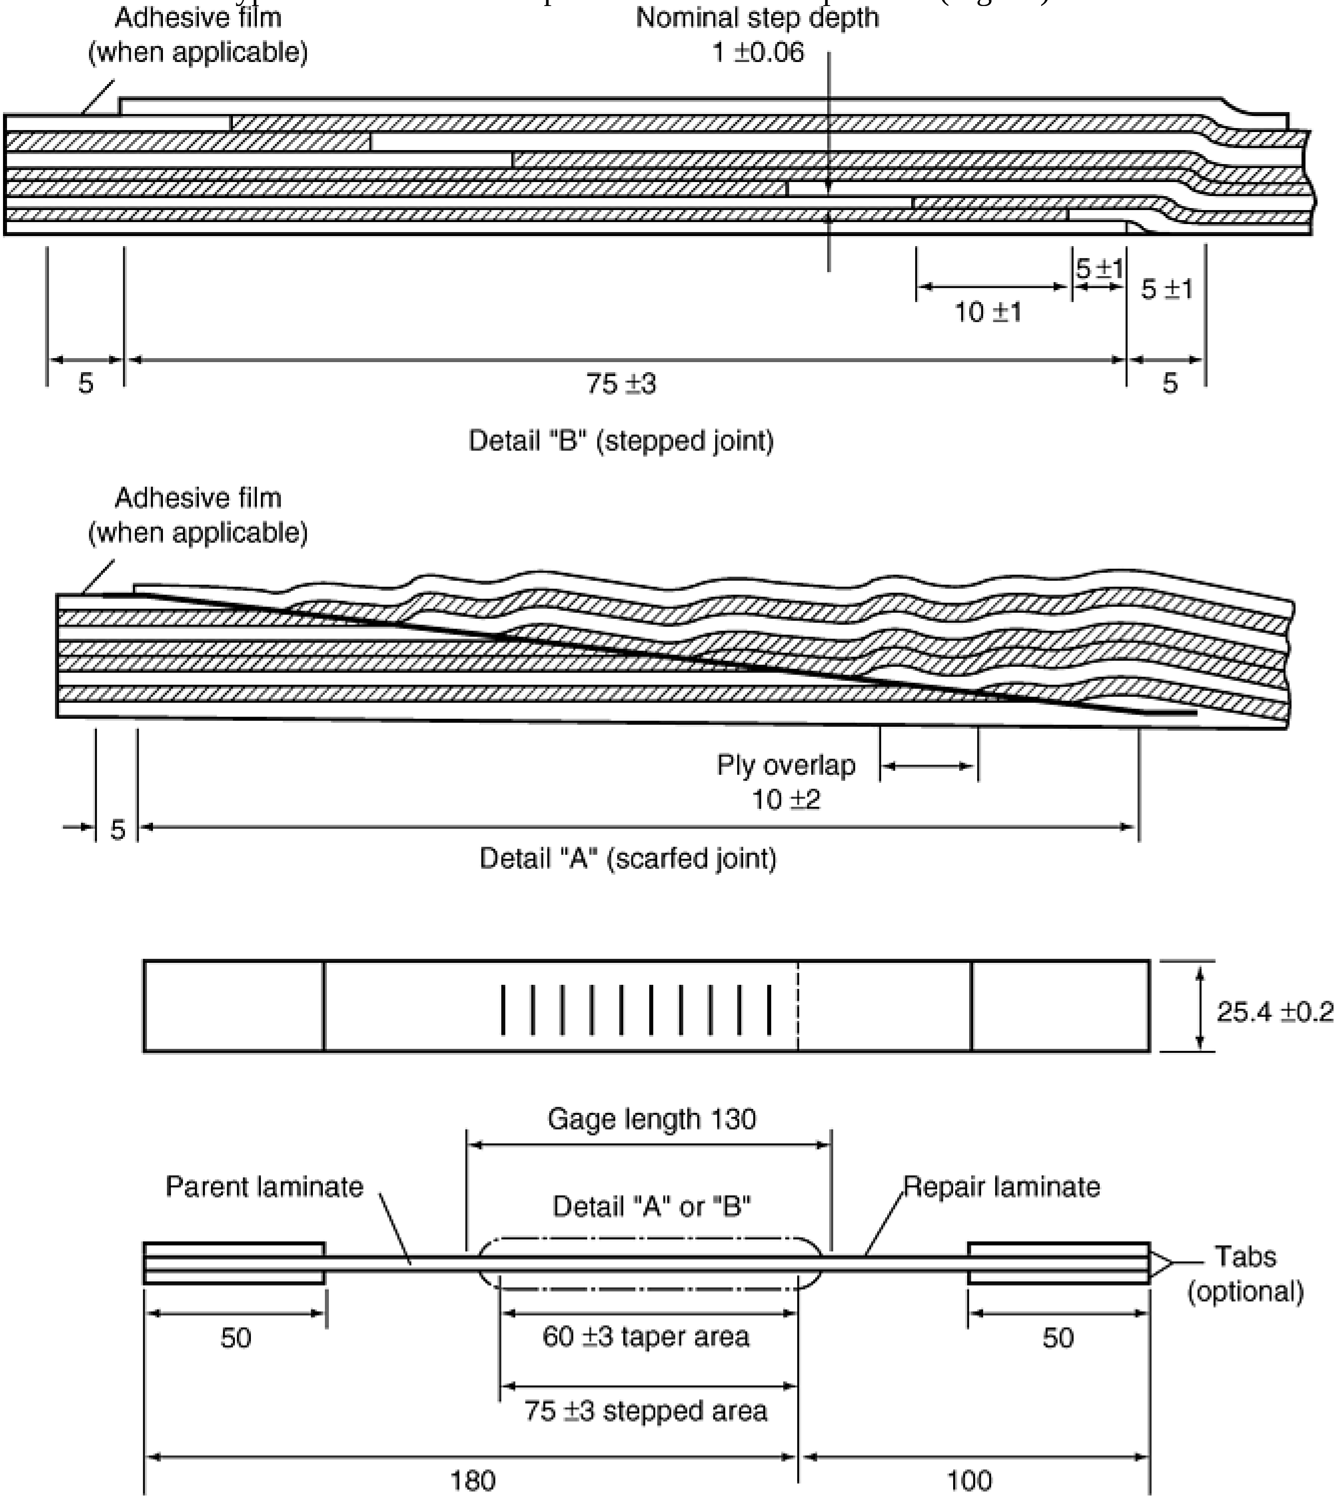

Fig. 22 Scarfed and stepped joint specimens. Dimensions in millimeters

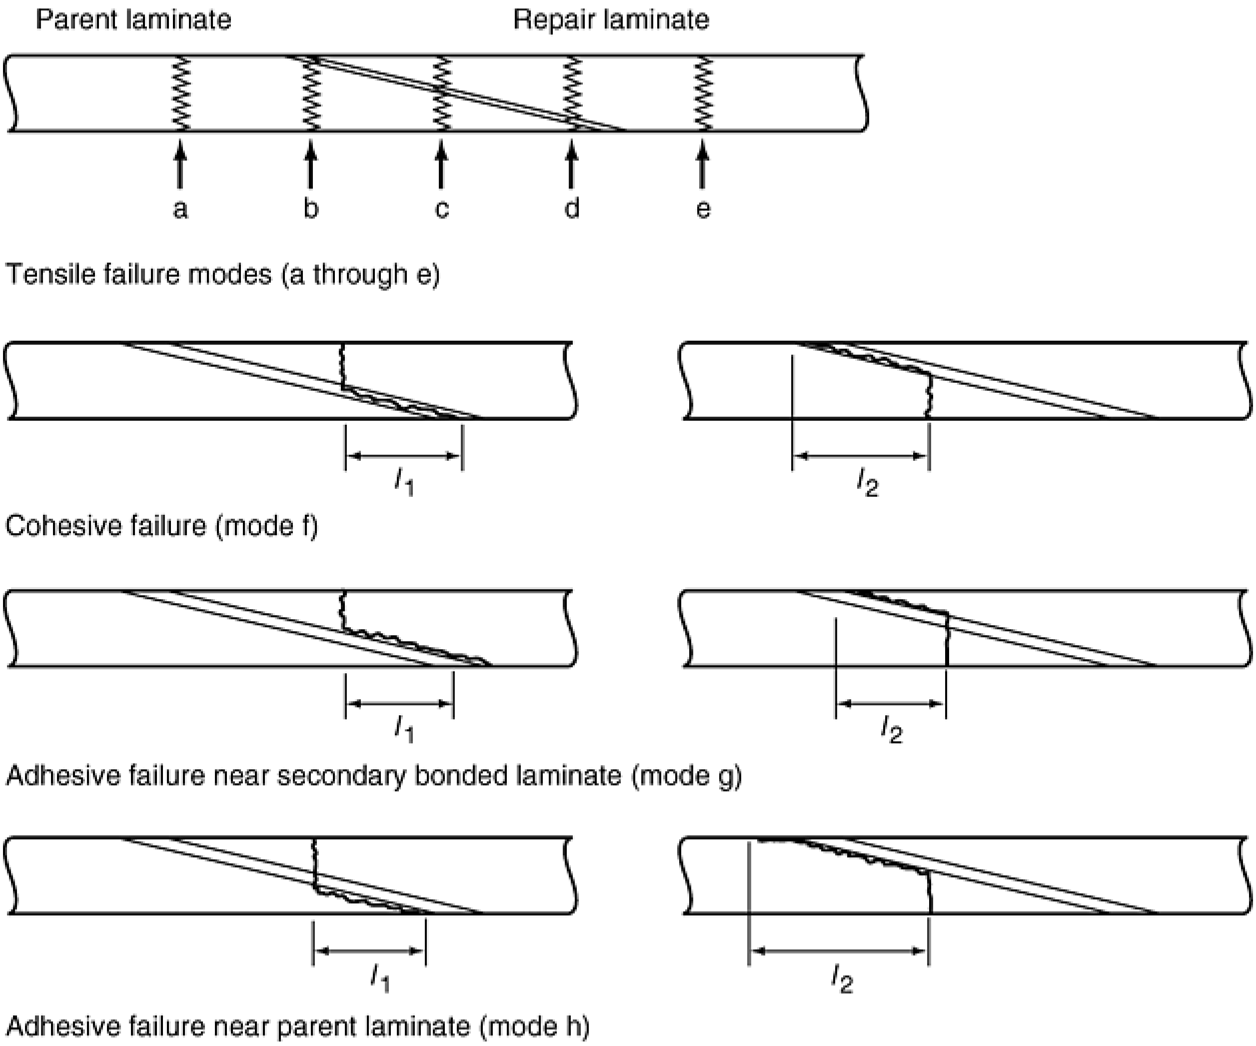

Fig. 23 Failure modes and dimensions for joint specimens shown in Fig. 22

Two-step and scarfed verification specimens are shown in Fig. 24 and 25 for the same spar- to-skin joint shown in Fig. 26. Such a specimen should be developed to validate any major joint design.

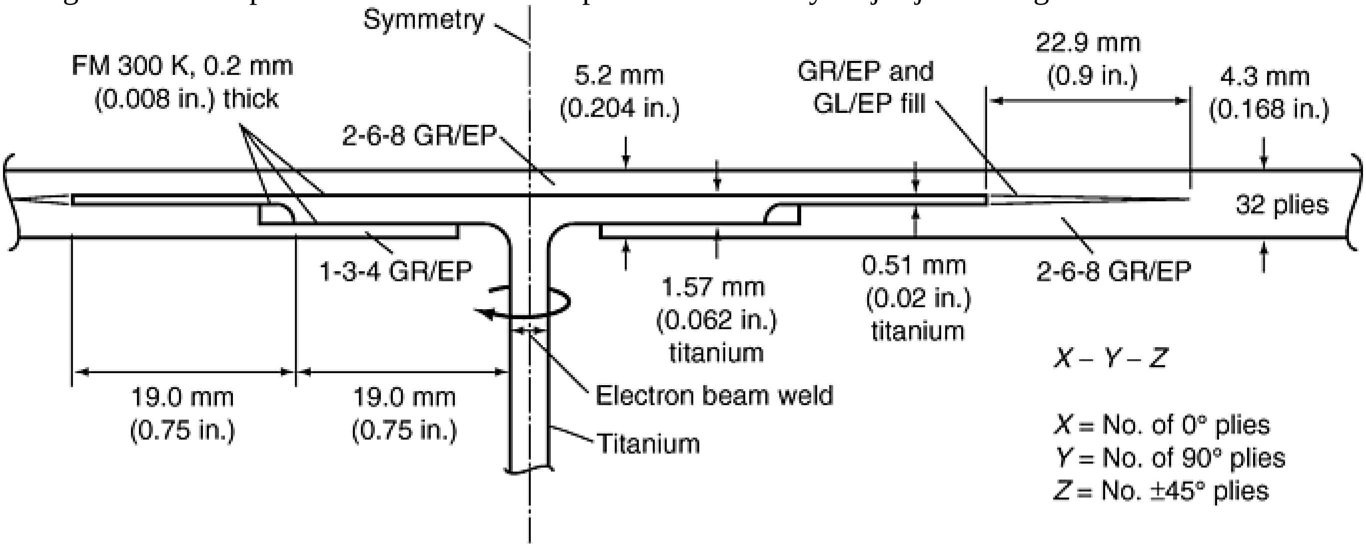

Fig. 24 One-sided specimen for a spar-to-skin joint. GR/EP, graphite/epoxy; GL/EP, glass/epoxy

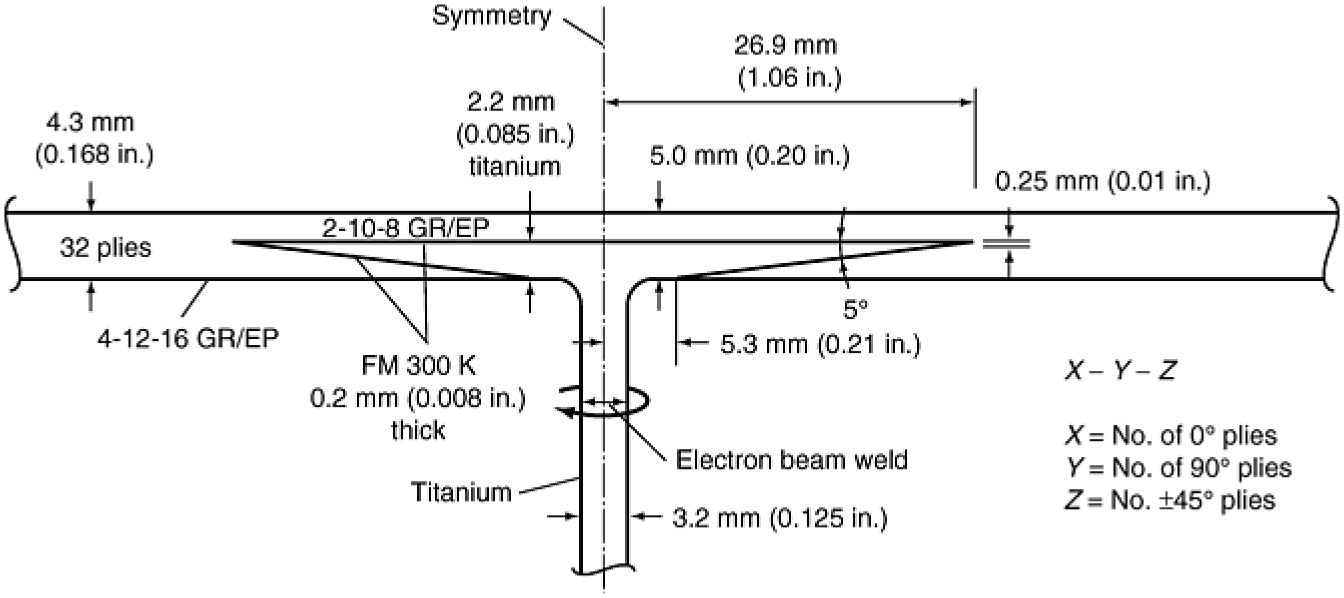

Fig. 25 Scarfed joint specimen for a spar-to-skin joint. GR/EP, graphite/epoxy

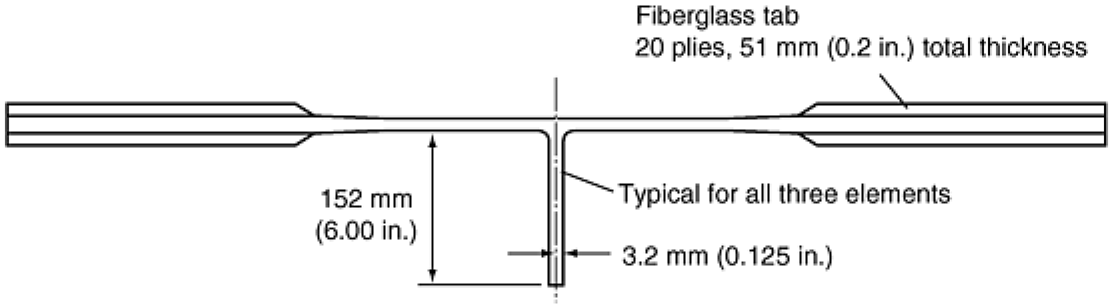

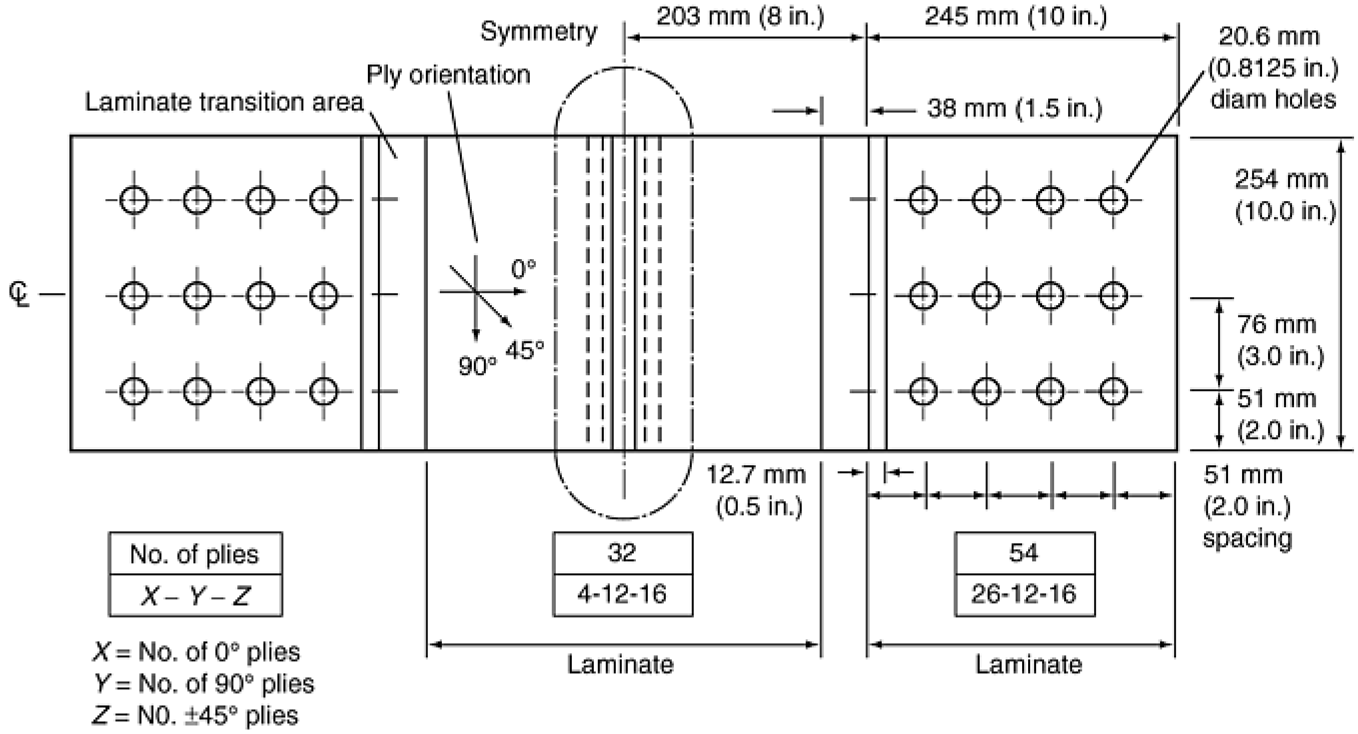

Fig. 26 Double-lap, two-step joint specimen configuration

Double-overlap specimens range between single-step type to ones containing many steps, and are usually loaded in tension. The complexity is dependent on what type of data is to be obtained or the structural application. An example of a specimen derived from ASTM D 3528 (Ref 20) is shown in Fig. 27. This test specimen is useful for determining adhesive shear strength, because the double-shear configuration reduces peel

stresses. This configuration is not usually used in design, because the load transfer capability can be increased significantly by tapering the outside adherends. For higher load transfer, double-lap joints will contain many steps. To validate this type of joint, specimens shown in Fig. 28 have been used. These types of specimens are quite expensive to fabricate and hence, are not replicated in large numbers. Because these specimens are to represent a particular design, care must be taken that the specimen is manufactured using the same processes as the actual joint. Another example of a joint-verification specimen is shown in Fig. 26 and 29. It represents a chordwise connection between a composite skin and a titanium spar, and is a double-lap two-step joint. The multistep joint specimen could be converted to scarf joint specimen if that was the actual design.

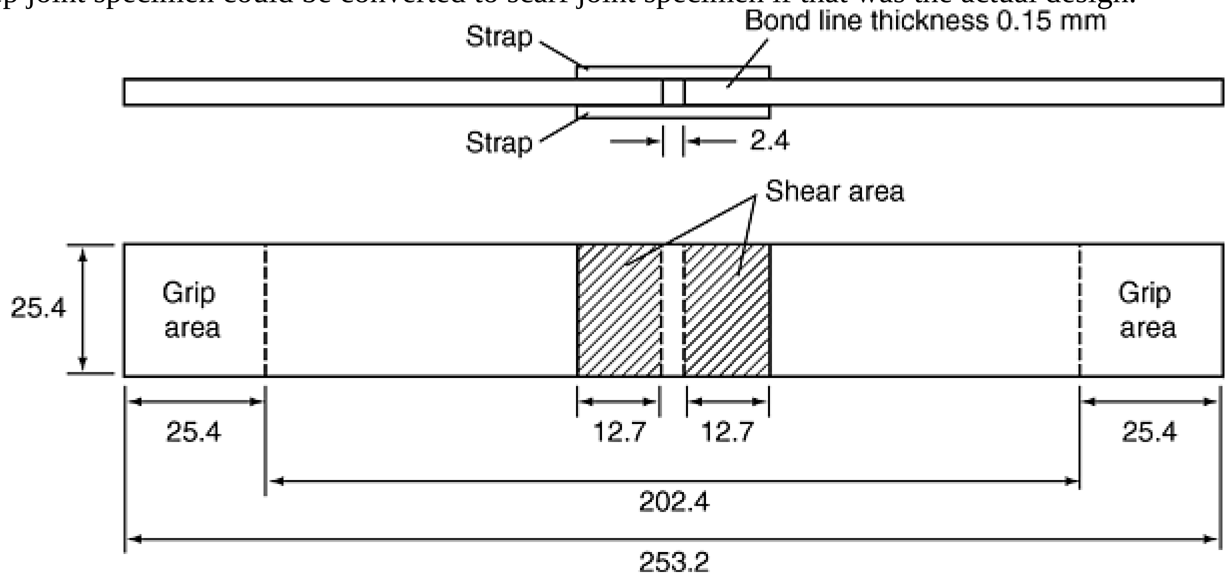

Fig. 27 Geometry of double-lap test specimens. The adherend is $[0]_{16}$ or $[0/90/-45/+45]_{2S}$ carbon/epoxy. The strap is $[0]_8$ or $[0/90/-45/+45]_S$ carbon/epoxy. Dimensions in millimeters

Element and Subcomponent Testing

Lawrence A. Gintert, Concurrent Technologies Corporation

Nonstandard Elements and Subcomponents

Examples of nonstandard elements and subcomponents are discussed subsequently. Each nonstandard element or subcomponent should be designed to represent an area of the structure having relatively complex load paths or failure modes, which are not easily characterized by simpler standard elements. The test specimen needs to be fabricated using materials and processes that are representative, if not identical, to those of the full-scale structure. As in element testing, adequate design consideration must be given to fixturing and load-introduction techniques, such that the proper failure mode is experienced during testing. For more specific information regarding fixturing, see MIL-HDBK- 17, Volume 1, Section 7.

Skin-to-Stiffener Bond Tests. To assess the strength of skin-to-stiffener bonded joints in situations where out-of-plane loads are being developed, that is, fuel pressure and postbuckling, fairly simple tests are being used in the industry. Although these tests cannot completely represent the behavior of the actual structure, they provide design data and early assessment of the adequacy of selected materials and geometry before commitment to large component validation tests. The maximum benefits from these tests are obtained when the specimens represent as closely as possible the geometry and fabrication processes of the simulated component. The schematics of two such tests are presented here. The “T” pull-off test shown in Fig. 30 is similar to the test described in ASTM C 297, except that only one block is needed. Because the bending of the skin and stiffener flanges are suppressed by the rigid loading block, the disbond failure will generally occur in the heel of the stiffener and not at the flange ends. This is a serious deficiency of the specimen if, in component tests, the

failure is at flange ends. The location of the failure is strongly dependent on the ratio of stiffener/skin stiffness; the lower the ratio, the more useful is the test.

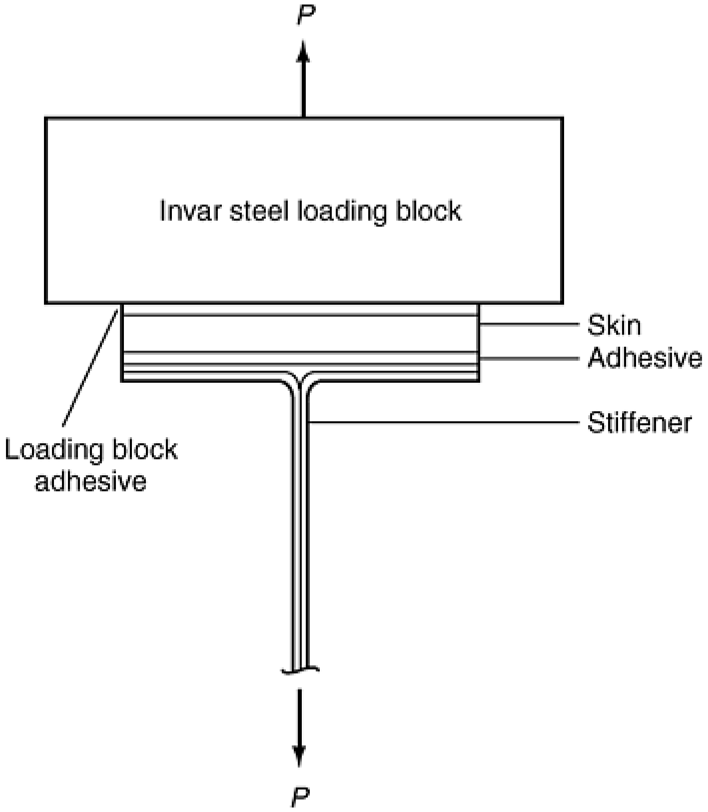

Fig. 30 "T" pull-off specimen for assessing the strength of skin-to-stiffener bonded joints

Using rollers to resist the pull-off load instead of the rigid block, shown in Fig. 31, can be a better method if the skin is more flexible. There is the problem how far apart to place the rollers to match the skin displacement. The specimen in Fig. 31 can be used to apply a moment to the bonded joint. This is represented by P_1 loads and R_1 reactions in Fig. 31. Postbuckling of shear panels introduces significant twisting moments in the interface, and the capability of the joint against them must be determined as part of the structural analysis.

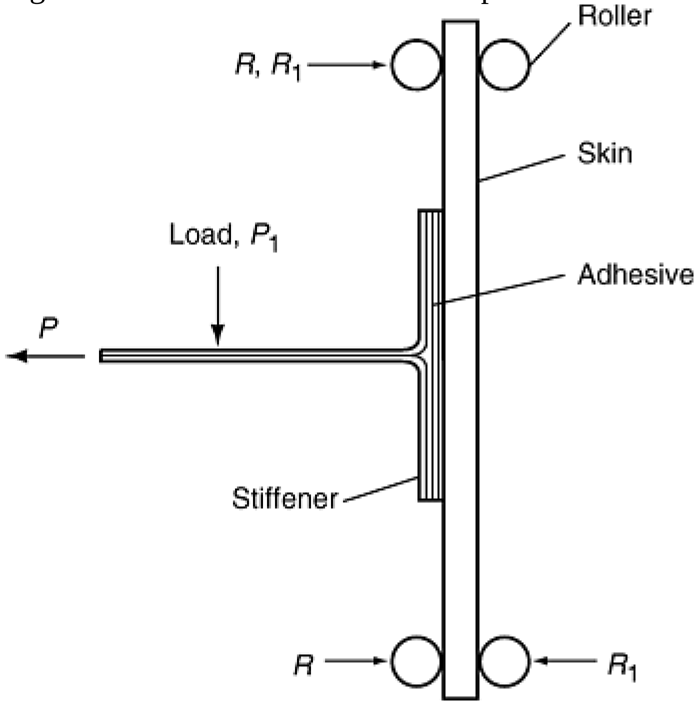

Fig. 31 "T" twist-off specimen for assessing the strength of skin-to-stiffener bonded joints

Blade-Stiffened Subcomponent. A typical in-plane tension-loaded or compression-loaded blade-stiffened composite subcomponent structure is shown in Fig. 32. This subcomponent and test set-up may be used for

both static and fatigue testing, although the load-introduction equipment and the instrumentation may differ for the two testing modes. Servo-hydraulic load-introduction equipment with load, strain, or deflection feedback and control may be used for either type of testing, but the power requirements and the test equipment cost may be relatively high. Electromechanical test equipment for deflection or strain-controlled fatigue testing requires less power and a lower financial investment. For either static or fatigue testing, computerized electronic monitoring/controlling is always the best method.

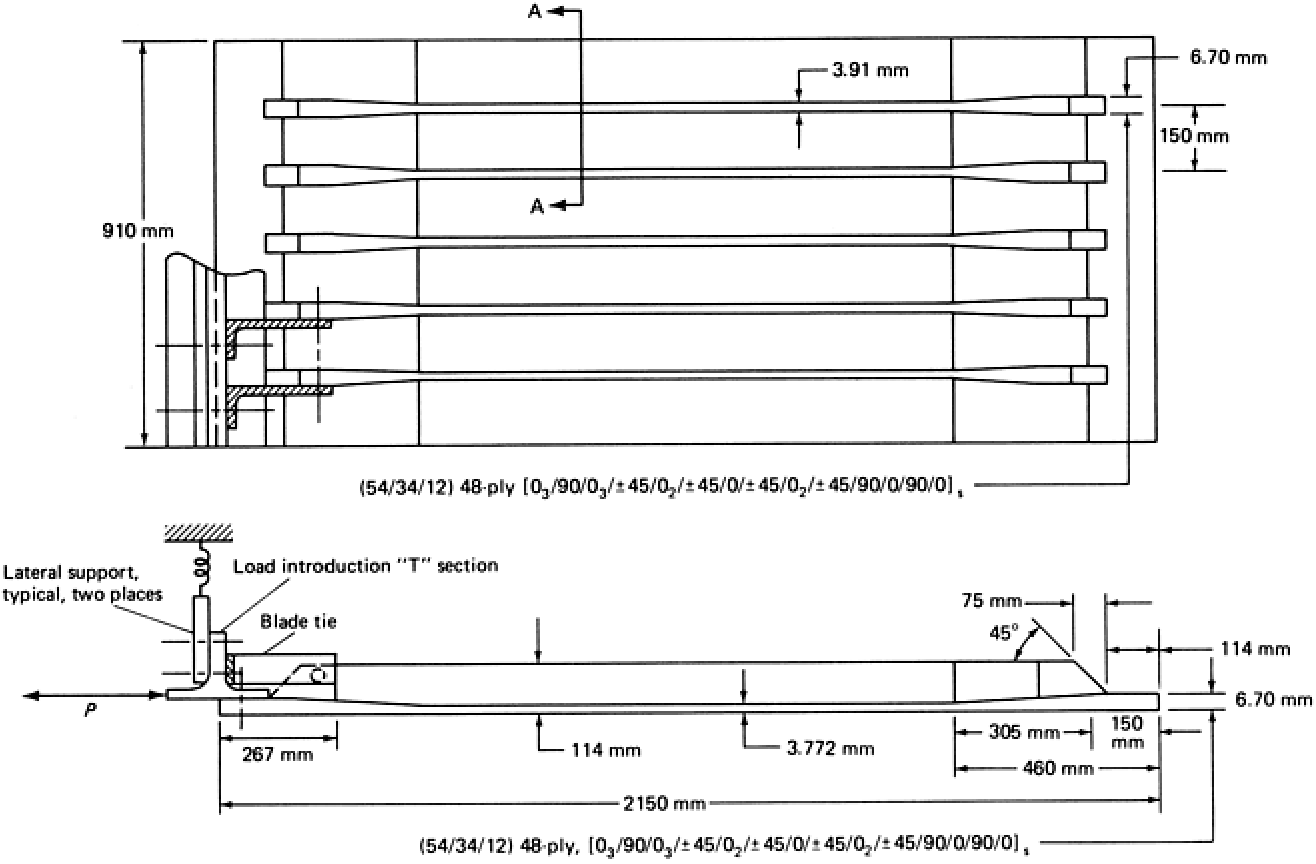

Fig. 32 Blade-stiffened subcomponent

Load-introduction attachments to subcomponent ends and side supports are designed to simulate those used in the full-size structure, which may take tension, compression, or both types of loading. The blade-stiffened subcomponent shown in Fig. 32 is typical, but the structural configuration might also be a plain, solid laminate, a sandwich panel with composite facesheets, a double-skin corrugation, or other configuration. Environmental (temperature and humidity) conditioning may be done before installation in the test fixture or in the environmental chamber used in the testing. Such a chamber requires additional expense and design effort.

Element and Subcomponent Testing

Lawrence A. Gintert, Concurrent Technologies Corporation

Durability and Damage-Tolerance Testing

Damage characterization is a key parameter in the use of composite materials. Damage such as internal delaminations may not even be visually apparent, and therefore must be considered in the design of a component, assuming that the damage exists and is undetected. Generally, a strain threshold at which damage does not propagate is established for a materials system based upon testing. Approaches for consideration of damage in design and certification are found in MIL- HDBK-17, Volume 3, Section 5.0.

Damage characterization can be divided into two groups: the resistance of a material to damage from impact (damage resistance), and the ability of a material or structure to perform safely after damage (damage tolerance). Damage may occur during the manufacturing process, while in use, or during maintenance operations. This damage can be the result of manufacturing defects or foreign body impacts. Impact and indentation tests that are commonly performed to evaluate the damage resistance and tolerance of candidate composite materials are discussed subsequently, as well as damage tolerance testing.

Impact Resistance. Damage resistance of a material is generally considered to be the material's resistance to impact damage. Impacts may arise from dropped tools, foreign objects such as rocks on runways, from hail and ice, and from ballistics. Impact testing at differing energy levels is commonly used to screen materials for damage resistance, damage tolerance, and as a part of larger element and subcomponent testing.

A common method for investigating impact resistance is the falling weight test. This type of impact is included as a portion of the compression after impact (CAI) testing discussed in MIL-HDBK-17. Generally, a flat panel is impacted normal to its surface. Commonly, a 13 to 25 mm (0.5 to 1 in.) diameter hemispherical tup (or striker) is used. Quasi-isotropic laminates approximately 5 to 10 mm (0.2 to 0.4 in.) thick are often used to screen materials for aircraft structural applications.

Energy levels for the falling dart test are generally given in foot-pounds or foot-pounds per inch of thickness. With variations of velocity, the damage may vary even with constant energy. This phenomenon is related to the type of damage, the rate it propagates in the specimen, and the deformation of the specimen during impact.

The falling weight used for CAI testing is generally dropped from a few feet, with a mass of 4.5 to 9 kg (10 to 20 lb), and is considered a low- velocity impact. Low-velocity tests such as a falling dart do not adequately simulate ballistic damage. Occasionally, investigators may accelerate the drop with elastic cords to gain a somewhat higher velocity. If very low velocity impacts are to be studied, a long fulcrum pendulum may be used to impact the specimen with a much higher mass.

Following the impact, an assessment of the damage is performed. Criteria for damage assessment may include measurement of the visually apparent damage area, measurement of dent depth, and non-destructive testing evaluation for the internal damage area. Following this assessment, additional mechanical tests such as CAI or fatigue may be performed.

Other Damage Resistance/Tolerance Tests. Other impact tests are often included at higher levels of the building-block approach. These may include ballistic impact, ice/hail simulation, bird strike simulation, and other program-specific tests. These are often accomplished through the use of an air gun that fires a projectile at the test specimen. Details of these tests have not been standardized and are not discussed in detail here.

Quasi-static indentation tests may be performed by supporting a flat panel in a frame and indenting the center of the panel with a tip attached to a universal-testing machine. Load and deflection are measured during the test.

Specialized tests are also performed to evaluate a material's performance and durability in specific applications. These include roller cart and spiked-heel resistance tests for flooring.

Full-Scale Structural Testing

John E. McCarty, Composite Structures Consulting

Introduction

STRUCTURAL DESIGN requires a continual assessment of structural functions to determine whether or not their requirements have been satisfied. First to be assessed are the initial functional requirements of the concept or configuration. The design is reassessed throughout the design process, as material selection, structural element identification, structural arrangement, manufacturing and quality-assurance methods, and in-service maintenance are defined and their effects on performance are quantified. The successful incorporation of each design element is determined by the in-service performance of the structure.

Because development and production involve a substantial financial commitment, the expected in-service performance must be assessed before the structure enters its service environment. Therefore, tests are performed throughout the developmental cycle to establish a database for the design and to evaluate the potential in-service performance of the selected elements. Full- scale testing of the completed structure (Fig. 1), or testing of large segments as a single unit (Fig. 2), is the major test in an extensive series. At their current stage of development, composite structures are very dependent on all levels of test in the validation process. This article describes the role of the full-scale testing in assessing composite structural systems of aircraft and qualifying them for in-service use.

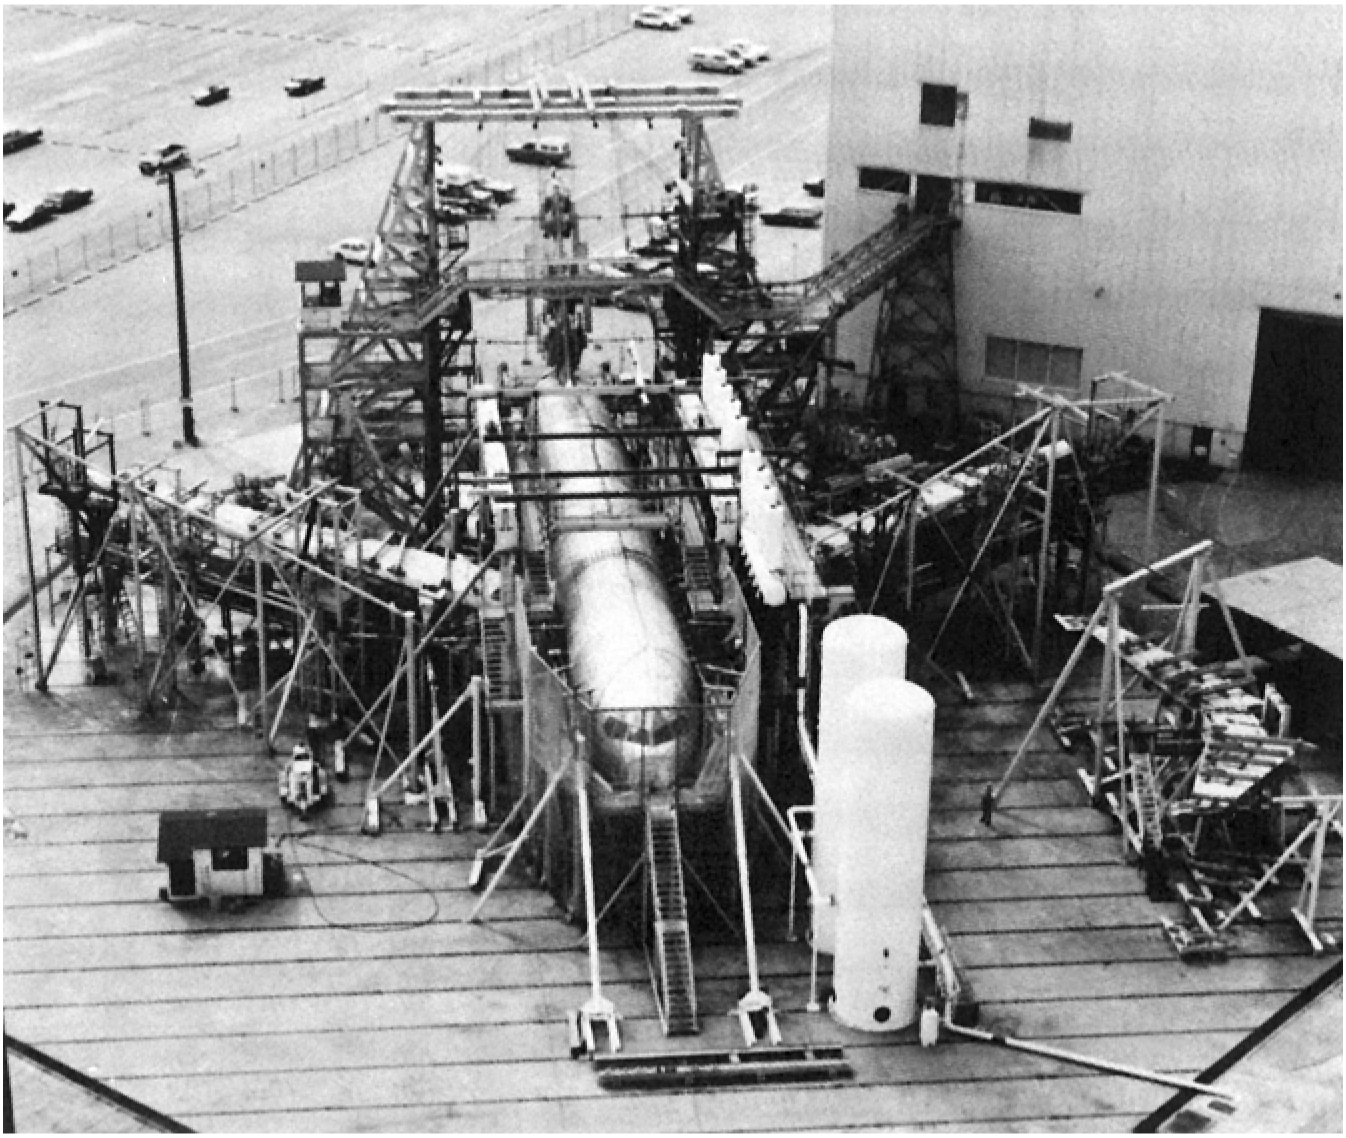

Fig. 1 Commercial aircraft full-scale fatigue test

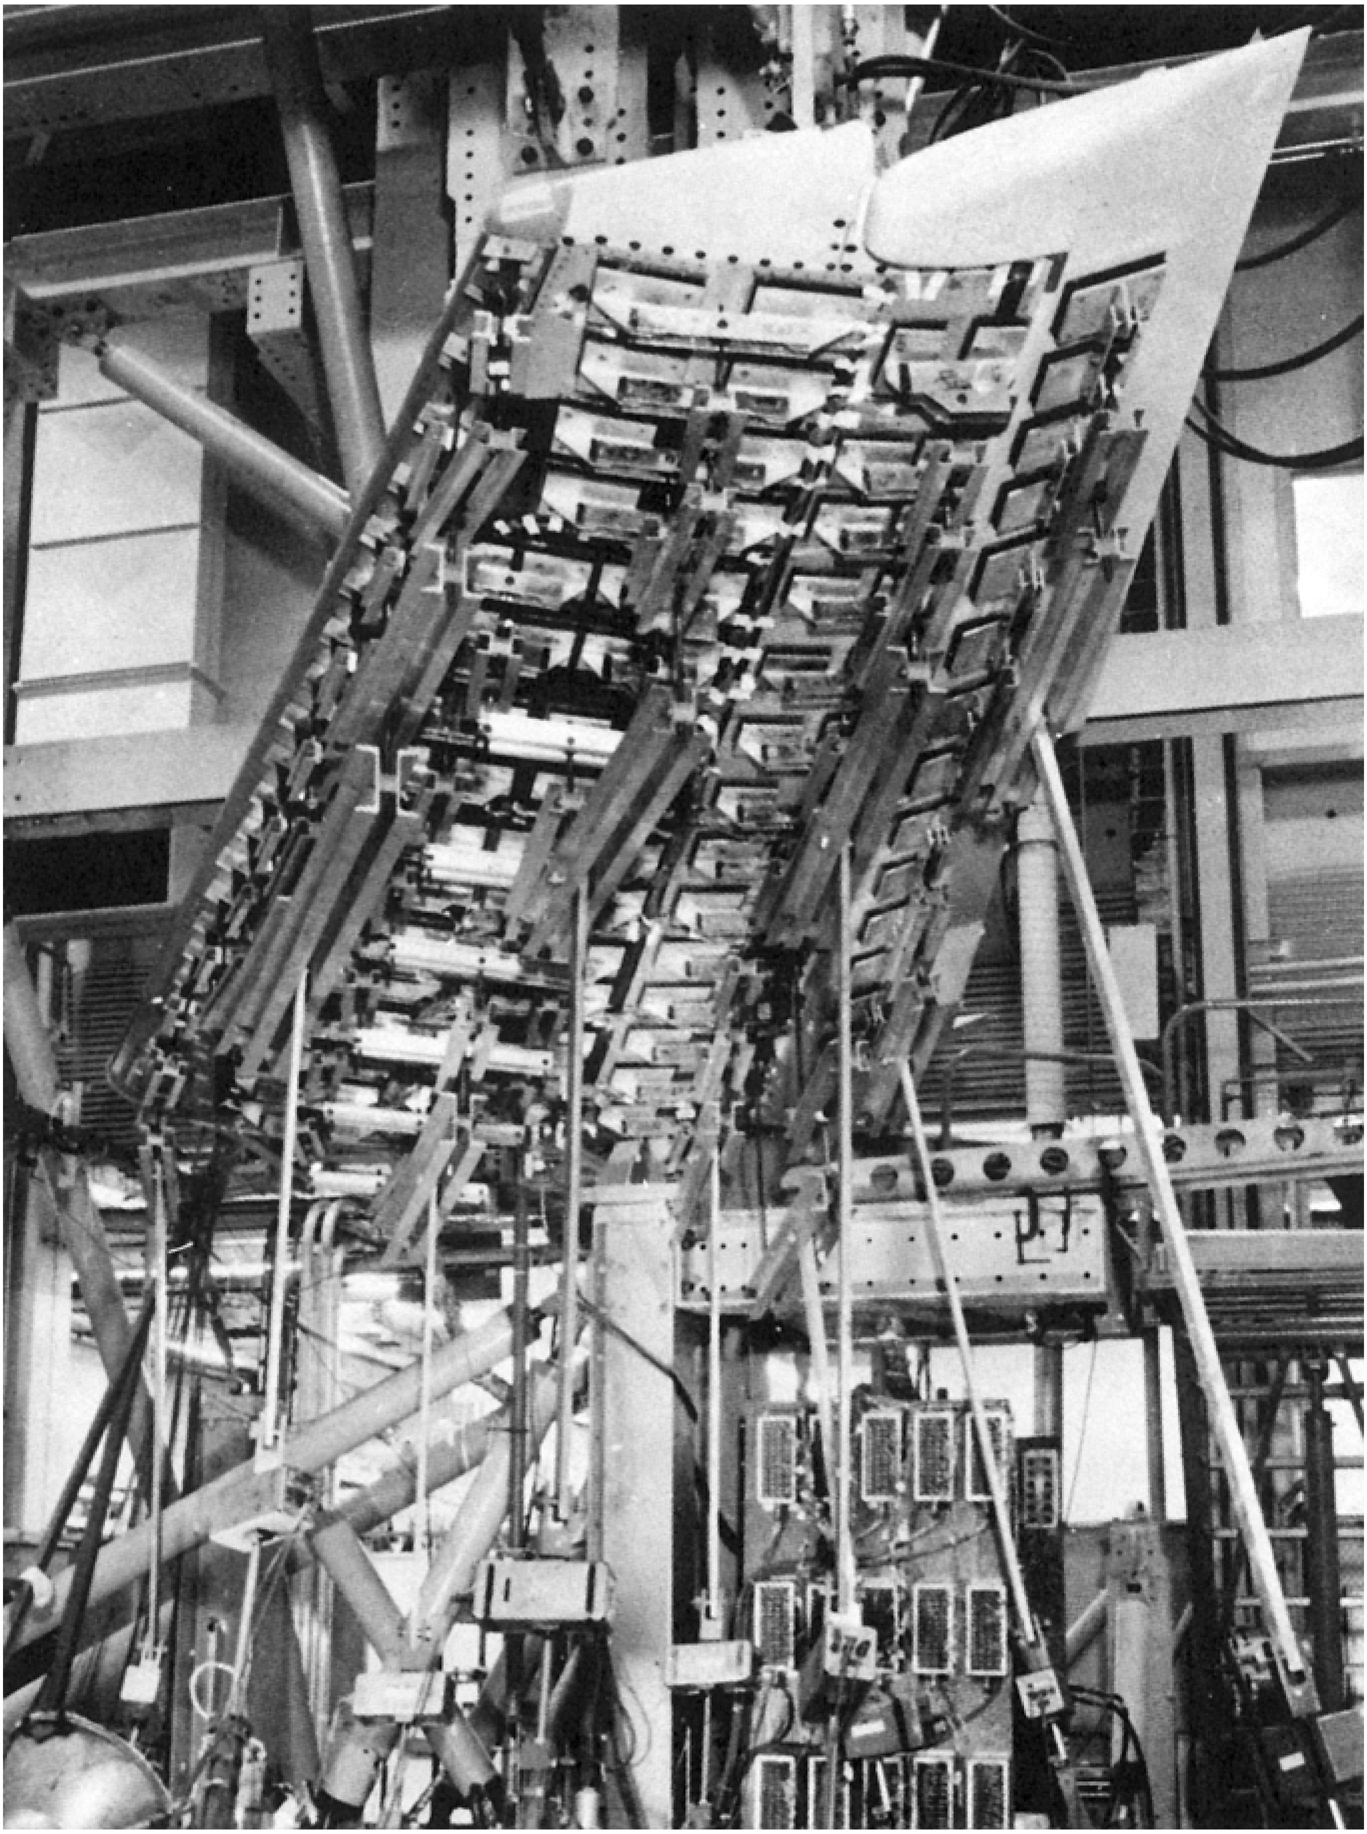

Fig. 2 Aircraft composite horizontal stabilizer full-scale test

The designer's first step in selecting an approach is to understand the need that the design is to fulfill. To define this specific need and ensure that the end product satisfies it, the designer must have a set of design requirements. The requirements usually do not define the structure itself, but rather its performance.

Performance requirements are divided into two categories: those related to structural function (for example, the structural wing box, which transmits lift forces to the body for payload support) and those imposed to ensure safety and durability of the structural component. This article focuses on the second set of requirements. The full-scale test is one of the primary means of demonstrating how successfully a structure meets these structural performance requirements and is extremely important because it tests all combined relationships of the critical elements of the structure in the most realistic manner.

In airframe production, the full-scale structural test is most often performed on one of the first three or four airframes manufactured. This places the full-scale test either well into the production commitment or critical to initiation of the production commitment. Timing of this test in the overall schedule if an unexpected failure were to occur has the potential to impact both the cost of the airframe and the delivery schedule to the customer. If major redesign and/or tooling changes were required, costs would increase and the delivery schedule would slip, which could involve financial penalties and customer dissatisfaction.

The full-scale test enables the internal load distribution and the stress-strain level of each structural element to be imposed correctly. As it is the best representation of the true structural performance of the system, it must be a significant part of the certification or qualification process. It is imperative, therefore, that the purpose of each test element in the process be defined.

There are two basic approaches to full-scale testing for certification: the structure is certified by analysis and supported by test evidence, or the structure is certified by a successful full-scale test validation of the structure and the analysis. Regardless of which approach is taken, full-scale testing is usually required to satisfy the requirements of the agency conferring qualification or certification. Depending on the approach, there may be some difference in the test steps or their sequence and in the data required from the full- scale test.

Typical full-scale tests are static, durability (fatigue), and damage tolerance, the last of which may not require a full-scale test. These full-scale tests are designed to address the following questions about the structure:

- Is the analysis of the internal load distribution correct?
- Have there been any errors or omissions in design, manufacture, or quality-assurance measures?
- Are there any unexpected deflections that impose functional constraints?
- Have composite structures that are sensitive to out-of-plane or through-thickness loads been correctly or adequately covered by analysis or lower-level testing?
- Are there any deflections that significantly alter the load path and increase the stress-strain level of a structural element (that is, are there large displacement effects)?
- Has the assessment of durability been correctly made for composites, metals, and the combined structure, particularly in the interface areas?
- Has the damage tolerance of the structure been correctly evaluated by testing and analysis? For composite structures in particular, have the nonvisual flaw or damage effects on the structures been adequately assessed?

The use of full-scale tests must recognize the unique characteristics of composite structures and their response to the expected in-service conditions as simulated by these tests. Each test type described in the following sections is oriented to aircraft testing requirements, with emphasis on the special considerations needed for testing composite structures. The aircraft structure was selected as the basis for discussion because it is the most generic type of vehicle structure that uses composites.

Full-Scale Structural Testing

John E. McCarty, Composite Structures Consulting

Static Test

The full-scale static test is the most important test in qualifying composite structures because of their brittle nature, sensitivity to stress concentrations, and insensitivity to fatigue cycling. The parameters to consider when

developing the basic requirements for the static test are the type of test article, the type and number of load conditions, the usage environment to be simulated, the load level, and the type and quantity of data to be obtained. The ability of the test data to meet certification requirements must be inherent in each of these static test requirements.

The full-scale test article, whether it is a major component or an entire airframe, is considered representative of the production structure. This implies both that it has been fabricated according to production drawings using specification-controlled materials on production tooling and following fabrication and assembly specifications and that it has been inspected according to production quality-control requirements. This inspection level represents the detection, acceptance, or rejection of manufacturing anomalies as required by the specifications and directed by the material review board.

To ensure that test data are a useful part of the certification database, additional special inspections are performed that further establish the test data validity. For composites, ultrasonic and x- ray inspection procedures are required to detect processing flaws such as porosity and delamination. This same level of additional inspection is performed after each critical test sequence.

Material Considerations. The type of test article used depends on its material composition, function, size, structural configuration, and the degree to which it represents the entire airframe or its full-sized major components.

The material composition of the test article can affect the test procedures and the load level. Carbon/epoxy is the composite material that is currently most commonly used. Properties unique to carbon/epoxy materials, as compared to metals, are displayed in Table 1. Carbon/epoxy materials are known to be generally linear to failure in their response to monotonic loading. This brittle nature of composites must be considered in selecting testing levels for test setup and checkout, strain surveys, limit load conditions, and the sequence of ultimate load conditions.

Table 1 Behavior of carbon-epoxy versus metals under various conditions

Condition	Carbon-epoxy behavior relative to metals
Stress-strain relationship	**More linear strain to failure**
Static notch sensitivity	**Greater sensitivity**
Fatigue notch sensitivity	**Less sensitivity**
Transverse properties	**Weaker**
Mechanical properties variability	**Higher**
Sensitivity to aircraft hygrothermal environment	**Greater**
Damage growth mechanism	**In-plane delamination instead of through-thickness cracks**

Moisture and Temperature Effects. Composites are also sensitive to temperature and can absorb moisture from in-service environmental exposure. As a full-scale test of even a small aircraft in a fully simulated environment would be very expensive and time consuming, alternative ways to determine environmental effects must be found. Although testing at room temperature and in ambient moisture is the most economical way to test a large structural system, it does not account sufficiently for environmental effects. The elements of the hot/wet (temperature and absorbed moisture) environmental test involve the same environmental considerations for both subsonic and supersonic flight environments. For flight and ground environments, only the temperature levels, time at temperature, and absorbed moisture content of the composite material will vary in magnitude.

The temperature profile of the structure as a function of heat input and its material and structural response must be accounted for by means of the analyses and tests required for certification. Changes in stress-strain caused by moisture absorption also must be accounted for by the same generic analysis and test sequences. The induced stresses and strains are caused by two levels of structural response. The first level is due to the physical compliance of the laminate, which is usually accounted for by ply-level properties and analysis at the laminate level or by laminate-level properties that include the effect of both moisture and temperature. The inclusion of this effect in the analysis of the structure can be accounted for by increased design stress- strain and by reduced allowables. The second level is introduced at the structural element or component level. It is induced by nonlinear temperature or moisture profiles imposed on the structure, the nonuniform coefficient of expansion of

the composite elements due to different ply orientations, and the inherent structural redundancy of a complex airframe structure.

Because satisfying both moisture and temperature requirements is difficult at the full-scale level, most composite structures have required a “building-block” testing approach (Fig. 3), in which environmental effects are addressed at the analysis, coupon, structural element, subcomponent, component, and full-scale levels. The sums of these levels of analyses and tests must be consolidated in such a way as to validate the consideration of environmental effects on the composite structure. The methods that have satisfied this requirement at the full-scale level are to:

- Select the maximum environmental factor (that is, allowable reduction factor) used to correct the room-temperature allowables for the effect of environment and factor up the critical load conditions by the reciprocal of this factor
- Select the environmental factor used with the minimum margin of safety in the structure for each load condition being tested
- Select the environmental factor from the elements of the structure that are loaded in such a way that the type of loading and/or the structural load paths are the most sensitive to either the magnitude or the rate of change in capability with change in the environment
- Select the environmental factor from the elements of the structure that are loaded in such a way that the type of loading or the structural load paths are through the area of the structure where the effects of environment are the most severe or are the most poorly defined in the allowables used to establish that margin of safety
- Test to the ultimate load for each condition considered critical, use the strain-gage results to extrapolate the strains that would be added by the environmental effects, and require that these extrapolated strains still show a positive margin of safety

All these methods are suitable for an all-composite structure. In structures containing metal structural elements, these methods would impose the penalty of either overdesigning the metal structure or necessitating two test articles: one with an augmented metal structure for the environmentally factored composite test and one with no factors on the metal being tested to the ultimate load level to validate the metal elements. The only method that avoids these penalties is the last one given in the list. The selection of the environmental factors by any of the listed scenarios is dependent on analysis. The effect on failure mode and location should be considered in the selection of test environmental factors.

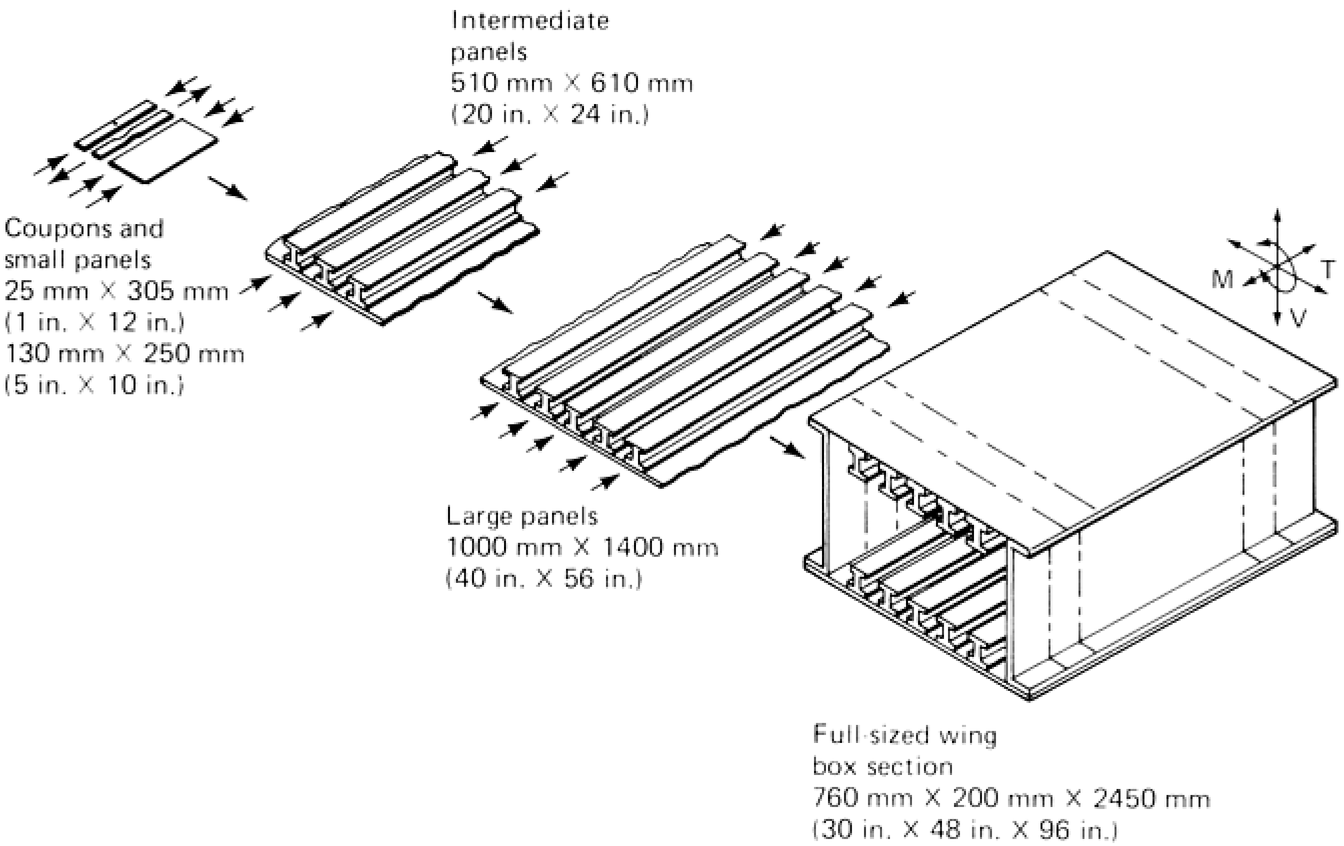

Fig. 3 Building-block testing approach

Structure Size. There are two considerations in choosing the size of the test structure: the cost of testing to get the environmental information on “allowables” to the statistical level usually considered acceptable and the cost of testing a full-scale small component in a simulated environment. If the component is small enough that a full-scale environmental test would be less costly than developing a large database that includes all relevant environmental allowables, combined with analysis to certify the structure, then testing in the environment is justified. Other considerations, such as type of structure (primary or secondary), type and complexity of loading, and structural configuration also play a role in the environmental conditioning required.

Critical Test Condition Selection. The steps in full-scale composite structure test procedure follow the same generic path as in a metal structure test procedure. These steps start with a review of the analysis of the structure. The selection of the most critical load conditions for the structure is based on this analysis.

The critical conditions selected are usually not based solely on the minimum safety margins, although this is the main consideration. Additional considerations may include:

- Stability-critical structures that have low but not minimum margins of safety
- Combined loading conditions that are difficult to analyze
- Major structural joints or intersections that are difficult to analyze
- Areas where the building-block approach to certification must be demonstrated, such as when there is concern for a failure mode change between testing in the simulated environment and testing in an ambient condition
- Areas where the environmental factors methods described previously must be demonstrated

Load Application Alternatives. Once the critical conditions have been selected, the means of load application must be established to facilitate the most cost-effective method of simulating the real flight and ground loads application. The details of the methods of loading a composite structure need careful consideration because most composites have weak through-thickness strength and sensitivity to stress concentrations. Selection of a load application method must take into account composite structure sensitivity, the engineer's desire for the truest simulation of the load distribution, and the cost of the test setup. Loading methods include: formers that contact the structure on the exterior where the surface is supported by substructure, direct fastening to the substructure by penetrating the surface panels, and bonding or mechanically fastening to the surface panels.

Formers (Fig. 4) usually concentrate the loading more and do not give as good a representation of the distributed air load as the other methods. This method usually has a less complex loading setup and is therefore often the least costly.

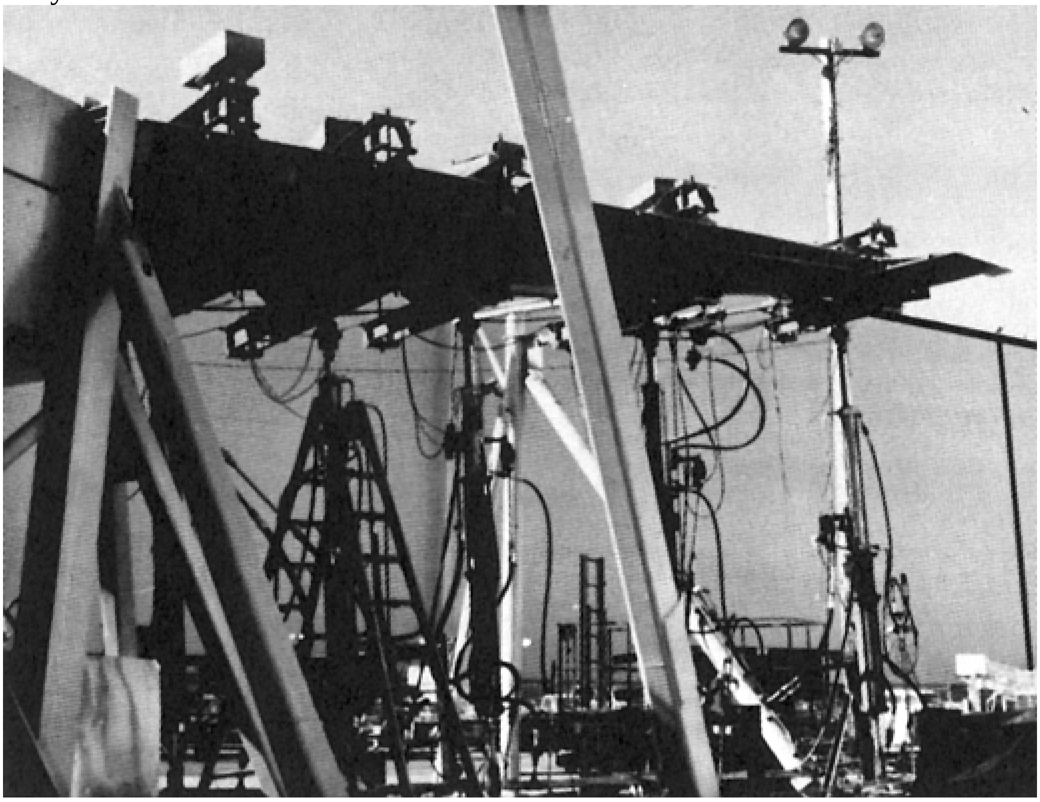

Fig. 4 Use of formers for loading aircraft horizontal stabilizer

Direct attachment to the substructure is usually similar in loading simulation and cost to the former method. However, for both composite and metal structures, care must be taken in the method of attachment to the substructure. If the attachment can be made at the same fastener locations that are used for attaching the surface panels and substructure elements together, the procedure is relatively easy. However, if special access holes are needed, this method is less acceptable for both metals and composites. The effects of holes are particularly bad for composites because of their stress concentration sensitivity.

Direct surface attachment (Fig. 5) usually offers a better chance of uniform load representation. This closer representation of the real vehicle structural load usually involves a more complex test setup. The application of the load directly to a composite surface must be done more carefully than to a metal surface because of stress concentration sensitivity and through- thickness weakness.

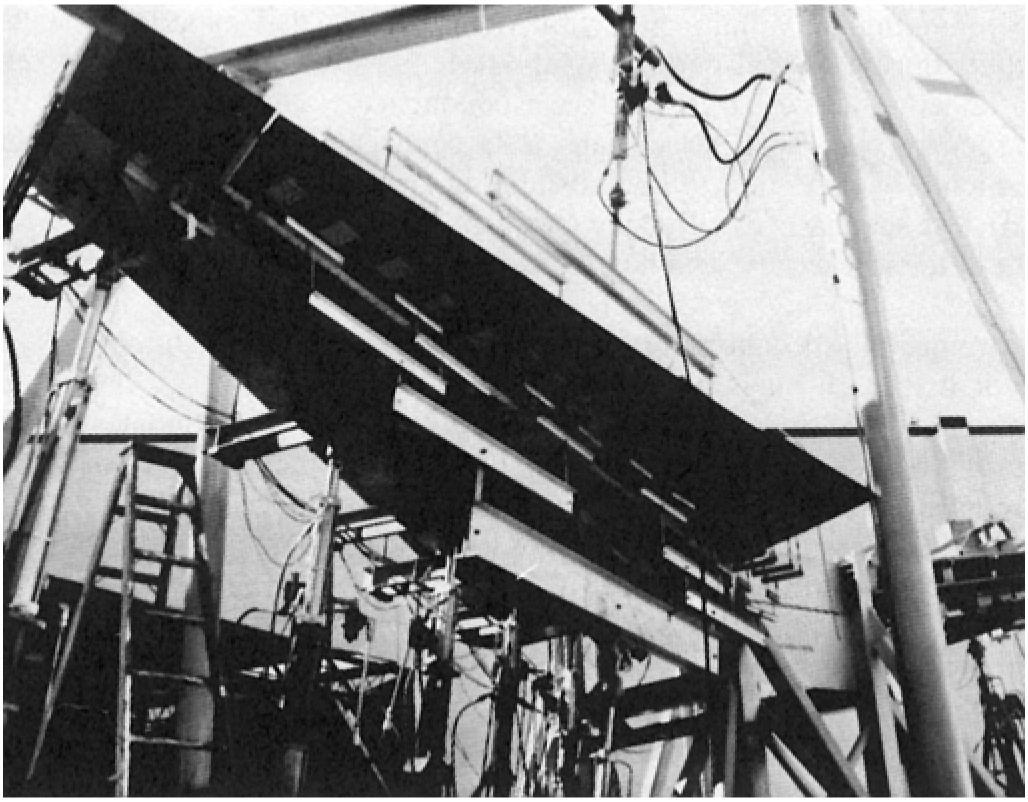

Fig. 5 Use of skin pads for loading aircraft elevator

Loading setup is now controlled mostly by computers, which control not only the loading applied by each hydraulic jack but also the rate of loading. They also check the displacement of the jack or the load cell to prevent overload of the specimen. Computer control of load application has allowed more complex test setups and load application in a truly representative manner.

Instrumentation Requirements. Once the load application method and test setup have been selected, the instrumentation required to collect data (for submittal as part of the qualification base for the structure) must be defined. The data display must:

- Ensure correct application and introduction of the load
- Allow monitoring of the testing in real time and protect the test article from being incorrectly loaded
- Validate that the loads applied produce not only the correct loading, but also the correct deflected shape
- Validate that the correct interaction of the applied load is being made in the correct ratio and magnitude for combined load conditions
- Provide a means to automatically terminate loading when loading errors are detected, precluding a human reaction to the error and avoiding loss of the test article
- Validate that the internal strain distribution is as predicted by analysis

The types of instrumentation that are often applied in full-scale testing are strain gages; deflection measurement indicators; stress coats; photo stress, moiré fringe, and acoustic emission detectors; and accelerometers. All data are electronically recorded, and computers can be used to enhance the data at critical locations.

Test Procedure Considerations. Establishing test procedures and test sequencing requires that all test participants have defined responsibilities both in planning the test and during the test itself. As specific assignments will vary from company to company, they will not be detailed here except to state that they generally include test planning, test fixture design and setup, test functional checkout, and test conducting and monitoring for continuance/discontinuance during a particular test loading. Deciding who will make the critical decision to stop loading or to proceed is the key to providing maximum protection of the test article during critical portions of the test.

Selecting and establishing the test sequence is generic to most large-scale tests and is particularly important to composite structures. The test sequence usually starts with a checkout of the test setup, which involves functional testing of loading jacks, instrumentation, data recording, and real-time critical data displays. A

simple loading case at low load levels is applied to ensure that loads are being introduced as expected. The unique features of each test may require more functional monitoring, data recording, and tracking procedures.

Following checkout of the test setup, a strain and deflection survey is usually run to determine whether the strain distributions and deflections are as predicted. This survey checks the analysis of the structure and the test setup again and is usually done at a loading level that will not affect the certification test results. For composite structures, the testing load level is usually in the range of 30 to 50% of the design ultimate load level. The load conditions applied are simple singular (not combined spectrum, or cyclic) types used to determine whether the strains for these simple cases agree with the analysis. Then, low load levels of the selected critical certification loads are applied.

These results can then be extrapolated to the design ultimate load levels to determine whether the structure can sustain ultimate load as predicted. If these extrapolations continue to show positive margins of safety comparable to the analysis, testing can proceed. If the extrapolations show negative margins of safety or deviations from the expected load distribution, then testing is delayed until these problems are resolved. A serious problem arises when the deviations are small but critical and there is some risk of failure before reaching the required design load level. A review should be conducted before proceeding.

With the stress and/or strain at the proper level and the test anomalies resolved, testing can proceed through the design certification critical load tests. These tests run in sequence, with the conditions for which there is the highest confidence of success usually being run first and those with the highest risk of premature failure being run last. The first loading cases are often the most simple, which minimizes the loading complexity before running critical combined loading cases.

Ultimate Load Requirements. It is necessary at this point to discuss the type of load levels required by the qualifying or certifying agencies to meet their validation requirements. The static test load level requirement for U.S. Federal Aviation Administration (FAA) certification is based on experience the manufacturer and the FAA have had with a particular type of structure. To meet FAA requirements, conventional metal structures are usually tested only to the limit load. This may also be true for composite structures if the manufacturer has had experience with similar composite structures; otherwise, testing to the ultimate load level is required. Various U.S. Department of Defense (DoD) agencies require the ultimate load level for the static test in order to qualify most structures.

After completing the required testing, whether to limit or ultimate load, the manufacturer often picks the most critical condition and tests the article to destruction. This destruction test further validates not only the ability of the analysis to predict the load distribution but also the strength of the structure. If the destruction test failure load exceeds the required ultimate load, vehicle performance growth is warranted.

Test Results Correlation. The final step in the static test sequence is a review of the data obtained from the test and evaluation of its correlation with the stress analysis. The structure is also carefully inspected using nondestructive techniques to determine whether damage that has occurred cannot be readily detected visually. This is of particular importance to composite structures because many of their failure modes and sequences are interlaminar and thus may not be visible.

Full-Scale Structural Testing

John E. McCarty, Composite Structures Consulting

Durability (Fatigue) Test

The effects of cyclic loading on current carbon-epoxy composites have generally been shown to be noncritical, due to the static load sensitivity of composite structures to stress concentration. In addition, the load level threshold at which composites become sensitive to cyclic loading is a very high percentage of their static failure load. Because this threshold is so high and most vehicles do not experience repeated loads that approach their ultimate loads, composite structures are not fatigue critical. Even if they were to experience loads near this threshold, or slightly above, there are so few of these high cycles in the spectrum life of the vehicle that no significant fatigue damage would occur that would affect structural capability. No industry acceptable-damage

rule has been developed for fatigue of composite structures because of this noncritical factor of fatigue loading and the complexity of the fatigue mechanism for composite materials.

Some of the new “tougher” matrix resin systems being used in composites may have characteristics that make them more fatigue-sensitive than the current epoxy systems. If this is true, the importance of the full-scale fatigue test for composite structures will grow significantly, along with the need to develop an acceptable-damage rule.

Spectrum Loading Considerations. To date, cyclic testing of composite structures has been conducted to evaluate a metal structure used with a composite structure. Lacking an accepted damage rule, validation of the durability of composite structures has generally used spectrum loading that represents a compromise between the spectra most critical for composites and metals. This compromise, necessitated by the difference in response of composite and metal structures to the magnitude of repeated loads in the applied spectrum, is particularly valid at the full-scale test level. Composites are cyclic-sensitive to loads high in the spectrum, which produce the most fatigue damage and shortest test life. Both the high and low loads in the spectrum can damage a metal structure. However, the high-spectrum loads that damage composites produce a generally unconservative test life (longer than the in-service life) for metal components of the structure.

In general, full-scale cyclic testing has been limited to two to four lifetimes of spectrum loading, including a spectrum load enhancement factor. The flat stress versus cycles curve for composite materials would require, from a statistically significant point of view, consideration of the large scatter in repeated load life in order to technically validate the fatigue performance of composite structures. This may be accomplished through a life and/or load factor.

Most of the test setup and performance considerations for the full-scale static composite structures test discussed in the previous section apply to the fatigue test. Only those requirements unique to the fatigue test are discussed in the following two sections.

Testing and Inspection Requirements. Selecting the loads to be applied represents a compromise for both the composite and metal structural elements. It is very easy to apply a random sequence of spectrum loads using computers to control the loading jacks. Most full-scale fatigue tests, if not all, are spectrum loaded. The methods of loading, attachment of load fixtures, instrumentation, data recording, and checkout of the test setup are all similar to those used in static tests. The fatigue test has the additional feature of inspection intervals throughout the test life. These inspections are conducted to determine whether any damage is progressing because of cyclic loading, to obtain fatigue performance of the structural details, and to catch a critical damage growth that could cause loss of the test article during load cycling.

Stiffness change of a composite structure has been found to be an indicator of fatigue damage. Therefore, stiffness checks should be conducted at various times throughout the test, in a manner similar to the imposed inspection sequence. Because a significant stiffness change in a full-scale test article is very difficult to detect, nondestructive (primarily ultrasonic and x-ray) inspection methods are commonly used to detect damage and monitor its growth throughout the fatigue test.

Accounting for Environmental Effects. After selecting the spectrum loading for a composite structure, a decision must be made as to a way to apply environmental effects during the fatigue test, or account for them in the test results. The cost of either conditioning or applying a real environment to a full-scale test article generally is prohibitive. Enhanced or factored spectrum loads are the easiest means of accounting for environmental effects. Although mechanically loading the full-scale structure in a manner that truly represents the effects of environmentally induced strains is very difficult, if not impossible, the factored spectrum load approach is currently the only real option. Modifying the test results by analysis will not be feasible until an acceptable-damage rule for composite structure fatigue is developed. With the full-scale fatigue test, as with the static test, a post-test inspection of the test article is very important to ensure that no fatigue damage has occurred.

Full-Scale Structural Testing

John E. McCarty, Composite Structures Consulting

Damage Tolerance Test

The damage tolerance test, like the static test, is a qualification requirement of both the FAA and the DoD. In the past, fatigue testing was not required by the FAA for structures designed as fail safe and/or damage tolerant, but was required for all so-called safe-life structures. Now, fatigue testing is required by the FAA if there is the possibility of widespread fatigue damage in service. To date, most composite structures have shown good fatigue resistance behavior, so there is little likelihood of widespread fatigue damage in service. However, because there is no large in- service database for composites in primary structural applications in commercial aircraft, the FAA most likely will require fatigue testing until such a database is available. As composites have been used in the primary structures of commercial aircraft since the late 1980s, the service data are becoming available. With industry review, the database will continue to improve. Also, because most of the current composite structures include metal components, the interaction of the metal and composite structural elements needs to have a good fatigue database from testing and in-service monitoring. Although the load level required by the FAA and the DoD varies, both specify residual strength requirements that vary with the flaw damage assumption, ability to inspect damage, type of in-service inspection used, and type of aircraft. The loading requirement must be carefully reviewed to establish the damage tolerance test residual strength requirements.

Testing composite structures for damage tolerance is particularly important, because it addresses the concerns associated with both the static and fatigue tests. As with the static test, the brittle nature and notch sensitivity of composites is a concern in the damage tolerance test. As in the fatigue test, the critical flaw or damage may be associated with either its initial state or its growth after cyclic loading. Because the full- scale damage tolerance test has many other similarities with the static and fatigue tests, information on instrumentation, load application, loading control, data display and recording, test setup and checkout, and test assignment responsibilities are not repeated; only concerns unique to the damage tolerance test are discussed.

The types of flaws or damage that are critical to current composite structures are penetrations, delaminations, and low-velocity impact damage. The following discussion is limited to impact damage, since it is currently the most critical type of damage for composite structures and its concerns are representative.

Cycling and Inspection Requirements. The damaged full-scale structure should be subjected to cyclic loading that substantiates a statistically significant life. Because structural response to impact damage is unique to composites, the imposed spectrum can be tailored to the needs of the composite structure only. Full-scale flaw or damage cyclic testing of a metal structure is not regularly done; therefore, the spectrum imposed for the damage tolerance test of composite structures can be tailored to a composite-sensitive spectrum. The repeated inspections required for the fatigue test are also required for this test.

The phasing of loads may be significant to crack growth in areas such as fastener holes. The phasing should be considered and, when justified, included in full-scale testing.

Accounting for environmental effects of temperature and absorbed moisture is a necessary part of the damage tolerance test. For the residual strength part of the test, the approaches noted for the static test can be applied here as well. The damage effect is usually so dominant that temperature and moisture do not have a strong effect on residual strength. However, the question of environmental effect during the cyclic test portion of the damage tolerance test is not easily addressed. Load enhancement of the spectrum, as suggested for the fatigue test, is currently the only option.

For verification of other damage tolerance, such as lightning strike protection, full-scale testing of certain components may be required.

Residual Strength Test. Once the lifetime spectrum loading requirements have been completed, the required residual strength loads are applied. As in the static test, there will be more than one type of loading required, and a critical loading selection must be made. If the structure successfully passes these residual strength tests, one option is to load it to failure to further integrate its damage tolerance capability. As for the other full-scale tests, a detailed inspection is made before the destruction test. The resulting test data are reviewed and correlated with the analysis as part of the certification of the structure for damage tolerance requirements.

Properties and Performance of Polymer-Matrix Composites

Introduction

THE DESIGN AND ANALYSIS of composite components and assemblies require a detailed knowledge of materials properties, which, in turn, depend on the manufacturing, machining, and assembly methods used. This article selects, from the many available composite fiber-resin combinations manufactured by conventional processing methods, a few that are representative of the common, high-volume types as well as a few of the more specialized types. These materials are identified and briefly described, and their properties are presented in graphic and tabular form. This collection of data is not intended to be comprehensive, but instead is meant to provide a general overview of the performance capabilities of selected polymer-matrix composite materials.

Materials and Properties Description

Composite components are in the form of fibers, resins, and fiber-resin combinations, as shown in Fig. 1. The fiber starts with single filaments grouped by 1000 to 12,000 into a fiber bundle, which can be chopped into short (3.2 to 50 mm, or $\frac{1}{8}$ to 2 in.) fibers, woven into fabric, or further combined into a fiber tow containing as many as 40,000 to 300,000 filaments. Fabrics and tows can be further processed into chopped 12.7 × 12.7 mm ($\frac{1}{2}$ × $\frac{1}{2}$ in.) fabric squares, or 6.4 to 12. 7 ($\frac{1}{4}$ to $\frac{1}{2}$ in.) chopped fiber tows, respectively.

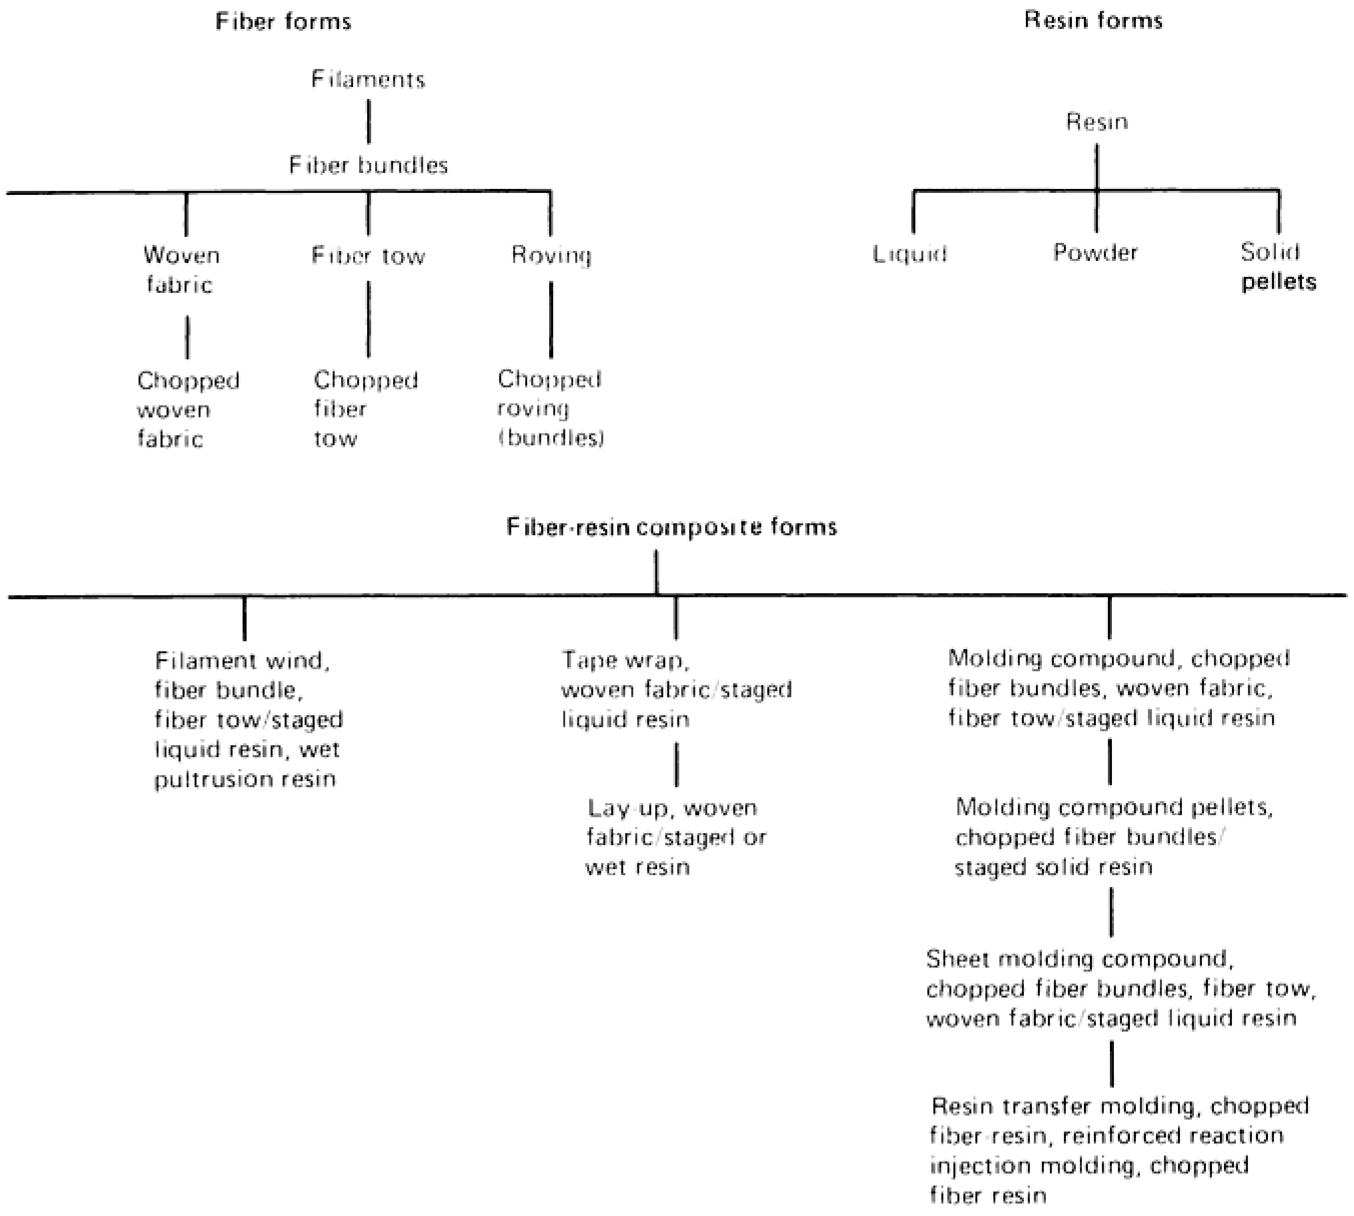

Fig. 1 Composite forms

Figure 2 illustrates four common types of fabric weave. In the plain weave, yarns are interlaced in an alternating fashion over and under every other yarn to provide maximum fabric stability and firmness and minimum yarn slippage. The thinnest and lightest-weight fabrics are also achieved by use of the plain weave. Fabrics as fine as 25.4 μm (1 mil) are being produced for the electrical industry for mica backing. The plain weave is the primary weave used in the coating industry.

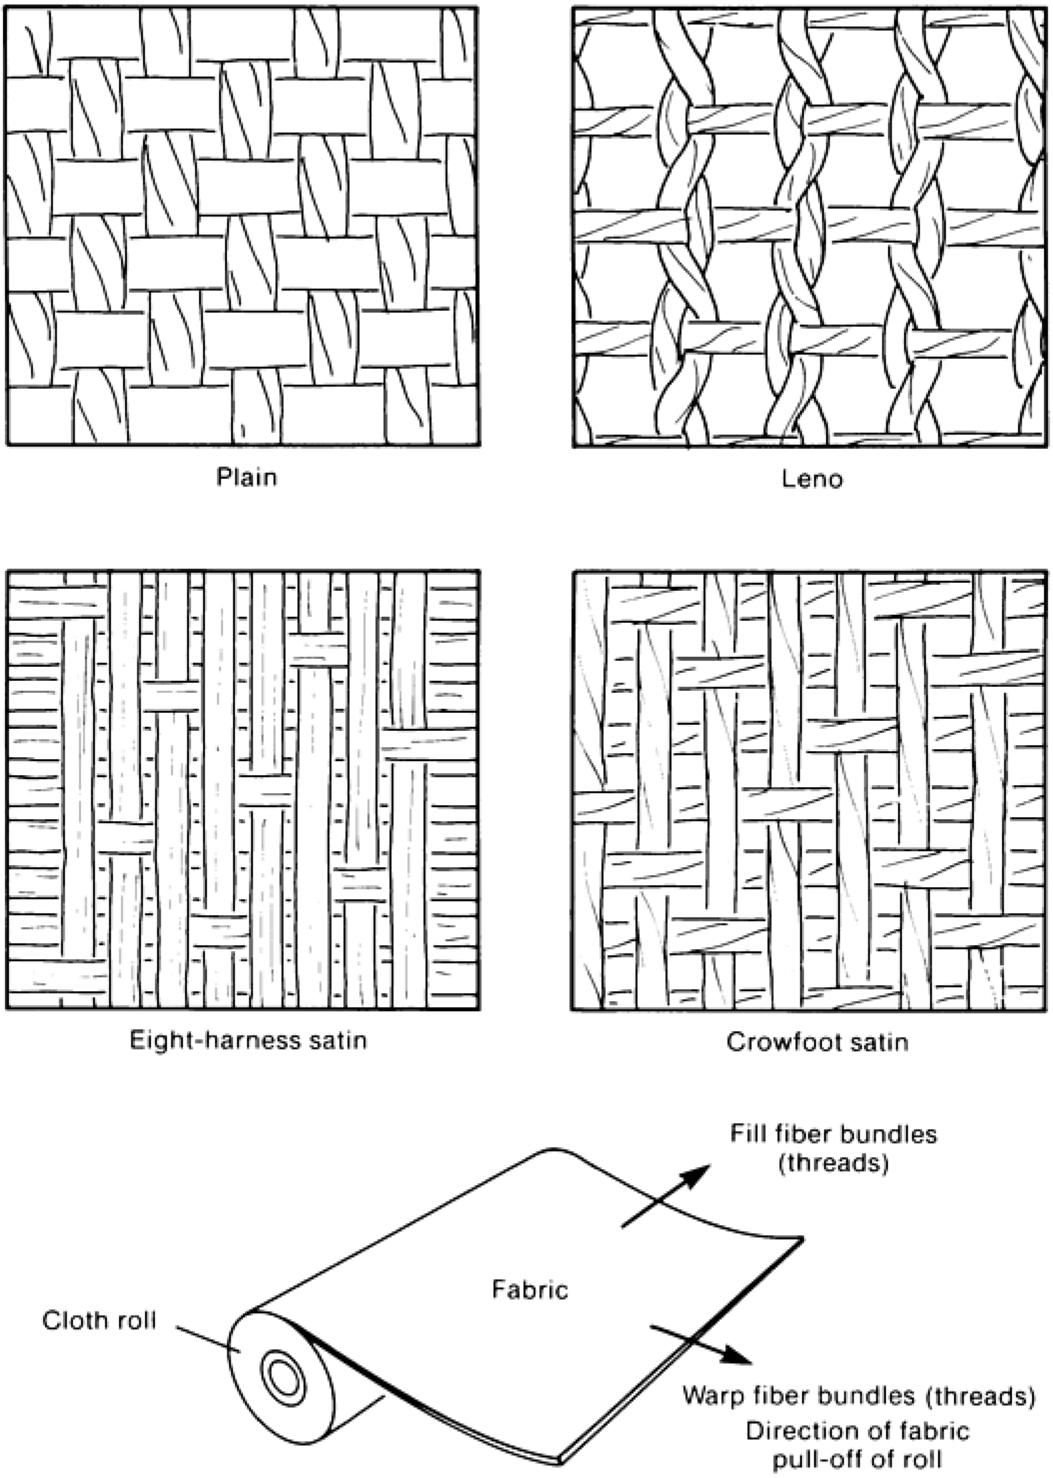

Fig. 2 Typical fabric weaves. Source: J.P. Stevens & Company, Inc.

The leno weave maintains uniformity of threads and minimizes distortion of threads where a relatively low number of threads is required. Grinding wheel reinforcements, light- weight membranes, and laminating fabrics used the leno weave to good advantage.

The eight-harness satin weave, a very pliable weave that conforms readily to intricately contoured planes, can also be woven with more threads per inch to achieve a high density. Satin weaves are used to best advantage in the reinforced plastic field, especially for prepregs for aircraft and missiles. Satin weave fabrics require more threads per inch to retain stability and are generally produced in the medium and heavy weight range (200 to 610 g/m^2, or 6 to 18 oz/ yd^2).

In the crowfoot satin weave, one warp yarn weaves over three and under one fill yarn. It is used primarily in unidirectional fabrics for fishing rod reinforcement. Crowfoot weave fabrics also conform easily to contoured surfaces.

Resin forms are categorized as liquid, powder, or solid pellets. They can be combined with fiber or have fillers, such as carbon, graphite, calcium carbonate, clay, hydrated alumina or silica powder, added to them.

The fiber-resin forms in a majority of structural component applications are either filament- wound fiber bundles or tows, unidirectional fiber tape laydown (tape wrapped), woven fabric, chopped fiber molding compound, or lay-up fabrics that are all either combined with a staged (partially cured) liquid resin or impregnated with a wet resin during the fabrication process.

The physical, mechanical, thermal, and electrical properties and in-service conditions of the forms that are presented in this article have been obtained from a survey of technical literature and publications and corporate product engineering data sheets and reports. Where a mulitude of data points exist for a given material property, multiple curves are drawn and the user can interpret the information based on the references.

Table 1 lists key physical, mechanical, thermal, and electrical properties and in-service conditions of concern for resin-matrix composites, many of which are covered in the following sections in this article.

EMI/RFI, electromagnetic interference/radio-frequency interference

The following general statements on material properties versus temperature represent guidelines for composite material use:

- Mechanical properties of fibers, resins, and fiber-resin composites decrease with temperature.
- Most mechanical properties of fiber-resin composites are higher than those for resin properties, but lower than those for fiber properties.
- Most thermal properties from room temperature to 260 °C (500 °F) increase with temperature.
- Carbon and graphite fibers increase the thermal and electrical conductivity of a fiber-resin composite material system.
- Properties may be different in all three planes, depending on fiber configuration.
- Factors that affect mechanical properties are resin-to-fiber ratio, resin and fiber types, resin-fiber interface, type of composite processing (filament winding, tape wrapping, or molding), and type of

composite cure (autoclave, hydroclave, vacuum bag molding, extrusion, or compression or injection molding).

In addition, these observations on material properties in respect to form of reinforcement should be considered:

- Maximum properties in load direction 1 are achieved by unidirectional lamination of continuous fiber reinforcement (Fig. 3).
- In a unidirectional laminate, mechanical properties in load directions 2 and 3 are much lower than in load direction 1 and are highly dependent on the matrix resin.
- Bidirectional reinforcement can be achieved by cross-plying unidirectional tapes or broad goods, and by using woven fabric reinforcement.
- Strength can be tailored to end-use requirements by directional placement of individual plies of reinforcement, such as 0°/90°/60°/60°/ 90°/0° or 0°/45°/45°/0°.
- Mechanical properties of discontinuous-fiber- reinforced composites (chopped-fiber or chopped-fabric molding compounds) are usually substantially lower than those of continuous-filament-reinforced composites.
- Properties of composites made from molding compounds are generally omnidirectional in the plane of the part, unless flow in molding causes directional orientation of the reinforcing fibers.

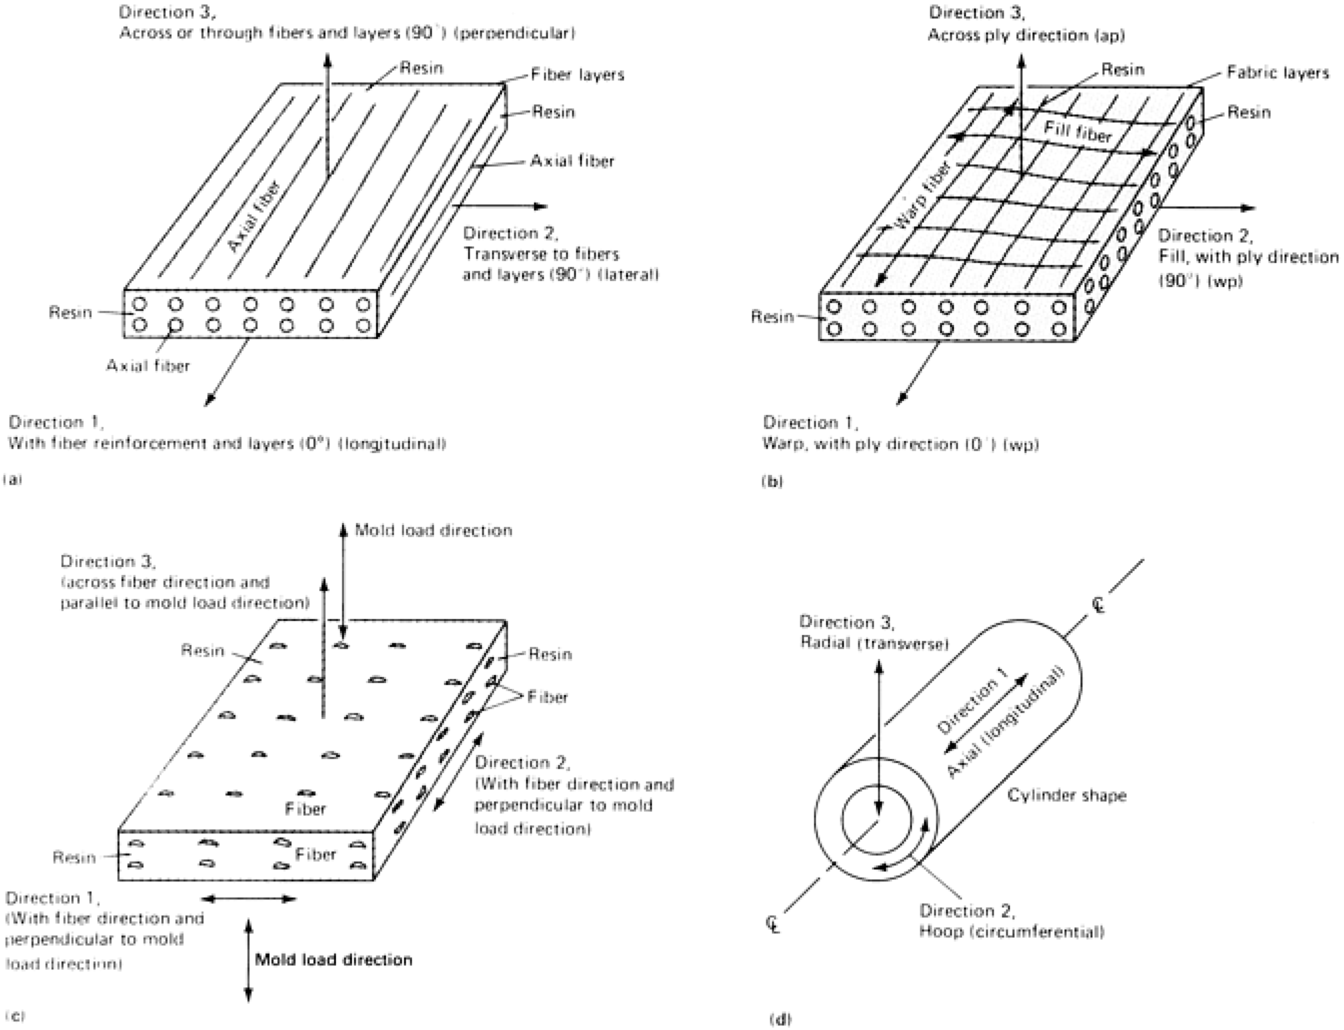

Fig. 3 Definitions of test axes for various composite types. (a) Unidirectional continuous fiber-resin composites (filament wind, tape lay-down, pultrusion). (b) Fabric-resin composites (tape wrap, lay-up). (c) Chopped fiber or fabric-resin molding compounds. (d) Shape components

Some data references for resin-fiber composites may not give fiber percentage by volume or weight, fiber length or diameter, resin type, supplier, or cure cycle. Despite the fact that complete data on these general properties are unavailable, the information given is intended to inform the engineer of the effects of fiber reinforcement. For individual applications of a fiber- resin composite, specific property data must be generated for design analysis, as well as to assist in manufacturing processes. More data references are available from raw material suppliers, the research and development laboratories of the user corporation, contract laboratories that service government and industry needs, and unclassified or nonproprietary documents. Basic material property data on a specific design application can be obtained by making a request to these information sources or by obtaining the necessary classification clearance, although designers will have to "flesh out" the data by property testing in their own test laboratories.

This article also contains descriptions and data that characterize each generic material according to its composition and method of manufacture. Because the composition and manufacture of virtually all materials are subject to change by their manufacturers, a composite may bear the same name for several years, but its mechanical and thermal properties may be modified appreciably.

Data sets for a particular material property may contain a single allowable curve. The curve and its extrapolation are based on knowledge of the material combined with engineering judgment. For this article, no attempt was made to derive an analytical function through the data set.

To assess properties, these factors need to be considered:

- Major axis of directionality
- Type of fabrication for component
- Fiber or fabric type, length, and fiber percentage by weight or volume
- Fiber finish and strength; fabric weave pattern
- Number of filaments and twist in fiber bundle
- Resin type and manufacturer
- Resin-to-fiber ratio, percent of filler, percent of volatile content, and percent of resin flow
- Test panel preparation and cure
- Test specimen preparation, test method, and number of tests
- Test specimen design, test fixture, and load ratio
- Test specimen condition, dry or wet

Axes Definitions, Symbols, and Special Property Calculations

Because composite materials can have different properties in each of the three directions, definitions of test axes are very important. Each test axis is defined as 1, 2, or 3 for unidirectional fiber, fabric, and fiber or cut-fabric molding compounds, as shown in Fig. 3. Directions 1 and 2 are usually either the direction of the fiber reinforcement or the direction transverse to the fiber, while direction 3 is perpendicular to the fiber or fabric layers, or across ply. Composite material shapes also have directional properties as illustrated in Fig. 3(d), with direction 1 being axial or longitudinal, direction 2 being hoop or circumferential, and direction 3 being radial or transverse. Figure 3(b), for example, indicates that ultimate tensile strength, with ply, could be expressed as σ_{tu1}, σ_{tu2}, σ_{tu12}.

For Poisson's ratio, ν, numeric subscripts are used:

$$\nu_{12} = \frac{\text{Strain in direction 2}}{\text{Strain in direction 1}}$$

where direction 1 is tension loaded and direction 2 is perpendicular to load application. Poisson's ratio, by convention, is expressed as a positive number even though the strain is actually a negative value, because most material shrink in the lateral direction when stretched in the longitudinal direction.

The coefficient of thermal expansion, α, is defined in Fig. 4 as the slope of the secant line from a reference temperature (20 °C or 70 °F, no expansion) to the expansion or contraction at the temperature of interest.

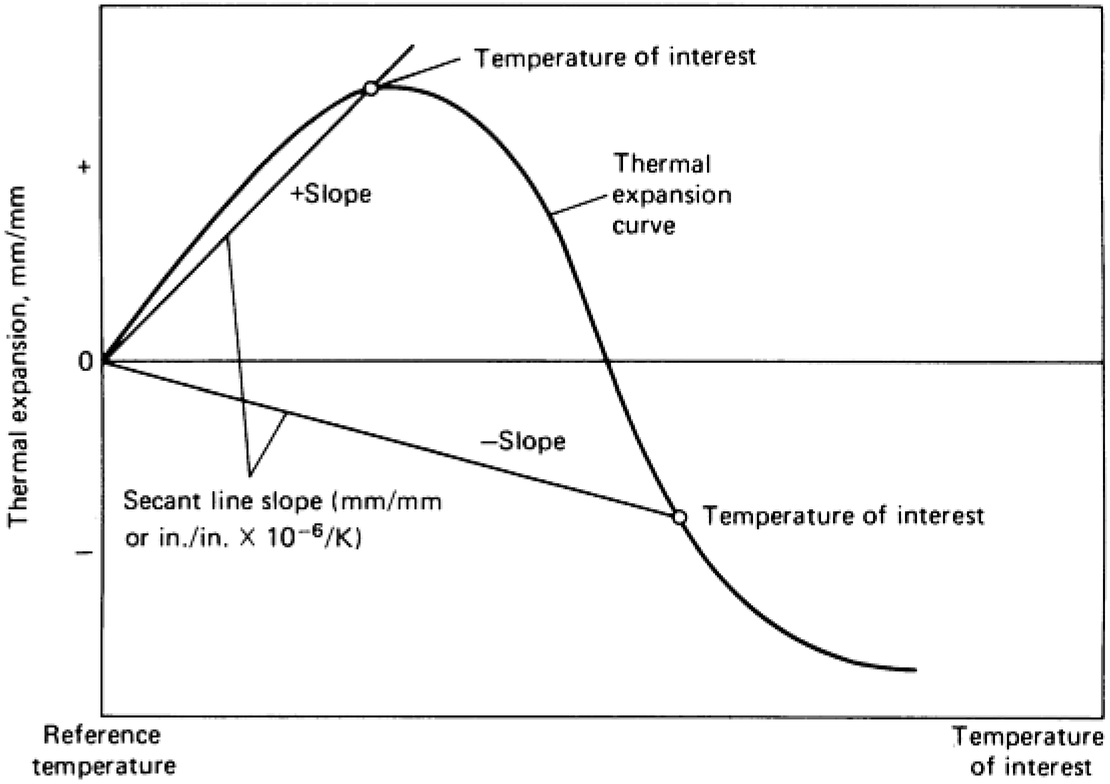

Fig. 4 Coefficient of thermal expansion is calculated as the slope of the secant line between the reference temperature (room temperature) and the temperature of interest. 10^{-6}/K × $\frac{5}{9}$=μin./in. ×°F

Definitions of the electrical properties used as standards for comparison of resins, fibers, and resin-fiber composites are:

- *Dielectric:* An insulating medium between two conductors to store and release energy
- *Dielectric constant:* Pure number indicating capability to store energy per unit volume
- *Dielectric strength:* The voltage that an insulating material of a given thickness can withstand before breakdown occurs
- *Volume (electrical) resistivity:* The electrical resistance between opposite faces of a unit cube of material
- *Dissipation factor (power factor) or loss tangent:* Multiplier used with apparent power to determine how much of the supplied power is available for use, that is, a measure of power loss in the material
- *Electromagnetic interference/radio-frequency interference (EMI/RFI) protection:* Provided by a material that will conduct an electrical signal away from the component that needs shielding or dissipate a localized electrical strike over a large surface area

The introduction of carbon fibers to all resin composite material will ensure a better EMI/RFI protective characteristic.

The definition of flammability characteristics of plastic materials is given by Underwriters' Laboratory (UL) rating tests for flammability of plastic materials. A typical test specimen for all ratings is 125 mm (5 in.) long by 12.7 mm ($\frac{1}{2}$in.) wide by 12.7 mm ($\frac{1}{2}$in.) thick. A Bunsen burner is applied at one end of a specimen that is held at the opposite horizontal or vertical end. Table 2 identifies the specifications for flammability ratings. Generally, a UL 94 V-0 rating is satisfactory, while 94 HB, 94 V-1, and 94 V-2 are less satisfactory. A 94 V-5 is the highest rating.

Table 2 Burn test criteria for Underwriters' Laboratory flammability ratings

Rating test	**Specimen**	Burn criteria(a)
94HB	Horizontal	**<38 mm (1.5 in)/min burn for 3–13 mm (0.120–0.500 in. thickness**
		<75 mm (3.0 in.)/min burn for <3 mm (0.120 in.) thickness
		No burn >100 mm (4.0 in.) specimen length
94 V-0	Veritcal	**<10 s burn after each of two FA**
		<50 s burn for 10 FA
		No total burn of specimen
		No dripping burn of cotton 305 mm (12 in.) below specimen
94 V-1	Vertical	**<30 s after second FA**
		<30 s burn after each of two FA
		<25 s burn for 10 FA
		No total burn of specimen
		No dripping burn of cotton 305 mm (12 in.) below specimen
84 V-2	Vertical	**<60 s glow after second FA**
		<30 s burn after each of two FA
		<290 s burn for 10 FA
		No total burn of specimen
		Brief dripping burn of cotton
		305 mm (12 in.) below specimen
95 V-5	Vertical	**<60 s glow after second FA**
		<60 s burn after fifth FA
		No drip specimens

Overview of Constituent Materials

For a standard composite panel or structural shape, the ratio of matrix material to the fiber reinforcement ranges approximately from 1:2 to 2:1. The fiber is the main tailoring element for the design properties, while fiber orientation and fillers can provide secondary fine tuning for the product application.

The resin matrix provides stable dimensional control to the fiber laminate, a small participating component for properties, and a shear resistance between reinforcing fibers. A coupling agent enhances resin matrix-to-fiber bonding, while the filler can fine tune such properties as density, cost/pound, processing viscosity, strength, and flame-retardant characteristics.

Reinforcing-fiber characteristics such as density; fiber diameter, strength, and modulus; fiber filament bundle size; and woven-fiber fabric type or chopped-fiber form are initially optimized approximately by the “rule of mixtures” to help meet the composite properties needed for the design application engineering criteria for product operation and performance.

In addition, the selection of the ratio of matrix to reinforcement constituents is influenced by the loading patterns to the product, environmental operating conditions, the standard manufacturing-processing methods, reinforcement forms, costs, and completion time for the particular company and industry.

Currently, twelve or more fiber-reinforcement systems are available for resin-matrix composite fabrication into industrial, commercial, and aerospace products. Figure 5 shows a comparison of the properties of four of the most widely used fiber types: glass, aramid, carbon, and graphite. Density ranges from 1.44 to 2.48 g/cm^3, strength from a minimum of 2200 MPa (320 ksi) to a maximum of 4585 MPa (665 ksi), modulus from 85 to 345 GPa (12 to 50 × 10^6 psi), and service-temperature capability in inert atmospheres from 500 to 3040 °C (930 to 5500 °F).

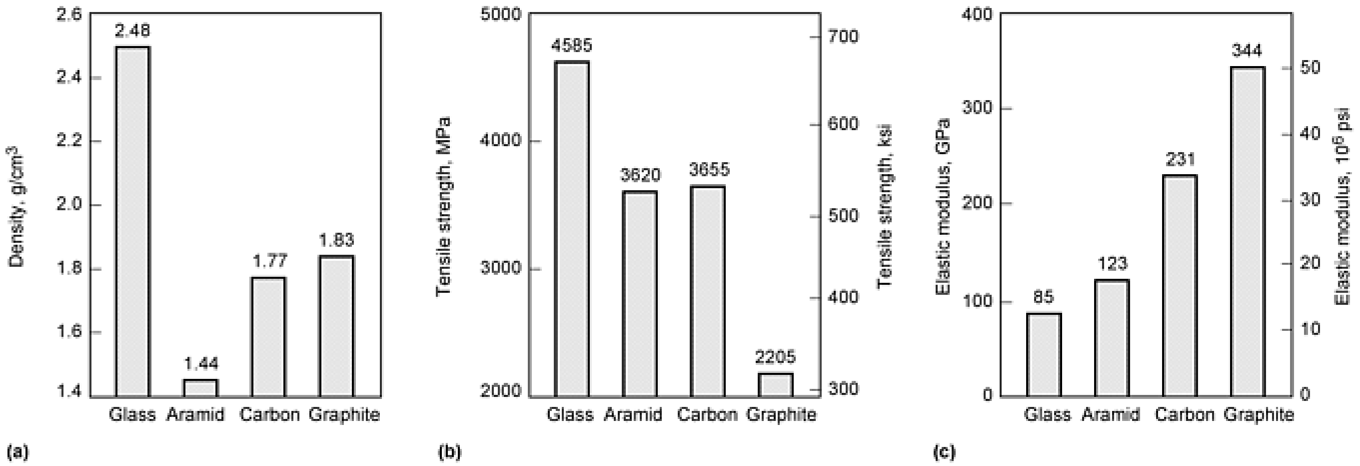

Fig. 5 Mechanical properties of selected reinforcement fibers. Inorganic fibers: glass (maximum temperature 970 °C, or 1780 °F) and aramid (maximum temperature 500 °C, or 930 °F). Organic fibers: carbon (maximum temperature 2500 °C, or 4500 °F) and graphite (maximum temperature 3000 °C, or 5500 °F). (a) Density. (b) Tensile strength. (c) Elastic modulus

More detailed property data for fibers are provided in the article "Introduction to Reinforcing Fibers" and in the articles on specific fiber types in the Section "Constituent Materials"in this Volume.

Resin systems include at least 36 types or hybrid combinations, divided into thermoplastics (heat affected) or thermoset (heat permanently cured) divisions. The baseline room-temperature properties and service temperatures of three thermoplastic and three thermosetting resins in Fig. 6 show the ranges of density from 1.14 to 1.43 g/cm^3, tensile strength from 53 to 112 MPa (7.7 to 16.2 ksi), tensile modulus from 875 to 4135 MPa (127 to 600 ksi), and service temperature from 130 to 370 °C (266 to 700 °F).

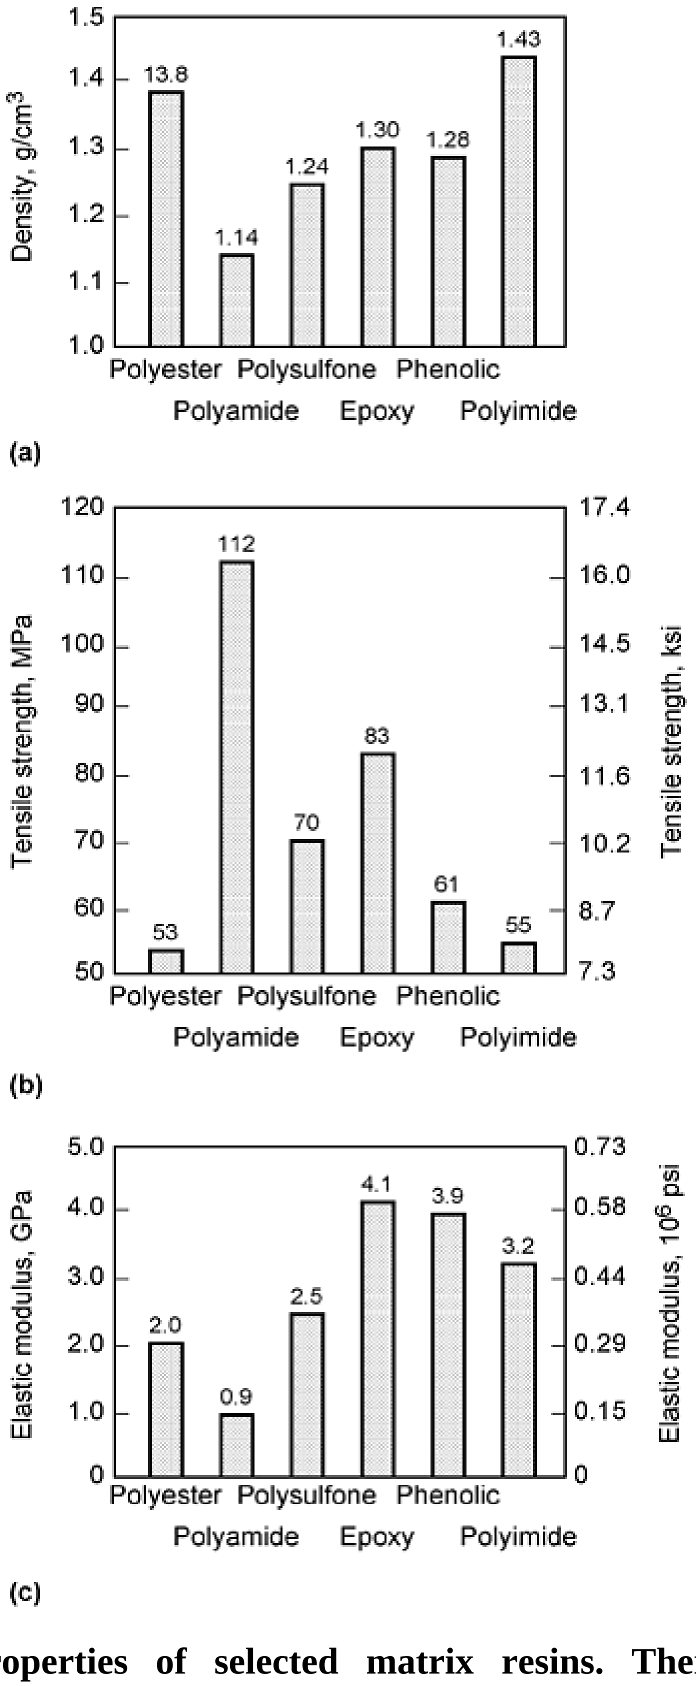

Fig. 6 Mechanical properties of selected matrix resins. Thermoplastics: polyester (unfilled; maximum temperature 140 °C, or 284 °F), polyamide (nylon 6/6, unfilled; maximum temperature 130 °C, or 266 °F), and polysulfane (standard; maximum temperature 160 °C, or 320 °F). Thermosets: epoxy (unfilled; maximum temperature 260 °C, or 500 °F), phenolic (unfilled; maximum temperature 230 °C, or 450 °F), and polyimide (unfilled; maximum temperature 370 °C, or 700 °F). (a) Density. (b) Tensile strength. (c) Elastic modulus

Most matrix materials commonly used are preformulated at the supplier for the preimpregnated fiber, resin, curing agent, and coupling system. However, the manufacturer will often add small amounts of a filler to aid in the processing; change surface texture, color, and thermal and electrical conductivity; provide moisture resistance; and serve as an antioxidant. Modifications to the composition, however, must be tested for compatibility and successful cure processing to achieve properties tailored to meet specific product performance and service operation requirements.

Additional data on neat and reinforced resins are provided in the following sections in this article and in the Section “Constituent Materials” in this Volume.

Overview of Constituent Materials

Properties and Performance of Polymer-Matrix Composites

Thermoplastic-Matrix Composites

Thermoplastic Polyester Resins and Fiber- Resin Composites (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11). Three polyester resin systems—aromatic copolymers, polybutylene terephthalate (PBT), and polyethylene terephthalate (PET)—are used to describe the family of properties of thermoplastic polyester resins (Table 3, Fig. 7 to 14). Short-length glass and carbon-fiber reinforcements of up to 55% of the fiber-resin composite are used to improve or alter the properties in molding compounds. The UL service temperature of the unfilled resins ranges from 120 to 240 °C (253 to 474 °F). Applications are electrical/electronic components, chemical processing and oil field equipment, aerospace and transportation vehicles, appliance and consumer products, furniture, and bottles for toiletries and food products. More information on these resin systems is available in the articles "Thermoplastic Resins" and "Thermoplastic Composites Manufacturing" in this Volume.

Thermoplastic Polyamide Resins and Fiber-Resin Composites (Ref 12, 13). Some variations of polyamide (nylon) resin include alloys of polyolefin and other copolymers to tailor properties for specific uses. The melt point varies with the different product families but is between 212 to 270 °C (414 to 518 °F). Polyamide resins are discussed further in the article "Thermoplastic Resins" in this Volume. Short-length carbon and glass-fiber reinforcements of up to 43% of the fiber-resin composite are used to alter or improve the properties in molding compounds. The range of properties listed in Table 4 and shown in Fig. 15 to 24 include unreinforced and reinforced polyamide resin systems.

It should be noted that because all nylons pick up moisture, final design properties and dimensions will change depending on the relative humidity.

Thermoplastic Polysulfone Resins and Fiber-Resin Composites (Ref 8, 14, and 15). Polysulfone resin exhibits the highest service temperature (150 to 205 °C, or 300 to 400 °F) of any melt-processable thermoplastic. The resin is strong, noted for high heat deflection temperatures, and stable in the presence of moisture. Care must be taken not to expose material to excessive ultraviolet rays or organic solvents. Polysulfone resins are discussed further in the article "Thermoplastic Resins" in this Volume. Glass-fiber reinforcements of up to 40% of the fiber-resin composite are used to alter properties. Property values listed in Table 5 and shown in Fig. 25 to 34 include resin with and without reinforcement. Applications include medical instrumentation, food processing equipment, chemical processing equipment, camera and watch cases, automotive and aerospace components, and water purification devices.

Properties and Performance of Polymer-Matrix Composites

Thermoset-Matrix Composites

Thermoset Polyester Resins and Fiber- Resin Composites (Ref 1, 8, 16, 17, 18, 19, 20, 21, 22, and 23). Thermoset polyesters are low-temperature resins generally produced from the reaction of an organic alcohol (glycol) with both a saturated (isophthalic) and an unsaturated (maleic or fumaric) organic acid. The polyester is then dissolved in a liquid reactive monomer such as styrene, and the solutions are sold as polyester resins. Some polyesters are supplied as pellets or granular solids, and some are premixed with glass fiber for bulk molding compounds (BMCs) or sheet molding compounds (SMCs). Polyester resins with fiber reinforcements can be formulated to provide different mechanical, thermal, electrical, and flammability properties.

Because of their low cost, ease of processing, and good performance characteristics, unsaturated polyesters are the most extensively used type of thermoset resin. See Table 6 and Fig. 35 to 46 for properties. Unsaturated polyesters are generally combined with chopped, continuous, or woven glass fibers, as well as fillers and additives, to alter the properties to fit the application.

Thermoset polyesters are widely used in transportation, construction, electrical, and consumer products. In addition, the versatility of polyesters allows them to be used in a broad variety of processes. Through appropriate selection of the cross-linking initiator, these resins can be cured at any temperature from ambient to 175 °C (350 °F). Resin and glass fibers are combined at the "mold" in hand lay-up, spray-up, filament winding, pultrusion, and resin transfer molding. Both BMCs and SMCs, as well as other molding compounds, are used as input materials for compression, injection, and transfer molding processes. Because the fibers are not "preplaced" in the later molding operations, fiber orientation caused by molding compound flow can produce variable anisotropy in the finished parts. Molding compounds are available from many manufacturers.

Thermoset Phenolic Resins and Fiber- Resin Composites (Ref 1, 18, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, and 42). Phenolic resin systems are medium-temperature thermoset resins formulated from the reaction between phenol and formaldehyde. The two main resin types are resoles and novolacs. Two-stage phenolic resins (novolacs) are used for general-purpose molding compounds, while hybrids of the novolacs are used as impregnating resins with glass, carbon, and graphite cloth for tape wrapping or hand lay-up of aerospace components, rocket nozzle ablative, and insulation liners. Chopped-fiber molding compounds are used mostly in the automotive, appliance, and electrical component markets. General characteristics of these materials that make them suited for the previously mentioned applications are high service temperatures, good electrical properties, excellent moldability and dimensional stability, and good moisture resistance.

The following sections of this article describe three types of tapes for tape wrapping and lay- ups: glass fabric-phenolic tape, carbon fabric- phenolic tape, and graphite fabric-phenolic tape.

Table 7 and Fig. 47 to 64 give specific mechanical, thermal and electrical properties for each type of phenolic resin thermoset. Physical properties are identified in the table, but some test data and references are described in the following sections.

Table 7 Physical properties and service characteristics of thermoset phenolic resin and fiber-resin composites

Property	**Phenolic resin**	Fiber-resin composites

Glass-fabric-reinforced phenolic resin is used for lay-ups, tape wrapping, and molding compounds in the chopped cloth (12.7 mm × 12.7 mm, or $\frac{1}{2}$in. × $\frac{1}{2}$in.) version.

Carbon-fabric-reinforced phenolic resin reinforcement materials include the base fiber, which is a special variation of high-tenacity rayon tire cord reinforcement, pitch fibers, and polyacrylonitrile fibers. The base fiber is woven into plain leno, and satin weaves and subsequently carbonized at below 1650 °C (3000 °F). Polyacrylonitrile fibers are processed in much the same way as rayon, but in the base process the pitch fibers are carbon, which need no further carbonization after cloth weaving. The material is supplied either as a broad goods roll that is 965 to 1200 mm (38 to 48 in.) wide and approximately 20 to 45 kg (50 to 100 lb) per roll, or as a slit tape roll width. The raw material is used for hand lay-ups, tape wrapping, and molding compounds in the chopped cloth (12.7 mm × 12.7 mm, or $\frac{1}{2}$in. × $\frac{1}{2}$in.) version.

The tensile, compressive, and shear (strength and modulus) mechanical properties decrease in value with an increase in temperature.

The conductivity and specific heat thermal properties increase with a temperature increase. The coefficient of thermal expansion (CTE) with the ply has the same characteristics versus temperature, except for a decrease around 540 °C (1000 °F) due to the phenolic weight loss and conversion to a carbon char. The CTE across the ply, directly related to the phenolic resin, increases to 400 °C (750 °F), decreases to 815 ° (1500 °F), then increases again to 1926 °C (3500 °F).

No electrical properties are currently available, because carbon fabric phenolic is too highly conductive for most electrical industry applications.

Graphite-fabric-reinforced phenolic resin is manufactured in a manner similar to that for the carbon fabric-phenolic resin, except that the rayon-based fabric is graphitized at over 2205 °C (4000 °F). Graphitization at a higher temperature stabilizes the fabric from further thermal shrinkage at application temperatures (about 3315 °C, or 6000 °F) in aerospace components and rocket nozzles, increases thermal conductivity, and lowers the strength levels.

Mechanical, thermal, and electrical properties of graphite-fabric-reinforced phenolic resin are much the same as for the carbon-fabric-reinforced type.

Additional information is provided in the article “Phenolic Resins”in this Volume.
Thermoset Epoxy Resins and Fiber-Resin Composites (Ref 1, 8, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, and 65). Epoxies are high-strength, medium-temperature resin systems that can be formulated into compounds, such as diglycidyl ether of bisphenol A (DGEBA); multifunctional epoxies, such as phenolic novolac; and aliphatic epoxies, such as cycloaliphatic. Temperatures up to 230 to 260 °C (450 to 500 °F) can be used for the latter two types of resin systems for short periods of time. At 540 °C (1000 °F), the hydrogen and oxygen have been driven off, leaving a weak carbonaceous char. Reinforced epoxy structures provide high strength-to-weight ratios and good thermal and electrical properties. Filament winding and machine or hand lay-up processes are used for advanced aircraft fuselages, wing and control surface panels, rocket motor cases, rocket nozzle structural shells, and commercial pressure vessels, tanks, and pipe. Glass fiber-fabric, carbon, graphite, quartz, and aramid fibers are used in molding compounds, hand lay-ups, and fiber- fabric prepreg composites for different applications to match pressure, temperature, service life, weight, and cost requirements (Ref 1, 8, and 43).
This section focuses on seven fabric forms:

- Epoxy resin with and without E-glass fiber reinforcement
- Glass-fabric-reinforced epoxy resin
- S-glass-fiber-reinforced epoxy resin
- Quartz-fabric-reinforced epoxy resin
- Kevlar-49-fiber-reinforced epoxy resin
- Carbon-fiber-reinforced (T300) epoxy resin
- Graphite-fiber-reinforced (HM) epoxy resin

Table 8 shows specific characteristics of several of these materials, including specific gravity, useful temperatures, and reinforcement percentage. The remaining mechanical, thermal, and electrical properties are shown in Fig. 65 to 97.

Epoxy Resin with and without Reinforcement Fibers, and Molding Compounds. Epoxy resin characterization includes DGEBA, phenolic novolac, and aliphatic epoxies without fibers or fillers, as well as other resin systems with glass- fiber reinforcement or asbestos fibers and aluminum filler.

Glass-fabric-reinforced epoxy resin, used as a lay-up, provides a structural material with a large variety of epoxies and at least two glass fibers (E and S). Characterization includes mechanical, thermal, and electrical properties.

S-glass-fiber-reinforced epoxy resin is used as a filament-winding prepreg to manufacture pressure vessels, tanks, tubes, and cones. Characterization includes mechanical, thermal, and limited electrical properties.

Kevlar-49-fiber- and fabric-reinforced epoxy resin is used as a lay-up fabric for boats, aircraft surface panels, and electrical circuit boards. The fiber prepreg is also used in filament winding pressure vessels, tanks, tubes, and cone shapes.

Carbon-fiber- and fabric-reinforced epoxy resin is reinforced with carbon fibers to form unidirectional prepreg tapes suitable for filament winding of components such as pressure vessels, tanks, and pipes, as well as shapes of revolution. It is also used for aircraft external structural panels and space structures.

Graphite-fiber-reinforced epoxy resin is reinforced with graphite fibers and supplied as unidirectional fiber prepreg tapes suitable for filament winding of components or as fabric prepreg rolls suitable for hand lay-ups.

Quartz-fabric-reinforced epoxy resin is reinforced with woven quartz (S/557 unidirectional fabric and S/581 eight-harness satin weave fabric).

Additional information is provided in the article “Epoxy Resins” in this Volume.

Thermoset Polyimide Resins and Fiber- Resin Composites (Ref 1, 8, 18, 66, 67, 68, 69, 70, 71, and 72). Polyimide thermoset resins reinforced with fillers and short fibers are used as molding compound. In addition, continuous fibers or fabric that is preimpregnated with resin polymer is used for lay-ups, filament winding, and tape wrapping. Resin polymer is popular for its high-temperature characteristics (315 °C, or 600 °F), for long durations, and 480 °C, or 900 °F, for short durations), low-temperature properties at–195 °C (–320 °F) for long durations, and low creep and deflection under load at temperature. In addition, its electrical properties are excellent. Properties information is provided in Table 9 and in Fig. 98 to 104. Major applications are in the aerospace and electrical industries.

Table 9 Physical properties and service characteristics of thermoset polyimide resin and fiber-resin composites

Properties	**Resin**	50% glass fiber composite
Heat deflection temperature at 1820 kPa (264 psi), °C (°F)	305–360 (582–680)	**350 (660)**

Thermoset Bismaleimide Resins and Fiber- Resin Composites (Ref 73, 74 75, and 76). The bismaleimide thermoset resins, which may be cured at the lower epoxy cure temperature (175 °C, or 350 °F) and pressure (690 kPa, or 100 psi), do not have gaseous byproducts and thus provide void-free parts. They also offer a new polymer system to combine with various fiber types for improved composite designs. Table 10 and Fig. 105 to 108 show properties data. Applications include aerospace wing skin ribs, helicopter firewalls, and printed wiring boards.

Table 10 Physical properties and characteristics of thermoset bismaleimide resin and resin-matrix composites

Properties	**Neat resin**	**68.3 vol% T300 carbon fiber composite**	57.7 vol% E-glass fiber fabric composite
Specific gravity	1.23	1.60	**2.0**

Properties of Metal-Matrix Composites

David E. Alman, U.S. Department of Energy, Albany Research Center

Introduction

METAL-MATRIX COMPOSITES (MMCs) are a diverse class of materials that consist of a metallic alloy matrix typically reinforced with a ceramic phase in the form of particles, platelets, whiskers, short fibers, and continuously aligned fibers (Ref 1, 2, and 3). Metal-matrix composites are used in structural applications, and in applications requiring wear resistance, thermal management, and weight savings. By far the most common commercial MMCs are based on aluminum, magnesium, and titanium alloys reinforced with either silicon carbide (SiC), alumina (Al_2O_3), carbon, or graphite.

Both continuously and discontinuously reinforced MMCs are used in structural applications. The incorporation of the reinforcement increases the stiffness and strength of the matrix. Figure 1 shows a comparison of the specific strength versus temperature for MMCs, conventional alloys, and other composites (Ref 4). However, the improvements in stiffness and strength generally come at the expense of ductility and fracture resistance. Hybrid laminated metallic (or ductile phase-toughened) composites combine strong materials with tough materials; they can offer an attractive combination of both strength and toughness.

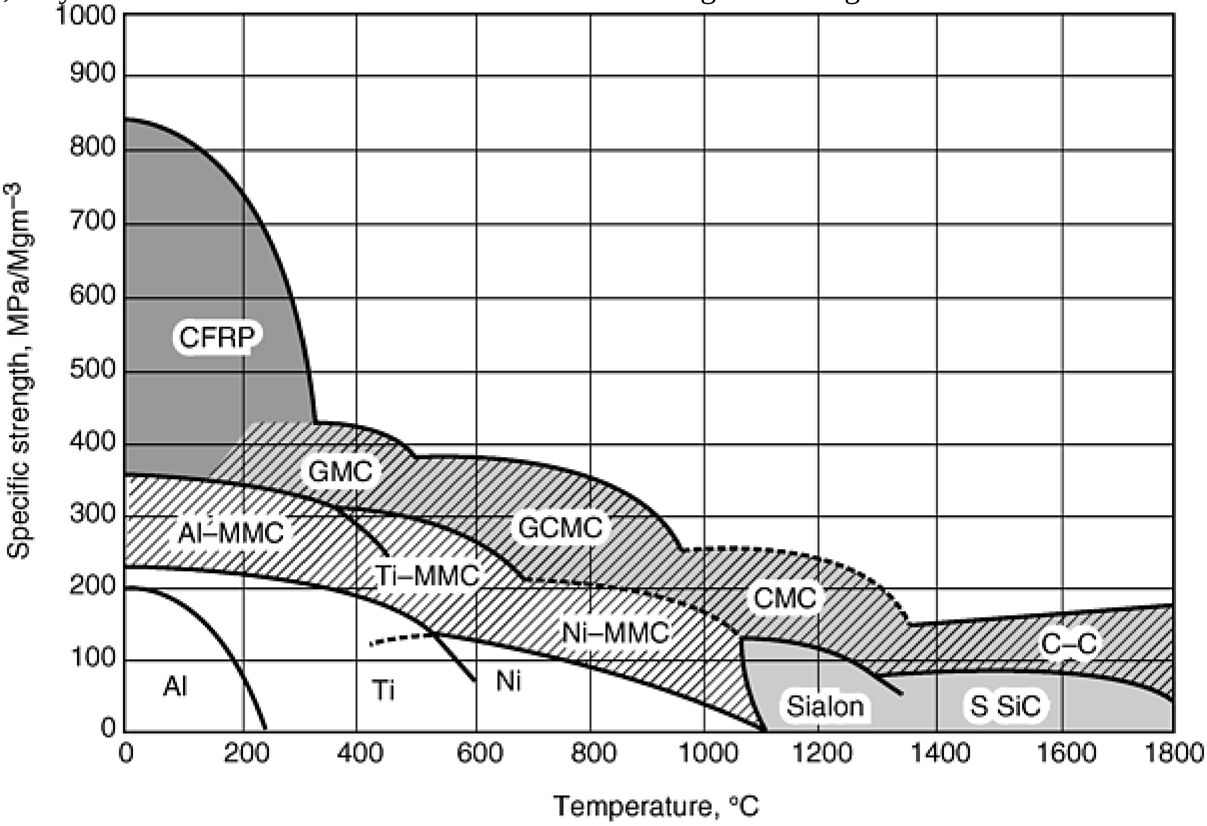

Fig. 1 Specific strength versus temperature. CFRP, carbon fiber reinforced polymers; GMC, glass-matrix composites; GCMC, glass-ceramic-matrix composites; CMC, ceramic-matrix composite; C-C, carbon-carbon composites; MMC, metal-matrix composites

Two types of MMCs are used in wear applications: composites with graphitic-type reinforcements and those with hard ceramic reinforcements. The addition of graphite to the matrix alloys alters the coefficient of friction between the composite and counterface, leading to prolonged wear life during sliding. The addition of hard ceramic particles increases the hardness of the composite, which enhances the resistance of the matrix to the penetration and reduces subsequent removal of material by wear debris and other third-body particles found in the wear environment. It should be emphasized that wear resistance is not a material property, but is a system

response dependent on intrinsic materials properties and extrinsic factors related to the wear environment. Unlike mechanical properties, no single definable material parameter exists to universally quantify wear behavior.

Advancements in casting technologies have resulted in methods of manufacturing reinforced Al-MMCs containing high volume fractions (>40 vol%) of reinforcements. These composites have a coefficient of thermal expansion (CTE) similar to those of integrated circuit materials. Consequently, these types of composites are used as thermal management and support structures for electronic packages (Ref 1, 2, and 3).

This article summarizes the properties of discontinuously reinforced MMCs, laminated metallic composites, and continuously aligned fiber reinforced MMCs.

Properties of Metal-Matrix Composites

David E. Alman, U.S. Department of Energy, Albany Research Center

Discontinuously Reinforced MMCs

Discontinuously reinforced MMCs are much less expensive to fabricate than continuously reinforced composites. Consequently, performance enhancement of the matrix comes at lower additional costs with discontinuous reinforcements compared with aligned reinforcements. Furthermore, the properties of discontinuously reinforced composites are nearly isotropic, whereas the properties of composites with continuous aligned reinforcements are highly anisotropic. Thus, in applications requiring isotropic properties, less expensive, discontinuously reinforced composites can outperform continuous fiber reinforced composites.

Typically, ceramics and graphitic materials are used as reinforcement phases in discontinuously reinforced MMCs. The properties of selected phases used as discontinuous reinforcements for MMCs are listed in Table 1 (Ref 5, 6). Silicon carbide, Al_2O_3, boron carbide (B_4C), and graphite are common reinforcements for aluminum matrices. Titanium carbide (TiC) and titanium boride (TiB) are common reinforcements for titanium alloys. Magnesium matrices are commonly reinforced with SiC, Al_2O_3, and graphite.

Table 1 Properties of selected discontinuous reinforcement materials used for MMCs

Reinforcement	Modulus of elasticity		Fracture toughness		Poisson's ratio	Specific heat,	Thermal conductivity,	Coefficient of thermal expansion,	Density, g/cm^3
	GPa	10^6 psi	MPa $\sqrt{m}$	ksi $\sqrt{in.}$		J/g · °C	W/m · K	10^{-6}/K	
SiC	400	58	4.6	4.2	0.20	0.67	52	4.3	3.20

(b) Theoretical value for graphite; density values for bulk graphite range from 1.3–1.9 g/cm^3.
Source: Ref 5, 6

Properties of Discontinuously Reinforced Aluminum Composites

Discontinuously reinforced Al-MMCs, or DRAs, are the most widely applied commercial MMCs. The incorporation of hard particles strengthens (Fig. 2a) and stiffens (Fig. 2b) the aluminum matrix, but at the expense of ductility (Fig. 2a). The addition of softer graphitic particles decreases both strength and ductility. Al- MMCs components are manufactured using both cast and wrought metallurgical methods.

Cast Composites. Al-MMCs are melted and investment cast into near-net shapes in a manner similar to the techniques used for unreinforced aluminum alloys (Ref 7, 8). Due to the density difference between the reinforcement phase (Table 1) and the aluminum alloy (~2.7 g/cm^3), ceramic particles tend to sink and graphite tends to float in the molten metal. Stirring the melt can prevent separation of the matrix and reinforcement. However, investment-cast composites are limited to about 30 vol% reinforcement without phase segregation. Adding nickel-coated graphite particles can prevent segregation of ceramic phases in the molten aluminum, such as in GrA- Ni alloys developed by Inco Limited (Ref 9). During casting, the Al_2O_3 or SiC reinforcements form clusters with the graphite particles. The more dense ceramic particles prevent the lighter graphite particles from floating in the molten aluminum, and vice versa, the graphite particles prevent the ceramic particles from sinking in the molten aluminum. The result is a uniform mixture of particles in the aluminum matrix. The XD process developed by Martin Marietta (now Lockheed Martin) produces composites having a uniform dispersion of fine reinforcements in situ during melting (Ref 10, 11). In this process, compounding elements (such as titanium and carbon or titanium and boron) are mixed with a solvent metal (Al). During heating of the mixture, the compounding elements exothermically react to form an in situ composite (e.g., Al + TiC or Al + TiB_2). This precursor composite is remelted with pure aluminum or an alloy to form a composite containing the desired volume fraction of reinforcement.

Other casting methods, such as semisolid casting and liquid metal infiltration are also used to produce Al-MMCs (Ref 6, 7, and 8). Semisolid casting methods, such as rheocasting, involve adding the reinforcement to the alloy in a semisolid state. Liquid metal infiltration involves infiltrating a porous preform (the reinforcement) with the molten matrix alloy. The preform can consist of either discontinuous (powders, whiskers, etc.) or continuous (aligned fibers) reinforcements. In processes such as squeeze casting, pressure is applied to the melt to force the liquid into the preform during solidification. Pressureless infiltration of the preform can also be accomplished in vacuum or in a gaseous environment, such as the Primex method developed by Lanxide Corporation. In this process, a ceramic preform (or a mixture of the ceramic with magnesium chips) is infiltrated by an aluminum-magnesium (or aluminum) alloy in a nitrogen (N_2) atmosphere (Ref 11). The magnesium reacts with the N_2 to form magnesium nitride (Mg_3N_2). The formation of these particles enhances the infiltration process, with the particles subsequently reduced by the aluminum to form aluminum nitride (AlN) in the final composite. Composites containing larger volume fractions of reinforcements can be produced more easily using molten-metal infiltration than by using investment casting.

Typical tensile properties for selected cast Al- MMCs are listed in Table 2. Gravity-fed investment-cast composites are commonly used in automotive (e.g., brake rotors, brake calipers, and materials for moving parts in engines) and recreational (e.g., sporting goods) applications. Al- MMCs are particularly attractive materials for use in automotive brake applications because they are lighter and conduct heat three times more efficiently than cast iron (Table 3).

Figure 2(c) illustrates the CTE as a function of volume fraction for the Al-SiC and Al-Al_2O_3 systems. The CTEs of several Al-SiC composites are similar to those of integrated circuit and electronic packaging materials, so these composites are used as heat sinks and structural supports for electronic packages. Al-MMCs are less dense than traditional heat-sink materials, Kovar (Fe-Ni) alloys, for example, which is advantageous in weight-sensitive applications such as avionics. Table 3 lists the mechanical and thermal properties for selected Al-MMCs, as well as properties for several related materials.

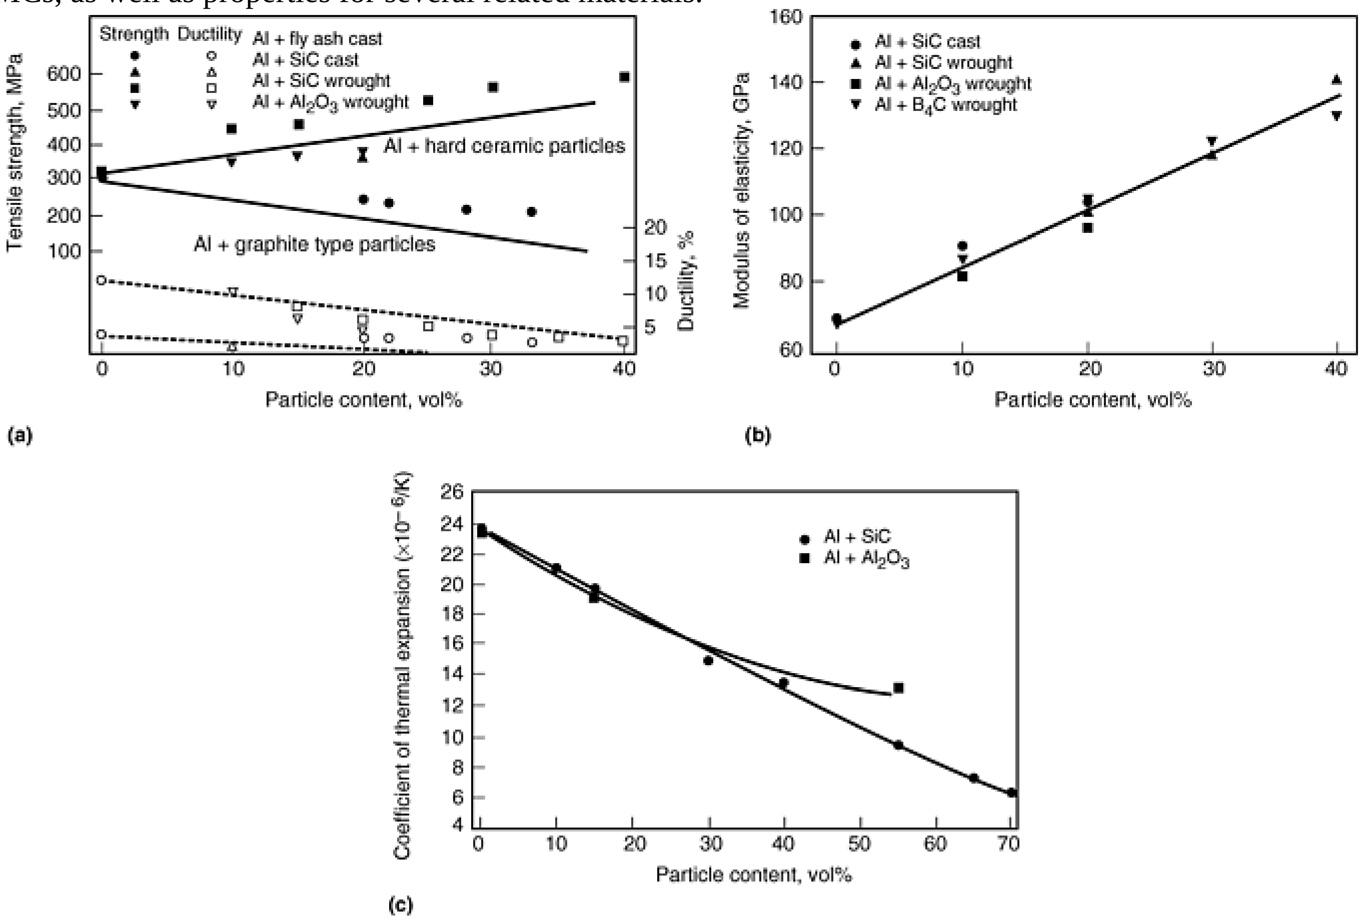

Fig. 2 The effect of particulate concentration on the properties of Al-MMCs. (a) Strength and ductility. (b) Modulus. (c) Coefficient of thermal expansion

The influence of SiC particle size on the tensile properties of squeezed-cast Al-4Mg + 50 vol% silicon carbide particulate (SiC_p) composites is shown in Fig. 3 (Ref 19). Particle size has a strong effect on the failure mode, strength, and ductility of the composite; both strength and ductility decrease with increasing particle size. The fracture process is dominated by metal failure (e.g., few broken SiC particles, Fig. 3b) in composites having small reinforcements (<6.5 μm) and by particle breakage for large reinforcements (>23 μm). The optimal combination of properties occurs in the intermediate-size regime where neither mode of primary failure predominates. A similar trend has been noted for the tensile strength of aluminum alloy 2014-55 vol% Al_2O_3 composites produced via pressure infiltration (Ref 20). The tensile strength decreases with increasing Al_2O_3 particle size (ultimate tensile strengths of 440, 360, and 300 MPa for composites having 5, 12.85, and 29.2 μm Al_2O_3 particles, respectively). The influence of particle size on strength can be rationalized by considering that the strength distribution of the ceramic particle population in the composite follows Weibull statistics. Therefore, larger particles are detrimental to strength as they are more likely to contain flaws and thus fail at a lower stress levels, which reduces the overall strength of the composite.

Wrought Composites. Wrought Al-MMCs typically contain less than 40 vol% reinforcement. These composites are manufactured by preparing a billet or an ingot, which is subsequently forged, rolled, or extruded. The billet can be produced using casting, spray forming, or powder metallurgy (P/M) methods. Extrusions are used as bicycle frames, automotive shafts, and fan exit guide vanes for gas turbines (Ref 21, 22). Sheet products are used in aerospace applications, such as fuel access cover panels and ventral fins for the F16 fighter aircraft (Ref 22). Forgings find applications as chip carriers for electronic packages (Ref 21). Table 4 lists typical properties for selected wrought aluminum alloys reinforced with SiC, B_4C, or Al_2O_3 particles.

Deformation processing breaks the reinforcement into smaller particles, enhances the bond strength between the particle and matrix, and aligns the reinforcement parallel to the direction of material flow. Reinforcement alignment imparts composite texture with respect to the orientation of the reinforcement phase, especially for composites reinforced with whiskers. Table 5 lists the influence of orientation on the properties of several deformation-processed Al-SiC composites. The properties of composites having SiC whiskers are more anisotropic than composites produced with particles. This is due in part to the texture effect, that is, composites having whiskers tend to be stronger than similar matrix composites reinforced with particles. However, this phenomenon is also related to the relative diameters of the whiskers and particles. The diameter of available whiskers are an order of magnitude smaller than the diameter of available SiC particles. Experimental composites produced using either particles or whiskers of similar diameters have nearly identical tensile properties; yield strength (σ_{YS}) is 167 MPa (24 ksi) and ultimate tensile strength (σ_{UTS}) is 299 MPa (43 ksi) for an Al + 20 vol% SiC composite containing 0.5 µm diameter and 2 to 3µm long whiskers compared with σ_{YS} of 172 MPa (25 ksi) and σ_{UTS} of 250 MPa (36 ksi) for an Al + 20 vol% SiC composite containing 0.5 µm diameter

spherical particles (Ref 23). The amount of deformation (extrusion reduction ratio) can influence the properties of the composites. Figure 4 illustrates the influence of extrusion ratio on the properties of 6061/Al_2O_3 particulate composite (Ref 24). Larger extrusion ratios result in stronger composites. This is attributed to the effect that extrusion has on reinforcement particle size (larger reductions result in composites with smaller reinforcements).

Age-Hardened Composites. The properties of any MMC that utilizes a matrix that can be age hardened (e.g., 2*xxx*, 6*xxx*, and 7*xxx* series alloys) will be influenced by subsequent heat treatment (Fig. 5) (Ref 1). The addition of reinforcement particles to aluminum alloy matrix may accelerate aging kinetics as illustrated in Fig. 6 and has been observed to occur in alloys reinforced with SiC, Al_2O_3, and B_4C particles and whiskers (Ref 25). Accelerated aging is due in part to the mismatch between the CTE of the matrix and reinforcement. During cooling, the strain field generated by the CTE mismatch is relaxed in the matrix through the generation of dislocations. These serve as nucleation sites for matrix-strengthening precipitates, and as a consequence the aging process is accelerated compared with unreinforced alloys.

Elevated-Temperature and Creep Properties. Elevated-temperature tensile properties for selected Al-MMC s are listed in Table 6. There have been numerous studies on the creep behavior of Al-SiC, Al-Al_2O_3, Al-TiC, and Al-TiB_2 composites reported in the literature (Ref 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, and 43). As with elevated-temperature strength, the addition of the reinforcement enhances creep life of the composite.

Early onset of tertiary creep occurs during creep testing of Al-MMC in tension and at high stress levels. Little deformation occurs in the composite until severe localized deformation (cavitation) initiates around the reinforcement. Consequently, the minimum strain rate determined in tension at high stress levels does not always correspond to the steady-state secondary strain rate. Tests performed in compression or shear delay the onset of tertiary creep, and thus may provide more accurate values for the steady- state creep parameters.

Powder-processed composites tend to have better creep resistance than cast composites due to the oxides associated with powder matrices (e.g., oxides on the surfaces of the starting aluminum powder), which inhibit dislocation motion (Ref 39). The size of the reinforcement is an important factor in determining creep resistance (Ref 39). Smaller, more numerous reinforcements are more effective in enhancing creep resistance via impeding matrix dislocation motion, stabilizing grain growth, and so forth. The distribution of the reinforcement has a critical effect on creep damage. Clustering of the reinforcement results in severe cavitation near the reinforcement and concomitant rapid failure of the composite. For isolated reinforcements, damage occurs at reinforcement angularities.

Creep in Al-MMCs is unique in several aspects. First, the dependency of the steady-state secondary creep rate on the applied stress, measured by the power-law creep stress exponent, *n*, is high, ranging from 7 to 25. This compares with about 4 for aluminum alloys. Second, the temperature dependence of steady-state creep rate, measured by the creep activation energy, *Q*, is much larger than for self-diffusion in aluminum; *Q* varies from 200 to 500 kJ/mol compared with 146 kJ/mol for aluminum (Ref 27). In these aspects, the creep behavior of Al-MMC resembles that of dispersion-strengthened alloys, where the creep behavior can be explained in terms of a threshold stress (σ_0) for creep. Unlike dispersion-strengthened alloys, where the origin of the threshold stress arises from the interaction of dislocations with a fine dispersion of particles, the origin of the threshold stress for Al-MMCs is complex and is not fully understood. Furthermore, in composites the applied load will be carried by both the matrix and the reinforcement. A modified power-law creep equation for discontinuous composites that incorporates a stress- partition parameter has been proposed, as follows (Ref 36):

$$\dot{\varepsilon} \propto \{(1-\alpha_{LT})(\sigma-\sigma_0)\}^n \exp\left[-\frac{Q}{RT}\right] \quad \text{(Eq 1)}$$

where $\dot{\epsilon}$ is the minimum creep rate, σ is the applied stress, α_{LT} is a stress partition function (experimentally determined for a 6061Al-30 vol% SiC_p as 0.55, 0.48, and 0.45 at 618, 648, and 678 K, respectively, Ref 36), *T* is the temperature, and *R* is the gas constant. (Note: in the original publication, Park and Mohamed (Ref 36) related minimum creep rate in shear strain rate, $\dot{\gamma}$, to shear stress, τ.)

Power-law creep analyses primarily account for deformation occurring through dislocation climb in the matrix. As previously mentioned, damage during creep initiates near the particles. Wakashima et al. (Ref 43) defined a micromechanics-based constitutive equation that incorporates this effect. They describe two components for creep: creep in the matrix and viscous (or diffusional) creep occurring at the matrix-reinforcement interface. The matrix creep rate is given in terms similar to Eq 1, incorporating parameters such as the actual stress carried by the matrix, the threshold stress for power-law creep, volume diffusivity, and matrix dislocation properties (e.g., Burgers vector). The diffusional flow rate is similar in nature to Nabarro-Herring creep and is associated with atomic transport in the matrix around the reinforcement phase, incorporating the stress carried by the reinforcement phase, size of the reinforcement, and parameters related to the mass transport in the vicinity of the interface (e.g., boundary-diffusion coefficient, the effective thickness of the boundary through which diffusive transport occurs, and the volume of diffusing matter). Steady-state creep is established when both components are balanced.

Fracture and Fatigue. The incorporation of discontinuous reinforcements generally decreases the fracture toughness of the matrix (Table 7). Generally, there is a slight tendency for fracture toughness to increase with increasing particle size (Table 8). This can be explained by considering that interparticle spacing increases with particle size and a greater volume of matrix material is available for unconstrained plastic flow in the wake of the propagating crack, resulting in the higher fracture toughness. Improvements in toughness of Al-MMC can be accomplished by producing hybrid laminated metal composites consisting of Al-MMCs and tougher unreinforced alloys (discussed later in this article).

Fatigue and fatigue crack growth studies have been performed on Al-MMCs (Ref 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, and 55). The fatigue life of the matrix can be either improved (Fig. 7) or degraded by the addition of the reinforcement phase, depending on the loading and type of fatigue test (Ref 45, 46, and 47). For stress-controlled fatigue, the composite exhibits a much lower total strain during a fatigue cycle than the unreinforced alloys (Fig. 8a). This is a result of the higher modulus and work-hardening rates of the composite compared with the monolithic matrix, and therefore fatigue life is improved with the incorporation of the reinforcement. Following the same reasoning, under strain-controlled conditions (Fig. 8b), the composite experiences a higher level of stress per cycle than the unreinforced alloy to accumulate a comparable strain level. This accelerates the formation of fatigue damage in the composite, and this degrades fatigue life.

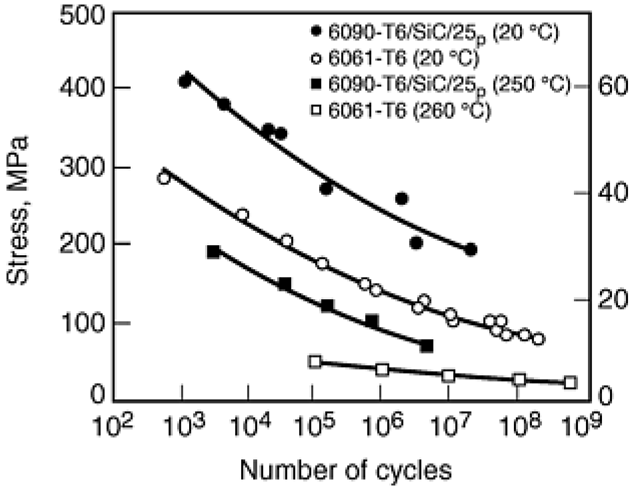

Fig. 7 Comparison of stress-life data for 6069Al and 6069Al + 25 vol% SiC_p. Source: Ref 47

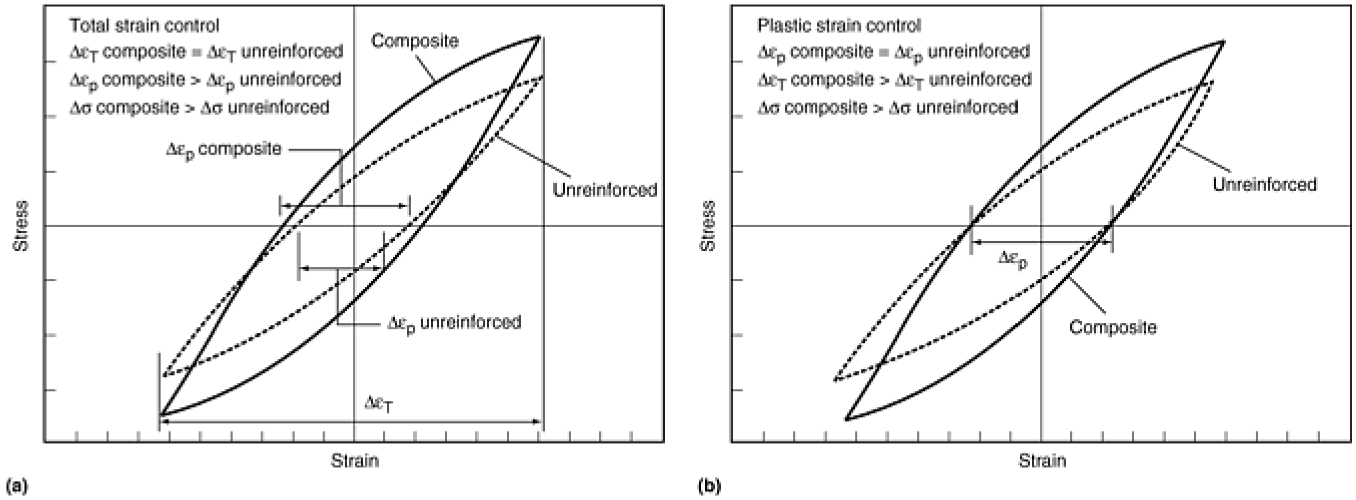

Fig. 8 Cyclic stress-strain loops for a discontinuously reinforced composite compared to unreinforced matrix alloy. (a) Stress-controlled conditions. (b) Strain-controlled conditions. Source: Ref 45

Under stress-controlled fatigue, increasing the volume fraction of the discontinuous phase will increase fatigue life, due to increases in modulus and work-hardening rates. Composites having smaller reinforcements tend to have longer fatigue lives (the fatigue strength at 10^7 cycles (*R*= 1) decreased from about 240 to 200 and 150 MPa (35 to 29, and 22 ksi) for a 2124 Al + 20 vol% SiC particulate composite, as the particle size increased from 2.5, 17.5, and 35 μm) (Ref 45). This behavior has been attributed to the interparticle spacing and fracture behavior of the particles. As mentioned previously, due to the statistical nature of the fracture of the ceramics, large particles have a greater propensity to crack than smaller particles. Thus, these particles are more easily fractured during fatigue, reducing fatigue life. Also for a constant volume fraction, the interparticle spacing decreases with decreasing particle size. Thus, the addition of smaller particles provides for a greater barrier to dislocation motion, which enhances fatigue life.

At low *R* values (under 0.3) Al-MMCs typically have a higher threshold stress intensity (ΔK_{th}) for fatigue crack growth initiation than the matrix alloys (Table 9) (Ref 48). Composites generally possess a steeper Paris region, and the transition to unstable fracture occurs at lower ΔK values (Fig. 9) (Ref 45, 46). This is a direct result of the lower fracture toughness of the composites. Particle morphology and distribution play an important role in fatigue crack growth (Ref 48). Fatigue cracks are attracted to stress concentrators, such as whisker ends, particle corners, and reinforcement clusters. ΔK_{th} tends to increase with increasing volume fraction, which is explained in terms of crack closure concepts. Closure levels appear to be determined by a crack path roughness mechanism, which is dependent on the size, distribution, and volume fraction of reinforcements. For wrought-processed, whisker-reinforced composites, ΔK_{th} is anisotropic, with higher values obtained in the L-T orientation than in T-L orientation. This is also explained in terms of crack closure and roughness mechanisms. A dependency on orientation, reinforcement morphology, and volume fraction of ΔK_{th} at higher *R* (0.7) is not

observed due to the minimal effect of crack deflection and thus the ineffectiveness of closure mechanisms (Ref 48).

Table 9 Tensile, fracture and fatigue crack growth threshold stress intensity data for 2124Al-SiC composites

Reinforcement content, vol%, and form	Rolling direction	Modulus of elasticity		Aging condition	Yield strength		Tensile strength		Elongation, %	ΔK_{th} threshold

Wear and Corrosion. As previously mentioned, wear is not a materials property, but a systems response. Wear behavior is dependent on materials properties and the wear environment. Small changes in environmental conditions can dramatically alter wear behavior, as a result changing the relative ranking of different materials. Thus, interpretation and application of results of wear experiments are difficult and should be made with caution.

Sliding wear is a common form of wear experienced by various automotive engine components (cylinder blocks, pistons, piston insert rings, etc.) that are fabricated from Al-MMCs (Ref 56). Sliding or adhesive wear is defined as the transfer of material from one surface to another during the relative motion of contacting surfaces. The repeated contact of asperities on the surfaces may cause them to be detached from the parent body during sliding. The detached particles, or wear debris, are either temporarily or permanently attached to the other surface. Other wear mechanisms include plastic flow and fracture, both of which can result in excavation and detachment of material. Important parameters that affect wear behavior are the relative hardness of the surfaces and the coefficient of friction between the sliding surfaces. Therefore, wear resistance of an alloy can be improved through the addition of hard particles, which enhances surface hardness, or through addition of softer graphitic-type particles, which alter the coefficient of friction between the surfaces by providing a self-lubricant. Two reviews on sliding wear of Al-MMCs can be found in the literature (Ref 56, 57).

Figure 10(a) illustrates the influence of reinforcement volume fraction on the sliding wear rate (related to material loss) of an Al-SiC MMC worn against a steel counterface (Ref 56). The addition of a small volume fraction of hard particles can significantly reduce the wear rate of the unreinforced aluminum. However, a decrease in the wear rate of the composite can be accompanied by an increase in the wear rate of the counterface. The improvement in wear resistance can be attributed to the hard particles remaining intact when struck by asperities or abrading particles, under conditions such that material would be plowed from the surface of the unreinforced alloy. Thus, high reinforcement strength and strong interfacial bonding are factors that lead to improved wear resistance of MMCs.

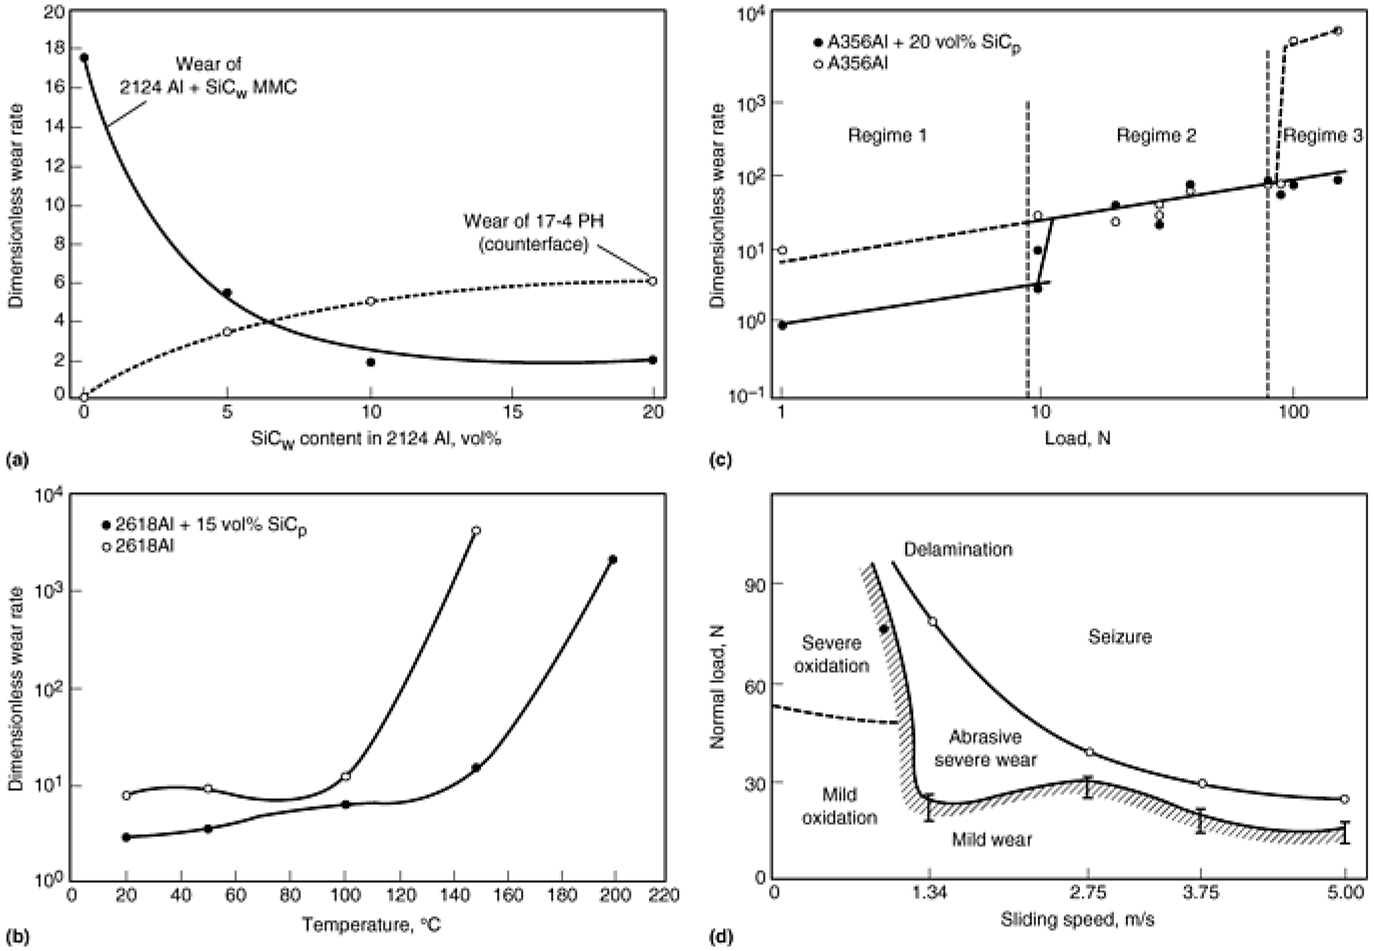

Fig. 10 Sliding wear behavior of Al-SiC MMCs. (a) Effect of SiC content on wear of composite and steel counterface. (b) Effect of temperature of wear rate. (c) Effect of applied load on wear rate. (d) A wear map for Al-SiC composite. After Ref 56, 58

The influence of temperature on the wear rate of an Al-15 vol% SiC composite worn against a steel counterface is shown in Fig. 10(b) (Ref 58). The main effect of the SiC reinforcement on sliding wear at high temperatures is to delay the transition from mild to severe wear by about 50 °C (90 °F). This is attributed to the presence of the SiC particles improving the high-temperature strength of the matrix.

Increasing applied load tends to increase wear rates during sliding (Fig. 10c). At low applied loads (regime I), composites typically are more wear resistant than unreinforced matrix alloys, and material removal occurs through oxidative wear processes. In this wear mechanism, oxide layers form on both sliding surfaces, resulting from the frictional heating associated with sliding. Oxidized asperities become detached from the surface and can be compacted on the countersurface to form a wear film. Wear rates tend to be low, as material removal is confined to the thickness of the oxide reinforcement. At intermediate loads (regime II), the wear mechanism changes from oxidative wear to metallic wear. In this regime, significant subsurface plastic deformation occurs, and when strain exceeds the fracture strain, material is detached from the surface. In this regime, composites have similar wear rates to those of unreinforced alloys. At high loads (regime III), the wear rates of the composite are much lower (typically, two orders of magnitude) than those of the unreinforced matrix alloy. The unreinforced matrix alloy experiences severe wear associated with adhesion and seizure during sliding. Wear maps delineate material removal mechanisms, and thus wear rates, for the wear conditions (applied load and sliding speed) of a specific wear environment. Figure 10(d) shows a wear map for a 6061Al-20 vol% SiC_w composite worn against a steel counterface (Ref 56). It should be noted that while the emphasis of this section is on Al-SiC particles, incorporation of Al_2O_3, B_4C, TiC, and other hard particles into aluminum has similar effects on wear resistance (Ref 56, 59).

Superior sliding resistance is obtained through the addition of softer graphitic-type reinforcements, as illustrated in Fig. 11(a) and (b). During sliding, the graphite reinforcement can become smeared on the surface and function as a lubricant, which decreases the coefficient of friction between the surfaces and extends component

life (Ref 1, 57). However, this effect is very sensitive to the ambient environment, as moisture content in the environment significantly affects the tribological properties of these types of composites.

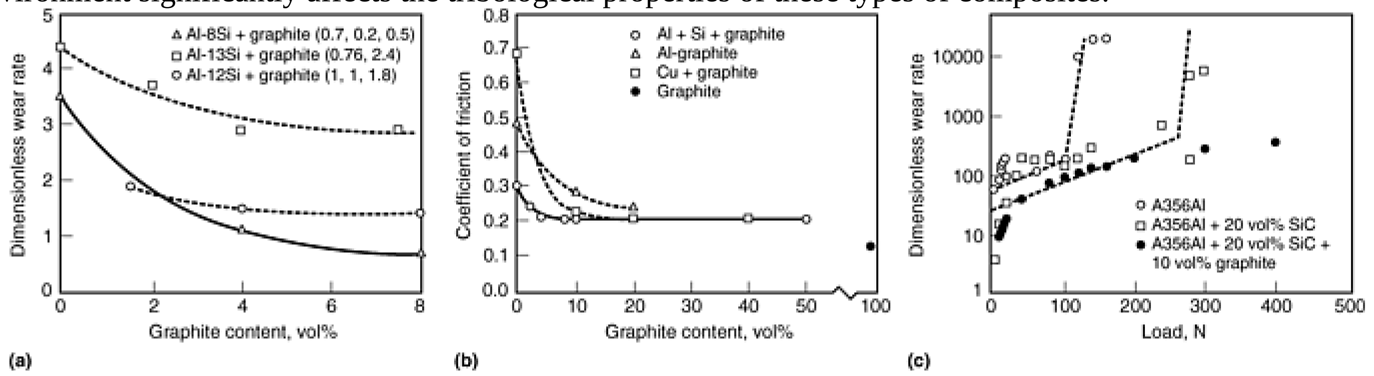

Fig. 11 Sliding wear of Al-graphite MMCs. (a) Wear rate versus graphite content (number in parenthesis in legend correspond to load, sliding speed, and sliding distance). (b) Measured coefficient of friction versus graphite content. (c) Comparison of wear behavior for unreinforced Al, Al + SiC_p, and Al + SiC + graphite composites. Source: Ref 1, 19, 57

Hybrid composites containing both hard and soft phases offer improved sliding resistance, particularly at high applied loads, as shown in Fig. 11(c) (Ref 9). Frictional heating decreases in the hybrid composites as a result of a lower coefficient of friction. This prevents the transition from mild to severe wear for the Al-SiC hybrid composite.

Corrosion of MMCs tends to center on localized corrosion, which arises from galvanic effects between the matrix and reinforcement, crevice corrosion at the interface between the matrix and reinforcement, and pitting reaction at interfacial reaction products (Ref 1). A brief summary of the corrosion behavior in MMCs follows, with more details found in Ref 60.

Galvanic corrosion is driven by the electrode potential difference between the two constituent phases. For Al-MMCs, galvanic effects occur in Al-graphite composites in solutions containing sodium chloride (NaCl), such as seawater, causing severe corrosion. Electrochemical experiments conducted on Al + 3 wt% graphite particulate composites in seawater show that the cathodic curve (hydrogen evolution) is strongly polarized by the presence of graphite, more than doubling the corrosion current density for this reaction for the composite compared with unreinforced aluminum. The corresponding anodic reaction (dissolution of aluminum matrix) proceeds at a higher rate for the composite material compared with the unreinforced alloy (Ref 1).

Galvanic corrosion does not occur in aluminum composites containing Al_2O_3 or SiC particles or whiskers to the extent that it does in graphite reinforced composites (Ref 60). Electrochemical experiments reveal that the corrosion potential does not vary greatly with SiC content. Al-SiC composites, however, are susceptible to localized corrosion at the Al/SiC interface in NaCl and acidic environments. The degree of corrosion increases with increasing SiC content.

Properties of Other Discontinuously Reinforced Composites

Magnesium MMCs containing discontinuous reinforcements can be fabricated via the same methods as Al-MMCs. Magnesium materials are attractive based on density (1.8 g/cm^3) alone. In general, the behavior of Mg-MMCs is very similar to Al-MMCs; that is, the addition of the reinforcement increases the strength and modulus of the matrix. Tensile properties of some of these MMCs are listed in Tables 10 and 11. The same microstructural factors discussed for Al-MMCs also influence the properties of magnesium- based composites. Stress-controlled, high-cycle fatigue behavior of AZ1D-SiC_p composite has been studied (Ref 62), and the fatigue life was very dependent on the size of the SiC_p. The addition of smaller (15 μm) reinforcements provides improved fatigue performance with respect to the unreinforced magnesium alloy. However, the fatigue life of composites containing larger particles (52 μm) is shorter than AZ91D. This behavior is attributed to a larger percentage of cracked SiC_p found both at and beneath the fracture surface of composites containing the larger- sized particles. Like aluminum-graphite composites, magnesium-graphite composites also undergo galvanic corrosion in NaCl solutions (Ref 60).

Titanium is another metal matrix commonly reinforced with discontinuous reinforcements to improve high-temperature strength and wear resistance (Ref 63). The most common reinforcements are TiB and TiC, and composites have been produced via ingot and powder metallurgical methods. Titanium boride particles and whiskers are formed in situ in the melt during alloy preparation (Ref 64, 65, and 66). Titanium boride reinforced composites also are prepared via powder routes (Ref 67, 68 69, and 70), in which TiB_2 is blended with the matrix powder, and the TiB_2 powder reacts with titanium to form TiB during processing. Titanium carbide reinforced composites are commonly produced via blending and consolidation of powders. Titanium carbide particles have also been formed in situ during gas atomization of carbon-modified Ti-6Al-4V alloys (Ref 66).

Room-temperature tensile properties of selected Ti-MMCs are listed in Table 12. As with the Al-MMCs, the incorporation of the ceramic phase increases both strength and modulus of the matrix, but at the expense of ductility. The strengthening effect of the reinforcements is retained at elevated temperatures (Table 13). The addition of TiB particles improves creep resistance (Fig. 12), fatigue resistance (Fig. 13), and wear resistance of the matrix (Fig. 14). The incorporation of TiC also improves wear resistance. Table 14 shows the fracture toughness of a Ti-6Al-4V + 20 vol% TiC particle composite from liquid nitrogen temperature to 750 °C (1380 °F).

Intermetallics. Alloys based on intermetallic compounds are an emerging new class of materials. In general, intermetallic compounds are characterized by having high strengths, low densities, high melting points, and good resistance to oxidation and corrosion. Unfortunately, these compounds tend to be brittle because they possess ordered crystal structures, like ceramics, which hinders easy dislocation motion. This has limited the engineering application of these compounds as oxidation-resistant coatings. Like ferritic steels, these compounds undergo a brittle to ductile transition at elevated temperature, but tend to have poor creep resistance above this transition temperature. Composite strengthening has been used to improve both toughness and elevated-temperature strength of these alloys. Discontinuous reinforcements can be added to improve strength and creep resistance. Table 15 shows tensile properties for titanium aluminide (TiAl) and nickel aluminide (NiAl) matrices reinforced by TiB_2 particles (Ref 73, 74, 75, 76, 77, 78, 79, and 80). The addition of particles not only strengthens the matrices at room and elevated temperatures, but also improves creep resistance, as shown in Fig. 15 for NiAl + TiB_2 composites (Ref 75, 79). XD-TiAl reinforced with <1 vol% TiB_2 particles is of specific interest because the particles refine the grain size of the TiAl matrix, which is beneficial for a variety of TiAl mechanical properties (Ref 80). NiAl-base composites may find use in applications where wear resistance is required, such as barrels for extruders for the processing of food, plastics, chemicals, and pharmaceuticals (Ref 81). The addition of TiB_2 particles is effective in improving wear resistance, as shown in Fig. 16 (Ref 82). The particles can, however, have a detrimental effect on oxidation resistance of the matrix.

Tests on NiAl-TiB_2 composites exposed to an oxidizing environment at between 800 and 1200 °C (1470 and 2190 °F), show that TiB_2 particles located on the surface tend to selectively oxidize, thereby reducing the oxidation resistance of the matrix. Composites with smaller TiB_2 particles are more oxidation resistant than similar composites containing larger particles (Ref 83).

Properties of Metal-Matrix Composites

David E. Alman, U.S. Department of Energy, Albany Research Center

Hybrid Laminated Metal and Ductile Phase Composites

Laminated metal composites (LMCs) consist of bonded alternating metal layers that have very distinct, or sharp, interfaces (Ref 84). The composites differ from functional gradient materials, which also can consist of alternating layers having less distinct, or diffuse, interfaces. Laminated metal-metal composites are produced via diffusion bonding or deformation bonding (roll bonding, coextrusion, etc.). A variety of layered composites have been produced including discontinuous reinforced aluminum (DRA) with unreinforced aluminum, ultrahigh-carbon steel (UHCS) with mild steel, and UHCS with brass (Ref 85, 86, 87, 88, 89, and 90). These types of composites are easily engineered by altering processing history and layer thickness to produce composites having prescribed properties (Ref 84).

Laminated metal composites can dramatically improve many properties including fracture toughness, fatigue, and impact behavior of an otherwise brittle material. As illustrated in Fig. 17(a), the Charpy-V notch behavior of UHCS/ mild steel laminate composite is superior to both constituent alloys. The composites were tested with the interface between the layers oriented perpendicular to the direction of crack propagation—in a crack arrester mode. Extensive delamination between the layers of the composite occurred during fracture. The added energy required for delamination results in the improvement in toughness. The strength of the interface is paramount in determining toughness of the composite. Sharp (chemically weak) interfaces promote toughness in these types of composites. When the UHCS/mild steel composite is heat treated to produce a stronger

chemical bond between the layers, the impact properties of the composite are degraded (Fig. 17b). More detailed information regarding these composites can be found in Ref 84.

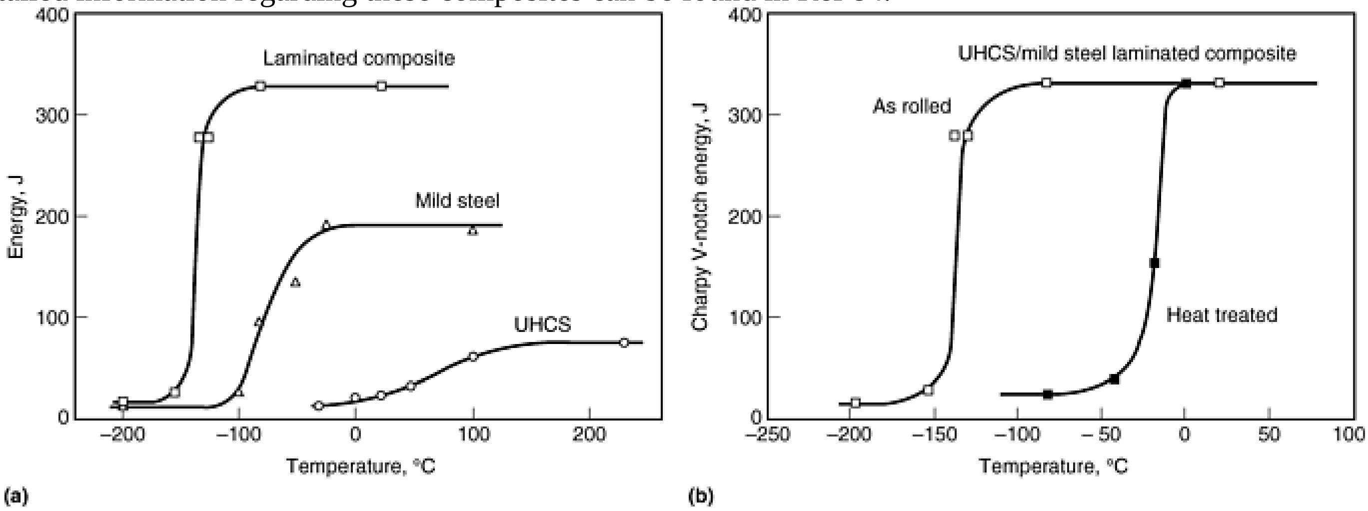

Fig. 17 Charpy V-notch impact energy versus test temperature. (a) Laminated ultrahigh carbon steel (UHCS)/mild steel composite compared to constituent alloys. (b) Effect of interface condition on impact behavior of UHCS/mild steel laminated composite (heat treating produced a strong interface between layer, as-rolled produced a weak interface between layers). Source: Ref 85

A variety of DRA-Al laminates have also been produced. Figure 18 illustrates the fracture toughness versus global SiC content of these composites (Ref 90). The laminate composites have higher fracture toughnesses than comparable base-particulate reinforced composites. The microstructure of these composites does not have to consist of laminates. For example, Microstructural Toughened composites (United Technologies) use tubular reinforcements instead of layers, and composites consisting of DRA with aluminum alloy tubes (Ref 86), DRA with commercially pure (CP) titanium tubes (Ref 86), and NiAl + B_4C with stainless steel tubes have been produced (Ref 87, 88). Another simpler method of producing these composites is by coextruding a mixture of the DRA powder blend with very large particles (e.g., 0.3 and 10 mm) of the unreinforced aluminum alloy. Note that the particle size of the unreinforced alloy is significantly larger than the size of powders that comprise the DRA blend (Ref 90). An advantage of this approach is that the properties of the composites are much more isotropic than those of laminate or Microstructural Toughened composites. These composites should also be less expensive to fabricate, as this method requires fewer manufacturing steps. The room-temperature tensile properties of these composites are listed in Table 16.

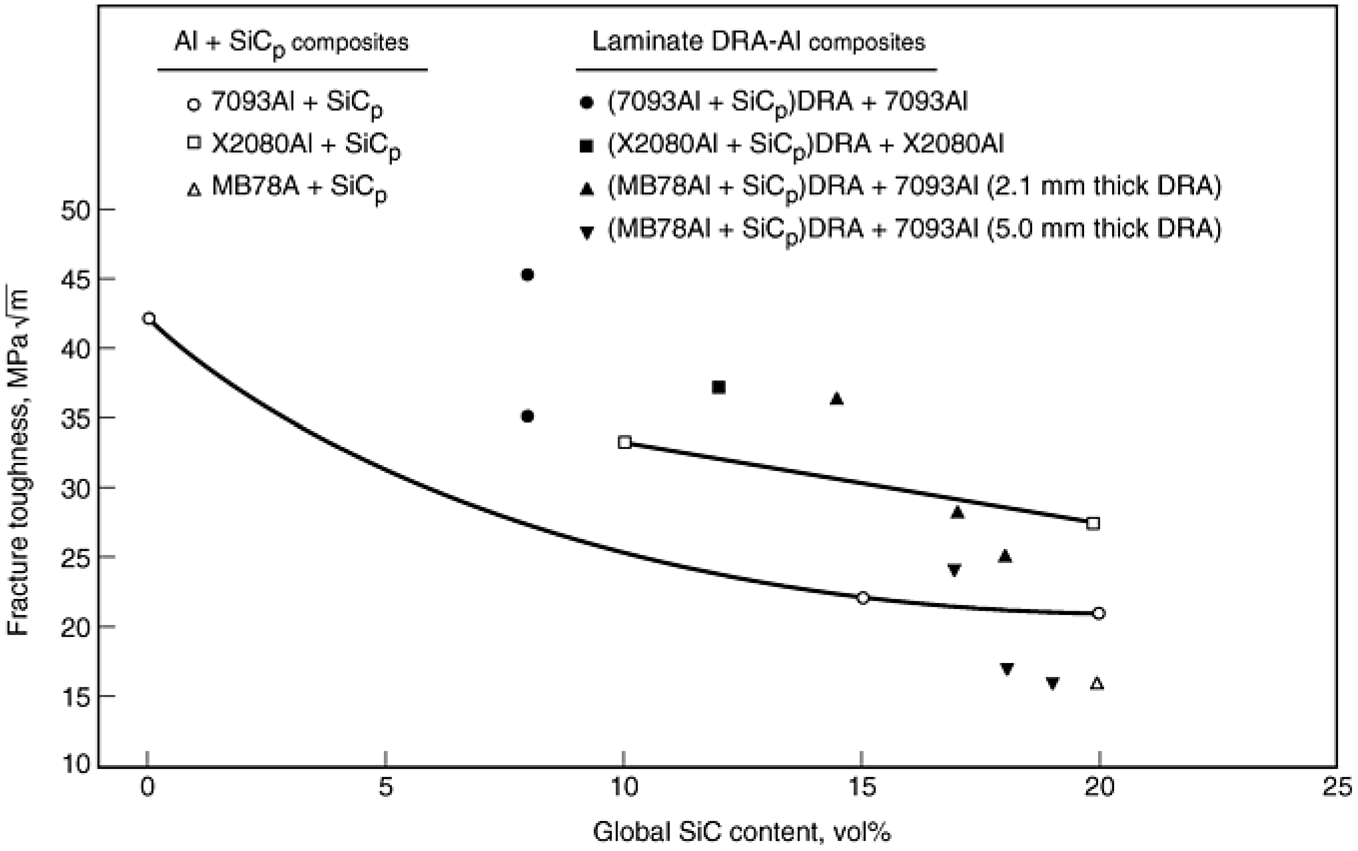

Fig. 18 Fracture toughness as a function of SiC_p concentration for particulate and laminated discontinuously reinforced aluminum (DRA) composites. After Ref 89

Ductile phase-toughened intermetallics are closely related to laminated composites. These composites combine a brittle matrix, such as a ceramic or intermetallic compound, with a ductile metallic alloy in the form of particles, fibers (wires), or layers. The fracture resistance of the matrix is enhanced by:

- Ductile rupture of the metallic phase at the tip of a crack propagating through the matrix
- Bridging of the crack by the ductile phase
- Deflection of the crack by the ductile phase

The degree to which these mechanisms are operational is dependent on the morphology (particles, fibers, etc.) of the metallic phase and the bond strength between the phases incorporated into the matrix. Both artificial and in situ composites have been produced, and a compilation of fracture toughness values for numerous ductile phase-toughened composites can be found in Ref 91. The in situ eutectic composites are particularly attractive because they are more readily fabricated than artificial composites and the microstructure (e.g., volume fractions) can easily be modified through adjusting the alloy composition (Ref 92, 93, 94, 95 , and 96). Nb/Nb_5Si_3-type in situ composites based on Nb-Si-Ti alloys appear to be ideally suited for use in high-temperature applications, because they have both elevated-temperature oxidation resistance and low-temperature fracture toughness (Ref 95, 96), as illustrated in Fig. 19.

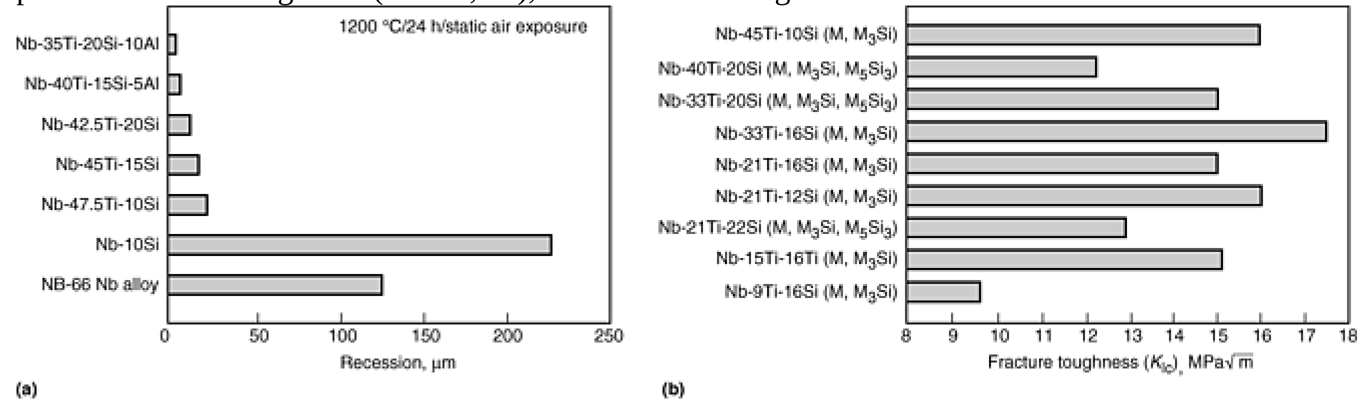

Fig. 19 (a) Oxidation and (b) fracture toughness of selected metal (M)-metal-silicide (M_3Si, M_5Si_3) in situ composites based on Nb-Ti-Si. After Ref 95, 96

Metal-polymer composites, such as GLARE (Akzo) and ARALL (Alcoa), consist of alternating layers of high-strength aluminum and fiber reinforced epoxy adhesives (Ref 97). ARALL composites consist of adhesive prepregs of 50 vol% high-modulus aramid fibers. GLARE composites consist of an adhesive prepreg consisting of 60 vol% high-strength glass fibers either uniaxially or biaxially oriented. Because the glass fiber is stronger than aramid fiber, GLARE laminates are stronger in a cross-ply lay-up in both L and LT orientation compared with ARALL laminates (Table 17). The principal benefit of these composites is the ability to impede and self-arrest fatigue cracks. In monolithic aluminum sheet, fatigue cracks can grow until the metal panel fails. In the layered composites, the fatigue crack only develops in the aluminum layer or layers. The fibers remain intact due to their high strength and toughness. As the crack grows, fibers bridging the crack carry an increasing portion of the load, decreasing the stress intensity at the crack tip and, consequently, arresting further crack growth. In addition to the superior crack growth properties, GLARE and ARALL composites are lighter and more damage tolerant than 2024-T3 Al sheet. A high-temperature version of these composites consists of

titanium, carbon fibers, and a thermoplastic resin (Ref 98). More details on these composites can be found in Ref 97.

Table 17 Properties of metal-polymer laminate composites

Continuous Fiber Reinforced Composites

Continuously aligned, fiber reinforced metal- matrix composites are used primarily in aerospace structural applications requiring high stiffness and strength (Ref 99). Common composite matrices reinforced with continuous fibers are aluminum, magnesium, copper, titanium and titanium aluminide (Ti_3Al-α_2 and Ti_2AlNb-orthorhombic) compounds. Common commercial fibers are SiC, Al_2O_3 and carbon, or graphite. Al_2O_3, SiC, carbon, or graphite fibers are used to reinforce aluminum matrices, Al_2O_3 and graphite are used in magnesium matrices, and SiC is used in titanium matrices. Potential aerospace applications for Ti-MMCs include compressor disks, blades, shafts, and casings. Weight savings of up to 40% are possible in using Ti- MMCs over conventional titanium alloys (Ref 99). Al-MMCs are being developed for use in two main aerospace applications, net-shaped castings, and simple shapes (such as I-beams and T-sections) for structural supports (Ref 99).

Emphasis in this article is on aluminum-, magnesium-, and titanium-matrix composites. Discussion of other aligned fibrous metal-matrix composites is not possible due to space limitations. However, other fiber reinforced metal-matrix composites systems that have been studied include intermetallics reinforced with Al_2O_3 fibers and superalloys with refractory metal wires. Detailed information regarding the properties of these other composites can be found in Ref 100 and 101, respectively.

Aligned fibrous composites are produced using solid-state methods; various fabrication methods have been developed with the objective of producing high-quality and cost-effective components. Titanium-matrix composites are commonly produced by diffusion bonding of matrix foils and fiber tapes (foil-fiber-foil method), plasma spraying fiber tapes with the matrix, and coating the fiber by physical vapor deposition (PVD) with the matrix.

The foil-fiber-foil method consists of the consolidation through diffusion bonding of alternately stacked layers of alloy foil (80–120 μm) and a fiber mat made of aligned monofilament. The fiber mat is produced by weaving the fibers together into a ribbon, or they are held in place using a fugitive organic binder that is outgassed in the final consolidation step. A major disadvantage of this method is that the fibers tend to be poorly distributed, and they touch each other, both of which have a detrimental effect on mechanical properties. Also, this technique can only be applied to matrices that are easily formed into thin foils. Powder cloths can be used for matrices that are not readily formed into foils.

Vacuum plasma spray is used to manufacture Ti-MMCs monotapes. Metallic powders are introduced into a plasma where they are melted and propelled at high velocity onto a single layer of fibers wound on a drum. The monotapes are subsequently cut, stacked, and hot pressed to form the composite. Typically, fiber distribution is superior in plasma spray composites than in foil-fiber-foil composites. However, the quality of the monotapes depends on the impurities associated with the powders. The PVD process consists of coating the fiber with a thick layer of matrix material by means of sputtering or electron beam deposition. The volume fraction of fibers in the matrix is controlled through the thickness of matrix coating. The coated fibers are then laid up and hot pressed to produce the composite. The main advantage of this technique is achieving a very uniform fiber distribution with no touching fibers.

Aluminum and magnesium composites can be fabricated using the methods described above and through the molten-metal infiltration of fiber preforms, as previously described. Two major advantages of the infiltration method are that near-net-shape components can be cast, and complex preforms (e.g., three-dimensional fiber weaves) can be used to produce composites having unique reinforcement architectures. Table 18 shows the influence of reinforcement architecture on the properties of selected Al-MMCs (Ref 17).

The addition of fibers improves the axial, or longitudinal (0° orientation; fibers aligned parallel to the tensile axis), stiffness of the matrix by a factor of 3. In this orientation, the composites take on the properties of the reinforcement, and the composites are an order of magnitude stronger than the unreinforced matrix. The composites retain their strength and stiffness at elevated temperatures, relative to the unreinforced matrices, as illustrated in Fig. 20. As loads rotate off-axis, the properties fall quickly once the direction of the fibers and the direction of the loads differ. Typically, transverse strengths (90° orientation; fibers perpendicular to the tensile axis) are about 10% of the longitudinal strengths. Higher transverse strength can be obtained by the use of cross-ply laminates.

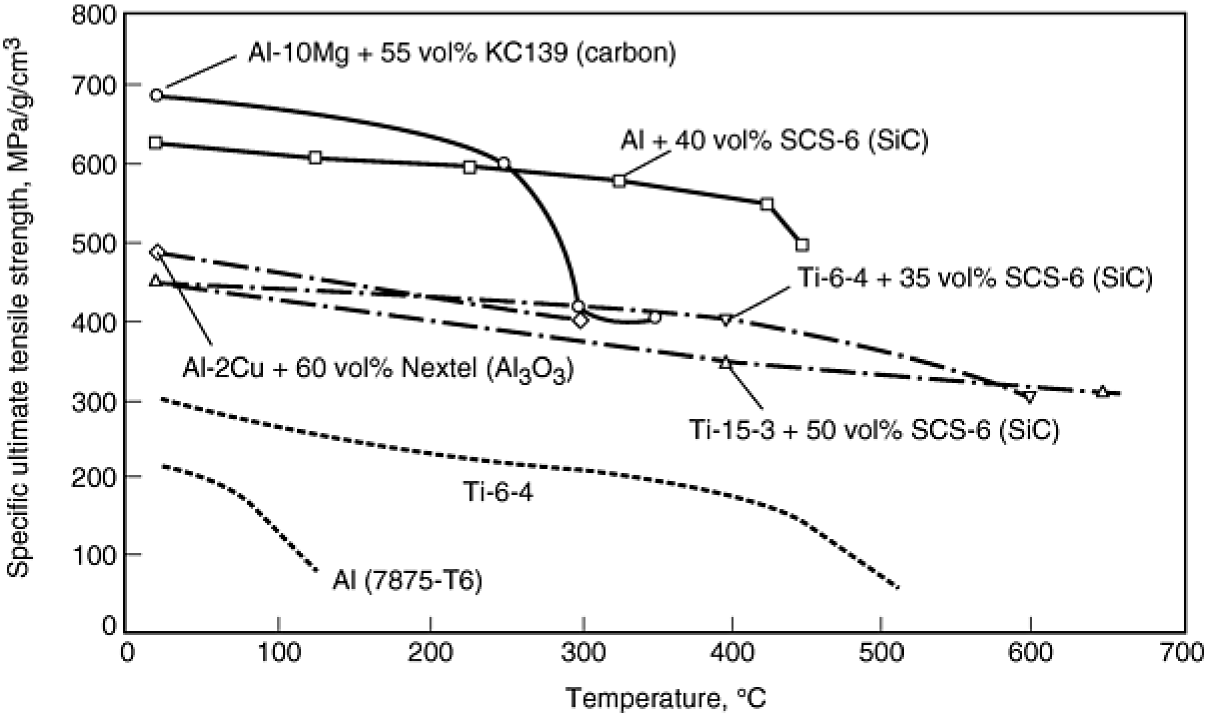

Fig. 20 Specific strength versus temperature for unidirectional fiber reinforced MMCs. After Ref 2 and 99

Interfacial properties have a pronounced effect on the mechanical behavior of the composites. Strong interfaces lead to moderate longitudinal strengths and good transverse strengths, while weak interfaces produce high longitudinal strengths, close to those predicted by the rule of mixtures, but with reduced transverse strengths. As discussed in the section "Creep and Fatigue," weak interfaces also improve fracture resistance and fatigue life.

Figure 21 illustrates the effect of fiber coatings on the longitudinal properties of Al-MMCs containing Al_2O_3 and carbon fibers. In the absence of a coating, both Al_2O_3 and carbon fibers form a strong bond with the matrix; carbon fibers react with aluminum to form an Al_4C_3 interfacial layer during molten metal processing. In principle, if the matrix yield stress is sufficiently low (e.g., such as for aluminum and Al-2Cu alloys), then shearing of the matrix in the vicinity of the fibers can occur, functioning as a weak interface. With stronger alloys, such as 6061, coatings can be applied to the surface of the fibers to promote a weak interface. For Al_2O_3 fibers, a C/TiB_2 duplex coating has been developed, and for carbon fibers, the deposition of a pyrolytic carbon coating can serve as a diffusion barrier (Ref 99, 109, and 110).

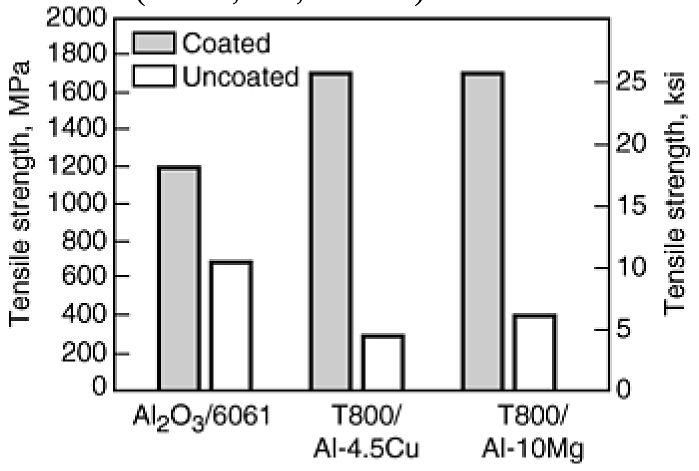

Fig. 21 Influence of fiber coatings on longitudinal tensile strengths of Al-MMCs at room temperature. C + TiB_2 coating on Al_2O_3 fiber, carbon coating on T800 carbon fiber. After Ref 99

For Ti-SiC composites, the longitudinal tensile properties are consistent with simple models in which the strength is dominated by the bundle properties of the fibers (Ref 111, 112, and 113). All other properties are

strongly dependent on interfacial properties of the composites. For composites having relatively weak interfaces (i.e, Ti-15-3 containing carbon-coated SCS-6 fibers), fiber debonding occurs readily via mode I and mode II fracture modes, and frictional sliding occurs at the debonded interface (Ref 111, 112, and 113). The sliding can be influenced by normal compression at the interface, suggestive of the Coulomb friction law (Ref 112). These interfacial features cause the composite flow strength in both transverse tension and shear to be appreciably lower than the matrix flow stress (Ref 112). Exposure at elevated temperatures can alter the interfacial properties and degrade the strength and stiffness of the composite (Ref 106, 111).

Thermal Properties. Graphite fibers have a negative coefficient of thermal expansion. Composites having unique thermal expansion and thermal conductivity properties (Table 25) can be produced by combining these fibers with aluminum and copper matrices (Ref 3). Composites can be designed to have a CTE of nearly zero, which is attractive for use in space applications in an environment where the temperature can vary by hundreds of degrees. These composites also have high thermal conductivities, and, as with particulate composites discussed previously, are being used in thermal management applications in electronic devices.

Table 25 Thermal properties of Al- and Cu-MMCs reinforced with graphite fibers

Composite	**Fiber content, vol%**	**Density, g/cm^3**	**Axial thermal conductivity, W/m · K**	Coefficient of thermal expansion, 10^{-6}/K

Creep and Fatigue. Creep rupture data for selected Ti-SCS-6 composites are listed in Table 26 (Ref 103, 114). Continuous fiber reinforced composites are expected to exhibit greater creep resistance than particulate or short fiber composites. However, as with strength and stiffness, the creep rate of a composite can be quite anisotropic (Fig. 22). Creep rates tend to be very low when loaded parallel to the fibers. Under transverse loadings, creep rates tend to be quite rapid, especially if the specimen is also exposed to thermal cycling. Research suggests that creep life is reduced when interfacial sliding occurs; thus, composites having strong fiber/matrix interfaces are desired for creep resistance (Ref 115, 116).

(b) Ref 109

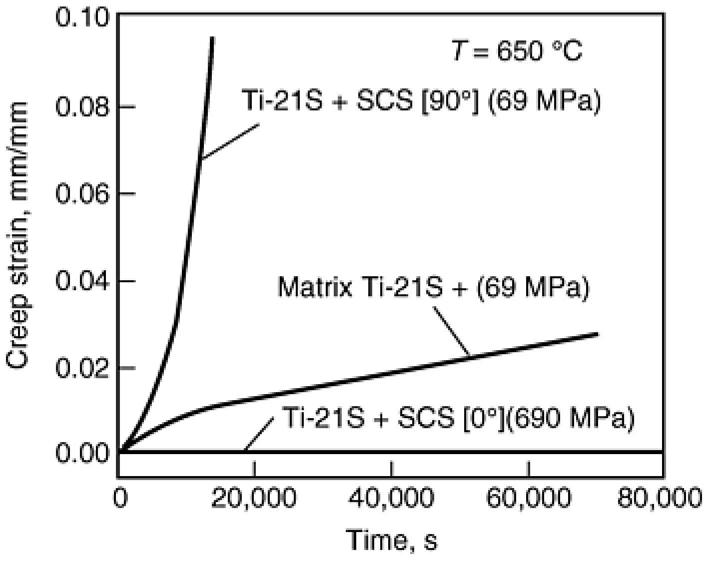

Fig. 22 Comparison of creep behavior of Ti- 21S+SCS6 fibers loaded parallel [0°] and [90°] to fibers with unreinforced matrix. Temperature, 650 °C (1200 °F). After Ref 111

Under parallel loading conditions, the fibers carry most of the applied load; therefore, the creep rate of the composite is dependent on the creep characteristics of the fiber. In this case, the fiber deforms elastically, and the overall creep strain of the composite (ϵ_c) rises asymptotically (Fig. 22) from an instantaneous value ($\epsilon_{t=0}$) to a maximum value (ϵ_{max}). The creep strain (ϵ_c) of the composite at any given time (t) can be given by a power law model (Ref 1):

$$\frac{1}{(\varepsilon_{\max} - \varepsilon_c)^{n-1}} - \frac{1}{(\varepsilon_{\max} - \varepsilon_{t=0})^{n-1}} = \frac{AE_M(1-f)}{E_c} \times \left(\frac{fE_f}{1-f}\right)^n t \qquad \text{(Eq 2)}$$

where the matrix creep rate is given by $A\sigma^n$, $(\epsilon_{t=0}) = \sigma/E_c$, and $\epsilon_{max} = \sigma/E_f$. E_c, E_M, and E_f are the modulus of the composite, matrix, and fiber, respectively, f is the volume fraction, σ is the applied load, and A and n are constants.

Fatigue life and fracture resistance are important parameters when considering aerospace engine applications—even more important than strength and stiffness. Therefore, considerable effort has been devoted to understanding the fatigue behavior of MMCs, particularly for Ti- MMCs. The following summary attempts to highlight salient features of the fatigue behavior of MMCs. Considerably more detail can be found by examining Ref 117, 118, 119, 120, 121, 122, 123, 124, 125, 126 127, 128, 129, 130, 131, 132, and 133.

The mechanisms of fatigue failure have been summarized in Ref 120, 124, 127, 131, 132, 133, 134 and 135. The effect of both *R* ratio and volume fraction of fibers on fatigue behavior have been studied (Ref 128, 129), and the fatigue of Ti-SiC cross plies (Ref 126, 130) and hybrid Ti-SiC- TiAl composites have been evaluated (Ref 124). Fatigue life of unnotched MMCs laminates is a function of the stress/strain range in the 0° fibers. At high peak stress levels, the fibers fail ahead of the crack tip and fatigue life is relatively short. The growth of the fatigue crack is dominated by the properties of the matrix, with minimal contribution from fiber pullout. Prior to catastrophic failure, a plastic strip forms ahead of the crack, similar to what is observed in ductile metals. In this region, all of the fibers break prior to final fracture. Typically, under these conditions, referred to as regime 1, the fatigue life of the composite is lower than the fatigue life of the unreinforced matrix. At low peak stress levels (regime 3), fatigue life is long (i.e., near the endurance limit) and damage is initiated in the matrix. Matrix cracks can grow past the fibers, leaving the fibers intact in the wake of the crack. Continued cycling is accommodated by debonding and sliding along the fiber/matrix interface. The bridging fibers exert closing traction forces on the crack faces, reducing the crack tip stress intensity range and rate of fatigue crack growth. Below a threshold stress level, the stress borne by a bridging fiber is less than the strength of the fibers. Consequently the fibers never break, and a steady-state fatigue crack growth rate is reached and is independent of crack length. Under these loading conditions the fatigue life of the composite is relatively long and is superior compared with the unreinforced matrix. Above the threshold stress level (regime 2) at intermediate peak stress levels, the fibers begin to break when the crack reaches a critical length, which is dependent on fiber strength and crack dimensions. Subsequently, the composite fractures. In this regime, the composites have similar characteristics to monolithic materials in that there is a power-law-type relationship between the stress range and fatigue life.

Substantial crack growth in the matrix can occur without unstable failure, as the fibers bridge matrix cracks. The bridged fibers can drastically improve fatigue crack growth (FCG) properties and can even result in crack arrest. Because the crack propagates through the matrix, FCG rates of the composite correlate with FCG rates in the unreinforced matrix alloy, provided that the driving force for crack growth in the matrix is corrected for the reduced stress intensity at the crack tip due to the fibers bridging. Because fiber debonding plays an important role in FCG, the strength of the interface is an important parameter in governing FCG behavior (Ref 121, 125). Generally, composites having weaker interfaces can significantly enhance FCG behavior. However, substantial fatigue resistance can also be achieved with strong interfaces (Ref 125). This is important because use of Ti-MMCs in aeroengine applications will require improvements in transverse properties.

Typically, exposure to oxidizing environments tends to decrease fatigue life of Ti-SiC composites, under conditions in which matrix cracking is the dominant failure mode (regimes 2 and 3) (Ref 123, 132). For Ti_3Al-SiC, oxidizing atmospheres can reduce the fatigue life by an order of magnitude compared with that in inert environments (Ref 132). Likewise, for a Ti-SiC composites, samples tested in inert environments had twice the fatigue life compared with that of similar samples tested in oxidizing atmospheres (Ref 123). Under fatigue conditions in which the fatigue failure is dominated by fiber fracture (regime 1), environment has little effect on fatigue life.

Fatigue life in MMCs can be complicated by combining thermal cycling with mechanical fatigue (thermal mechanical fatigue, or TMF). Fatigue life is prolonged when the temperature cycling is in phase with the mechanical cycling (i.e., maximum temperature level coincides with the maximum stress level) as opposed to

out of phase (i.e., maximum temperature level coincides with minimum stress level), as shown in Fig. 23 (Ref 121).

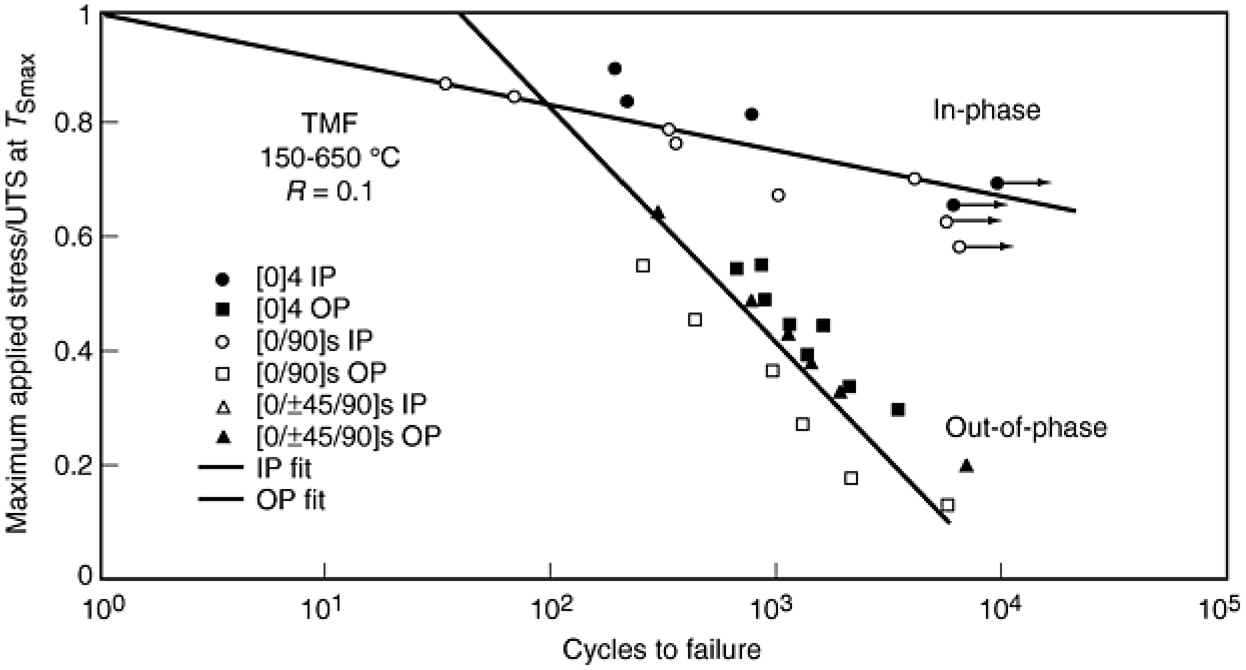

Fig. 23 Thermomechanical fatigue life for SCS-6/Ti-21S composites, normalized for maximum applied stress basis. Source: Ref 120

The corrosion resistance of fiber reinforced composites is different from that of particulate reinforced composites because of the interfacial coating applied to many fibers. Also, many fibers are not pure materials. For instance, SCS-type SiC fibers are produced by depositing SiC around a carbon core. Also, these fibers commonly have carbon layer on their surfaces. The core and any interfacial coating alter the electrical properties relative to the pure phase. Thus, galvanic corrosion can occur in Al-SCS fibrous composites in environments where such corrosion does not normally occur in Al-SiC particulate composites. Furthermore, the interfacial region can become a region for localized corrosion. Similarly, with Al_2O_3 fibers, interfacial reaction phases can preferentially corrode.

As mentioned previously, Al-graphite particulate composites are susceptible to severe galvanic corrosion. The same is true for fibrous reinforced composites. Al-graphite fiber composites swell upon exposure to chloride-containing environments; corrosion products penetrate deep into the subcutaneous layers of the composite. Al-graphite fiber MMCs are also susceptible to exfoliation, with debonding along the fiber/matrix interface due to localized corrosion at the interface. Furthermore, aluminum and graphite can react during processing to form an Al_4C_3 reaction layer. In the presence of moist or humid environments, Al_4C_3 hydrolyzes, producing methane and aluminum hydroxide. Al-graphite composites readily decompose in water.

Methods evaluated to prevent the corrosion of Al-graphite composites include cathodic protection, use of protective coating, and electrical decoupling. Normal cathodic protection methods that are generally applied to prevent galvanic corrosion in unreinforced aluminum alloys are unsuitable for Al-graphite MMCs. Overprotection occurs, and corrosion rates actually increase because of alkalization of the cathode surface. The effectiveness of coatings on surfaces of the bulk composites is related to the integrity of the applied coatings. Corrosion rates follow the corrosion rate of the unreinforced alloy until the coating is breached, exposing the underlying Al- graphite MMC. Electrically decoupling of the graphite fiber from the aluminum matrix through the deposition of insulating coating of the fibers, as well as the deposition of metallic (nickel) interlayers to alter the coupling behavior have also been examined to improve the corrosion resistance of Al-graphite composites. Greater detail can be found in Ref 60.

Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites

Cynthia Powell Doğan, U.S. Department of Energy, Albany Research Center

Introduction

TECHNOLOGY has made giant strides in recent decades so that when engineers today apply their ideas they frequently are limited only by the materials that are readily available at a reasonable cost. After centuries of wondering “What can I make with this kind of material?” scientists and engineers have reached the point of asking “What kind of materials need to be developed in order to advance this technology?” The answer to this question is often a composite material, in which the performance requirements of the specific application are engineered into the component by combining materials of different characteristics. Composites can be made of ceramics, metals, intermetallics, polymers, or some combination of these materials. For most ceramic-matrix composites (CMCs), the driving force for taking the composites approach is to enhance the mechanical reliability of a traditionally brittle material, while retaining such properties as low density, high hardness, high strength, high stiffness, thermal stability, corrosion resistance, and wear resistance.

The current interest in ceramic-matrix and carbon-carbon (C-C) composites derives primarily from the need for materials that can operate reliably at very high temperatures in harsh environments. The need for high-temperature materials spans the range of industries, from aerospace to pulp and paper, and is often driven by the desire to increase energy efficiency and/or reduce emissions. Current metals-based technology can produce materials that are stable to 1000 °C (1830 °F), and superalloys can be utilized to slightly higher temperatures if thermal barrier coatings and cooling systems are included. However, further technological advances in the high-temperature arena will probably not come from the use of metallic materials. Components produced from ceramic-based materials can operate at temperatures that are hundreds of degrees above the melting point of superalloys. Carbon- base components are stable to temperatures approaching 3000 °C (5430 °F). Clearly the next step is to fully exploit the high-temperature capabilities of these materials. Ceramic-matrix and carbon-carbon composite technology is one way to do so.

Ceramic-matrix composites can be broadly classified into three types: discontinuously reinforced ceramic-matrix composites (DR-CMCs), continuous fiber ceramic composites (CFCCs), and carbon-carbon composites. In the following sections, the mechanisms for enhancing the reliability of each type of composite is discussed, along with examples of the mechanical and physical properties, and the current limitations of the materials. Examples of the properties of commercially available materials are provided where available. Because the mechanisms of toughening are much the same, glass-matrix composites are not discussed here as a separate type of CMC, but are included in the general discussion of DR-CMCs and CFCCs.

Cynthia Powell Doğan, U.S. Department of Energy, Albany Research Center

Discontinuously Reinforced Ceramic-Matrix Composites

Discontinuously reinforced ceramic-matrix composites are a class of materials designed to retain the attractive properties of monolithic ceramics, while enhancing their reliability for structural applications. Although strictly speaking almost any multiphase ceramic can be classified as a DR-CMC, the materials referred to in this section are those in which discrete particles, platelets, whiskers, fibers, and so forth are incorporated into a ceramic or glass matrix in order to enhance composite performance. For the purposes of this discussion,

transformation-toughened zirconia ceramics such as the partially stabilized zirconias (Ref 1, 2, and 3) are not considered DR-CMCs, although ceramic matrices with added zirconia particles, such as the zirconia- toughened aluminas, are included.

In addition to the specific advantages of each composite system, DR-CMCs are characterized by the following:

- Their processing methodology is similar to that of monolithic ceramics, and therefore any increases in the cost of the composite relative to the monolithic should be small.
- Their mechanical and physical properties are approximately isotropic.
- Their fracture toughness is typically 25 to 100% higher than the corresponding monolithic ceramic (Ref 4, 5).

However, even though the possible increases in fracture toughness are relatively large with the addition of discontinuous reinforcement, DR- CMCs remain similar to monolithic ceramics in that they will fail catastrophically when a crack or flaw grows beyond a critical size.

Currently DR-CMCs are in the early stages of commercialization, with applications that include cutting tools, dies, advanced turbine engine components, heat exchangers, pressure seals, and wear-resistant parts. Although the principal driving force behind the addition of a discontinuous reinforcement to a ceramic matrix is most often the need to increase its structural reliability, it is important to remember that other properties of the material can also be enhanced, or tailored, by the composite approach (Ref 6).

Toughening Mechanisms. The magnitude of the change in the properties of a material that result from the addition of a discontinuous reinforcement phase can frequently be estimated by a rule of mixtures approximation. However, any changes in the toughness of the composite depend on the specific toughening mechanism(s) that are activated by the addition of the reinforcement, and the magnitude of the change can be difficult to predict. Possible toughening mechanisms for these materials include: crack deflection, crack bridging, pullout, microcracking, crack pinning, and phase transformation, as illustrated in Fig. 1. In most instances the toughening observed in a DR-CMC is the result of the combination of two or more of these toughening mechanisms. The effect of these mechanisms on the room-temperature strength and fracture toughness of several DR-CMCs is presented in Table 1.

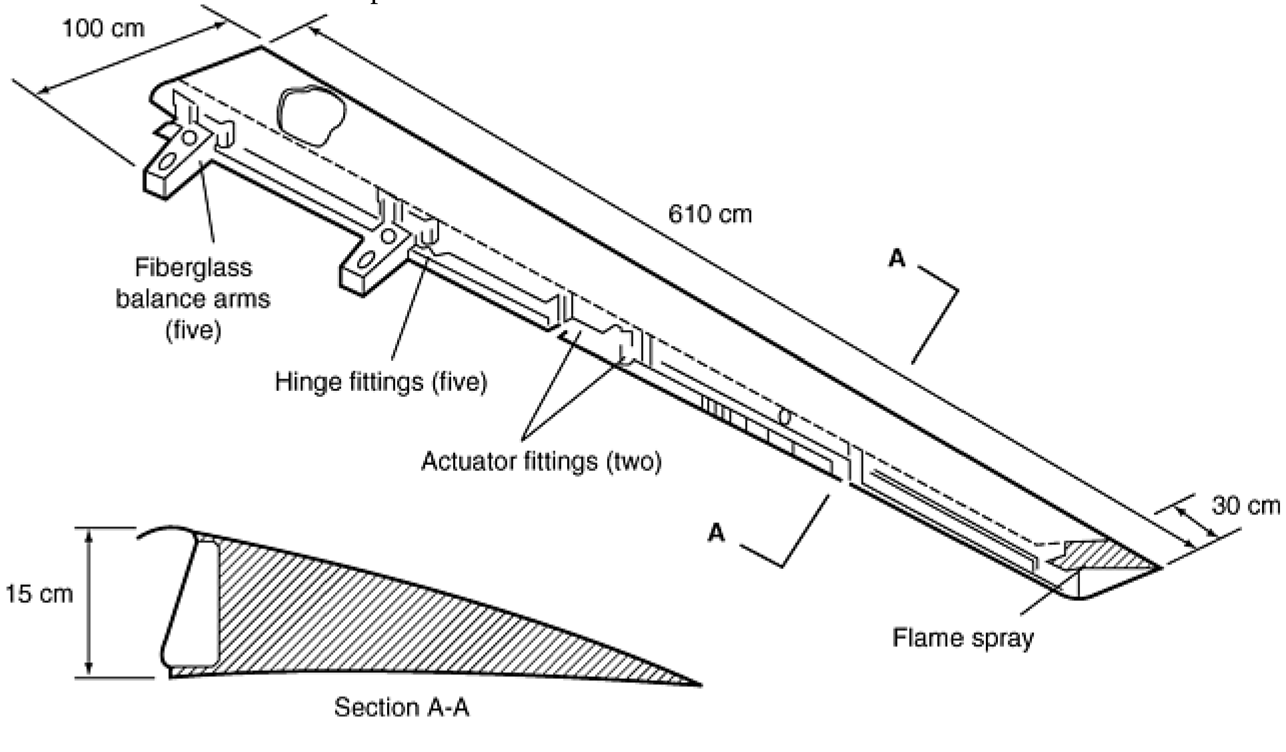

Fig. 1 Toughening mechanisms that can be activated in a discontinuously reinforced ceramic-matrix composite. Source: Ref 7

Table 1 General trends in room- temperature strength and toughness for ceramic-matrix composites with the addition of a discontinuous reinforcement phase

Composite	**Fracture strength**	Fracture toughness
Particulate Reinforced CMC		
Glass + Al_2O_3 (p)	Increase	**Increase**
Al_2O_3+ ZrO_2 (p)	Increase	**Increase**
Al_2O_3+ Ni (p)	Decrease	**Increase**
Platelet Reinforced CMC		
Al_2O_3+ SiC (pl)	Decrease	**Increase**
Whisker Reinforced CMC		
Glass + SiC (w)	Increase	**Increase**
Al_2O_3+ SiC (w)	Increase	**Increase**
Si_3N_4+ SiC (w)	Increase	**Increase**
ZrO_2+ SiC (w)	**Decrease**	**Increase**

Reinforcement: p, particulate; pl, platelet; w, whisker.
Source: Ref 7

With crack deflection, a crack propagating through the matrix is deflected by the reinforcement phase, causing the crack to travel a longer distance and resulting in a corresponding decrease in the stress intensity at the crack tip (and thus an increase in the fracture toughness). Deflection results from the residual strain caused by the presence of the reinforcement phase and/or from the relatively weak reinforcement-matrix interfaces. This mechanism is operative in almost all DR-CMCs, although it may not be the dominant toughening mechanism. For most composite systems, the following generalities about toughening by crack deflection hold (Ref 8, 9): the increase in toughness depends on the reinforcement particle shape and volume fraction, but not on the reinforcement particle size; a rod shape is the most effective reinforcement morphology for increasing toughness; and the toughness increases with increased volume fraction of reinforcement particles up to a volume fraction of ~20%, but increases very little at higher volume fractions.

In crack bridging, the reinforcement phase does not fracture as the crack front passes by, creating "bridges" of material that remain intact behind the crack tip. The presence of these bridges limits the opening displacement of the crack, inhibiting further crack propagation, and thereby increasing fracture toughness. Whiskers, fibers, ductile metallic particles, or even large matrix grains can act as bridging elements in DR-CMCs. Typically, crack bridging is enhanced by an increase in the strength, diameter, and/or volume fraction of the ceramic reinforcement phase. With ductile reinforcement, on the other hand, toughness generally increases with volume fraction up to 15 vol% metal; however, composites containing greater than 5 vol% metal particles typically experience some degradation in strength and hardness.

When the shear strength of the reinforcement- matrix interfaces is less than the strength of the reinforcement phase, fracture along these interfaces will occur, leading to pullout of the reinforcement phase. Pullout increases the work of fracture of the composite and therefore increases its fracture toughness. Both fibers and whiskers can enhance the pullout toughness of a DR- CMC, although the pullout lengths of whiskers are relatively small, and thus their toughening effects are correspondingly less. When pullout is the dominant toughening mechanism, a balance between composite strength and fracture toughness must be achieved by carefully engineering the reinforcement-matrix interfaces so that they are sufficiently weak to maximize the number of pullouts that will occur, but not so weak as to compromise the integrity of the composite. Interfacial strength is governed by both the chemical reactions that occur at the interface and the degree of mechanical bonding.

A misfit in the coefficients of thermal expansion between the matrix and reinforcement phases can produce stresses in the composite that, if sufficiently high, will result in the spontaneous microcracking of the material. Composite toughening can occur if these microcracks are not initiated until an external stress is applied to the system. In this case, microcracks form only at the tip of the primary crack, reducing the stress intensity and therefore increasing fracture toughness. However, increases in the composite toughness as a result of this mechanism are generally not greater than 10%, and if not carefully controlled, excessive microcracking can lead to a decrease in the fracture toughness and strength of the material.

With crack pinning, the crack is pinned by the reinforcement phase, causing an increase in the fracture energy (toughness) as the crack front bows out between the pinning points. Effective crack pinning requires both a strong reinforcement-matrix interface and a strong reinforcement phase. In addition, the spacing between the individual pinning points (reinforcement particles) must be small relative to the crack size.

Transformation toughening occurs in DR- CMCs primarily through the addition of tetragonal zirconia particles to the ceramic matrix. Toughening occurs when these particles undergo a martensitic transformation to monoclinic symmetry in the presence of an external stress, resulting in a volume expansion that exerts closure stresses on the crack tip (Ref 1, 2, and 3). Transformation toughening is maximized when the tetragonal zirconia particles are below a critical size, typically 0.5 to 0.8 μm in alumina-base materials. Microcracking, which may also occur during the tetragonal-to-monoclinic phase transformation, can also impact composite fracture toughness.

Optimal toughness in DR-CMCs is typically achieved by first determining which toughening mechanisms are possible within a particular composite system and then selecting the reinforcement particle type, shape, size, and volume fraction that maximize each of them. Because strength is typically a secondary concern in these materials, most DR-CMCs are designed for enhanced toughness, with little change in strength relative to the monolithic ceramic. In addition, it is important to recognize that while these various toughening mechanisms are active at low to intermediate temperatures, almost all of them can be predicted to degrade during prolonged exposure to temperatures above ~1100 °C (~2010 °F) (Ref 10). To date little experimental work has focused on the high-temperature stability of DR- CMCs; however, toughening mechanisms that rely on mismatches in thermal expansion or phase transformations will certainly not have the same influence at elevated temperatures. Long- term exposure to high temperatures is also likely to change reinforcement particle size and morphology and to influence the chemical nature of the matrix-reinforcement interfaces, potentially reducing the contributions of mechanisms such as pullout, bridging, and deflection to the overall toughness of the composite. Finally, characteristics of the composite unrelated to the reinforcement can also influence the high-temperature performance of the material, such as the presence of an amorphous grain-boundary phase within the matrix.

A list of the effect of the various types of ceramic reinforcement on the room-temperature strength and toughness of several ceramic and glass matrices can be found in Table 2.

Table 2 Room-temperature strength and fracture toughness of selected discontinuously reinforced ceramic-matrix composites

Composite Architecture. The ceramic matrix in a DR-CMC may either be an oxide or nonoxide material and, depending on the processing techniques employed, may also contain some residual metal. The more common oxide matrices include polycrystalline alumina (Al_2O_3), silica (SiO_2), and mullite ($3Al_2O_3$- $2SiO_2$), and barium-aluminosilicate, calcium- aluminosilicate, and lithium-aluminosilicate glasses. However, alumina and mullite are by far the most common oxide-matrix materials because of their thermal and chemical stability and their compatibility with most of the common reinforcement materials. Nonoxide-matrix materials tend to have superior structural properties to their oxide counterparts, and they have better corrosion resistance in some environments. However, they are sensitive to oxidizing environments at elevated temperatures. The more common nonoxide matrices are silicon carbide (SiC), aluminum nitride (AlN), silicon nitride (Si_3N_4), and boron carbide (B_4C). Of these SiC is the more widely used, although AlN may be employed when high conductivity is a requirement, and Si_3N_4 may be selected when higher strength is needed.

The reinforcement phase in a DR-CMC can have a variety of morphologies and is typically composed of one of the following: SiC, Si_3N_4, AlN, TiC, TiB_2, BN, or B_4C. Because of its stability in a wide variety of ceramic matrices, and because of its commercial availability in a variety of morphologies, SiC is the most widely used reinforcement phase. However, for applications that require long-term exposure to high temperatures, an oxide reinforcement may be a better choice. Silicon carbide is susceptible to degradation in oxygen-containing environments at temperatures above 1200 °C (2190 °F), and even when used as a reinforcement at these temperatures, it must be protected by some sort of coating system to ensure reliable service.

Particulate Reinforced CMCs. The technique of adding a distribution of particles to a ceramic or glass matrix in order to enhance its properties is well known, and a wide variety of particle-matrix systems have been explored over the years. The particle reinforcements added may either be ceramic or metallic, with their effectiveness generally determined by their chemical compatibility with the ceramic matrix and other factors such as thermal expansion and elastic mismatch. The toughening mechanisms that are activated in these types of composites may include crack deflection, crack pinning, microcracking, and transformation toughening in zirconia-containing composites; however, crack deflection is most often the primary toughening mechanism in ceramic-ceramic systems. In these cases, the degree of chemical interaction between matrix and particle is important in determining the ease of debonding at the matrix-reinforcement interface and therefore the level of toughening that can be achieved by crack deflection. In addition, for maximum toughness it is important that the reinforcement particles remain as a discrete phase within the matrix; in other words, it is important that chemical reactions between particles and matrix are not so extensive that a variety of second phases are formed at the expense of the reinforcement. The level of thermal expansion mismatch between matrix and reinforcement phases is also important in defining composite reliability. When there is a mismatch in thermal expansion, stresses form within and around the particles that can lead to spontaneous microcracking of the material. This may either enhance or degrade the toughness of the composite, as described previously. When microcracking does not occur, stress fields around the reinforcement particles may activate a crack deflection mechanism, enhancing composite toughness.

In metal particle reinforced CMCs, optimal toughness occurs when the particles can deform in the wake of the crack, bridging the crack and thereby reducing the crack opening displacement. Very high toughnesses can be achieved in these composites by this mechanism, with reports of room-temperature toughness values as high as

$35 MPa\sqrt{m}$ ($31.8\ ksi\sqrt{in.}$) for an aluminum reinforced alumina (Ref 29). However, use of metal particle reinforced CMCs is severely hampered by the temperature and oxidation limits of the metal reinforcement.

Platelet Reinforced CMCs. Ceramic particles in the shape of platelets have only recently become widely available, and therefore the number of studies on the physical properties of platelet reinforced CMCs is relatively small. Work to date suggests that ceramic matrices reinforced with platelets will not be as tough as whisker reinforced CMCs, although they can be as tough, or tougher than particle reinforced CMCs (Table 2). However, composite strengths are frequently reduced by the addition of platelet reinforcements, either because of excessive microcracking in the case of larger platelets, or because they can act as strength-limiting flaws in the case of smaller platelets (Ref 5). Crack deflection and platelet crack bridging appear to be the primary toughening mechanisms in these materials (Ref 30).

Whisker Reinforced CMCs. The addition of ceramic whiskers (defined here as rod or needle- shaped single crystals) to ceramic matrices results in composites that are stronger and tougher than similar materials with particulate or platelet reinforcement (Table 2). This increase in material reliability results from the combination of superior reinforcement properties and the wide range of toughening mechanisms that are invoked by the presence of the whiskers. Silicon carbide whiskers, with a tensile strength approaching 7 GPa (1×10^6 psi) and a high elastic modulus of 550 GPa (79.8×10^6 psi), are the most commonly used whisker reinforcement, although a variety of other ceramic whiskers are also available. The presence of these whiskers can activate as many as five different toughening mechanisms, including crack bridging, whisker pullout, crack deflection, crack pinning, and microcracking. Which of these mechanisms will be activated at any given time depends on the local stress state and the orientation of the whiskers at the crack tip. However, in general each of these toughening mechanisms leads to increasing composite toughness with an increase in whisker content (Ref 31, 32).

Whisker-toughened CMCs typically retain their high toughness to temperatures of approximately 1100 °C (2010 °F). At higher temperatures, the apparent toughness will increase due in part to longer pullout and bridging lengths and the nucleation of creep cracks; however, this increase in toughness is typically offset by the onset of creep, which occurs at around 1200 °C (2190 °F). In addition, nonoxide whiskers are reactive at elevated temperatures, which affects their usefulness as structural components in severe environments. Both SiC and Si_3N_4 decompose to gaseous by-products in the presence of oxygen at temperatures as low as 1200 °C (2190 °F), and they will react with most matrix materials at high temperatures to form compounds such as SiO_2 and mullite, which will further reduce composite toughness.

In addition to toughness, the incorporation of ceramic whiskers into a ceramic matrix can result in an improvement of other material properties such as hardness and thermal conductivity. Increases in hardness translate to better wear resistance, although this can be tempered by a localized decrease in the fracture toughness at the microscale (Ref 33). Increases in thermal conductivity, combined with toughening mechanisms that resist the coalescence of thermal- shock-induced cracks into critical flaws, result in enhanced thermal shock resistance relative to the monolithic ceramic.

Because of their superior properties and their relative ease of manufacture, whisker-toughened CMCs have enjoyed more commercial success to date than any of the other ceramic-based composite systems. Alumina toughened by SiC whiskers (Al_2O_3/SiC_w) is used with considerable success as a cutting tool for nickel-base superalloys. The advantages of these CMCs in this application include: increased tool lifetimes, reduced downtime, improved surface finish, lower maintenance costs, and increased production rates. Although the Al_2O_3/SiC_w composites cost more to manufacture than the more traditional carbide tools, their increased cost is more than compensated for by their superior performance.

Hybrid DR-CMCs. Reinforcements of several morphologies and/or compositions can also be added to a ceramic matrix to produce hybrid DR-CMCs. In many cases, this can lead to an enhancement in the mechanical properties of the composite, as indicated for several systems in Table 2. However, it cannot be assumed that all material properties will benefit from this combination. For example, the combination of SiC whiskers and tetragonal ZrO_2 particles in an alumina matrix results in an increase in composite toughness relative to either a whisker-toughened alumina or a zirconia-transformation-toughened alumina. However, when this hybrid composite is exposed to an oxygen-containing atmosphere at elevated temperatures, the oxidation of the SiC whiskers is enhanced by the presence of zirconia, resulting in severe degradation in composite properties in a relatively short time (Ref 34).

Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites

Cynthia Powell Doğan, U.S. Department of Energy, Albany Research Center

Continuous Fiber Ceramic Composites

Continuous fiber ceramic composites represent the ceramic industry's best success thus far in overcoming the inherent brittleness characteristic of most ceramic materials, while retaining many of their attractive qualities. As a result, CFCCs can be produced that have the high hardness, high strength, high melting point, chemical inertness, good wear resistance, and low density common to monolithic ceramics. However, unlike monolithic ceramics, CFCCs can be designed to be strain tolerant and therefore to have a much lower probability of failing catastrophically in a high stress environment. The development of CFCCs for application at high temperatures is not without its challenges, however. Because the fibers and fiber-matrix interfacial regions of the most successful CFCCs tend to be either carbides or nitrides, they can exhibit poor stability at elevated temperatures when exposed to oxygen-containing environments. The performance of CFCCs depends critically on the integrity of these regions, and thus their degradation can be catastrophic. In addition, because they require

specialized materials and processing techniques, CFCCs are expensive to produce relative to either monolithic ceramics or DR-CMCs.

Most CFCCs are currently in the precommercial/demonstration stage of development, with the best of the current generation CFCCs considered to be competitive with the best metallic materials for specific niche applications. However, once problems with poor creep resistance are resolved, oxide-oxide CFCCs are predicted to be the ultimate materials solution for many high-temperature structural applications in the military, power-generating, and transportation industries.

Composite Architecture. Continuous fiber ceramic composites consist of a continuous network of ceramic or carbon fibers in a ceramic or glass matrix. A wide variety of ceramics have potential as matrix materials for CFCCs, including SiC, Si_3N_4, $MoSi_2$, Al_2O_3, mullite, yttrium- aluminum-garnet (YAG), and spinel. However, SiC and Al_2O_3 are currently the most commonly used matrix materials. Silicon-carbide-matrix CFCCs are designed for applications where high thermal conductivity, low thermal expansion, light weight, and good corrosion and wear resistance are desired. Alumina-matrix CFCCs are better in applications where a high tolerance to salt corrosion, molten glass, or oxidation is required in combination with light weight and high thermal shock resistance. In addition, a variety of glass and glass-ceramic matrices can be used in applications that do not require structural stability above the softening temperature of the glass (for example, ~600 °C, or 1100 °F, for a borosilicate glass or ~1150 °C, or 2100 °F, for a high silica glass). For such applications, the relative ease of processing glass-matrix CFCCs can result in a significant cost savings.

The fiber reinforcement within a CFCC is typically either SiC or carbon, although a number of other oxide and nonoxide fibers are currently under development and several are commercially available. The properties of several ceramic- and carbon-base fibers can be found in Tables 3 and 4. In order to act as a reinforcement, the fibers must have the following characteristics: high strength, environmental stability (particularly in oxygen-containing environments), creep resistance, and a coefficient of thermal expansion that is close to that of the matrix. In addition, the ideal fibers must be processible with a small enough diameter to allow weaving, and their production should be relatively inexpensive. Currently, it is oxidation and creep resistance that are the limiting factors for most fiber reinforcement. In the absence of oxygen, carbon is the choice fiber for most applications. However, carbon fibers can suffer from oxidation at temperatures as low as 350 °C (660 °F). Silicon carbide fibers have good strength up to 1000 °C (1832 °F), but begin to creep at higher temperatures. In addition, all SiC fibers will suffer from oxidation at temperatures greater than 1200 °C (2190 °F) and have a maximum-use temperature of not more than 1400 °C (2550 °F). Current-generation oxide fibers, such as Al_2O_3, are polycrystalline materials with silica at their grain boundaries. As a result, alumina-base fibers begin to creep at temperatures as low as 900 °C (1650 °F) and retain almost no strength at temperatures above 1150 °C (2100 °F). Thus, although alumina and other oxide fibers have considerable potential as CFCC reinforcement because of their oxidative stability, their poor high-temperature mechanical properties currently limit their usefulness. The application of single-crystal oxide fibers, currently under development, may be the solution to this problem of high-temperature stability.

The fibers within a CFCC can be oriented in a variety of ways, depending on the performance requirements of the specific application. A unidirectional (0°) alignment of fibers results in the highest level of property translation efficiency, but at the expense of intralaminar and interlaminar strength. A two-dimensional, planar interlaced fiber architecture results in better intralaminar properties; however, the interlaminar strength is limited by the properties of the matrix due to the lack of through-thickness reinforcement. A three-dimensional, integrated, fiber architecture results in enhanced interlaminar properties by providing reinforcement in the through-thickness direction. The type of fiber architecture that is best suited for a particular application will depend on the performance requirements of that application.

Mechanical Behavior. The mechanical behavior of a CFCC is determined to a large degree by three factors: the strength of the reinforcing fibers, the characteristics of the fiber-matrix interface, and the residual stress present in the composite due to thermal expansion mismatch between fibers and matrix. High-strength fibers are important because once a matrix crack is initiated and extended, load is transferred from the matrix to the fibers in the wake of the crack. As a result, the ultimate load-bearing capability of the composite is determined by the load-bearing characteristics of the fibers. The level of toughening imparted by the fibers depends on how well the interface between matrix and fibers is engineered. In an ideal composite, the interface will be strong enough to transfer load from the matrix to the fiber, yet weak enough to allow debonding of the fiber in the path of a crack. Actual composite toughening then occurs by the mechanisms of crack deflection, crack bridging, and

fiber pullout when the fibers finally do fail, as shown in Fig. 2. In addition to the chemical bonding at the interface, residual stresses from thermal expansion mismatch between the matrix and fibers can contribute to the mechanical strength of the fiber-matrix interface and thus influence composite toughness.

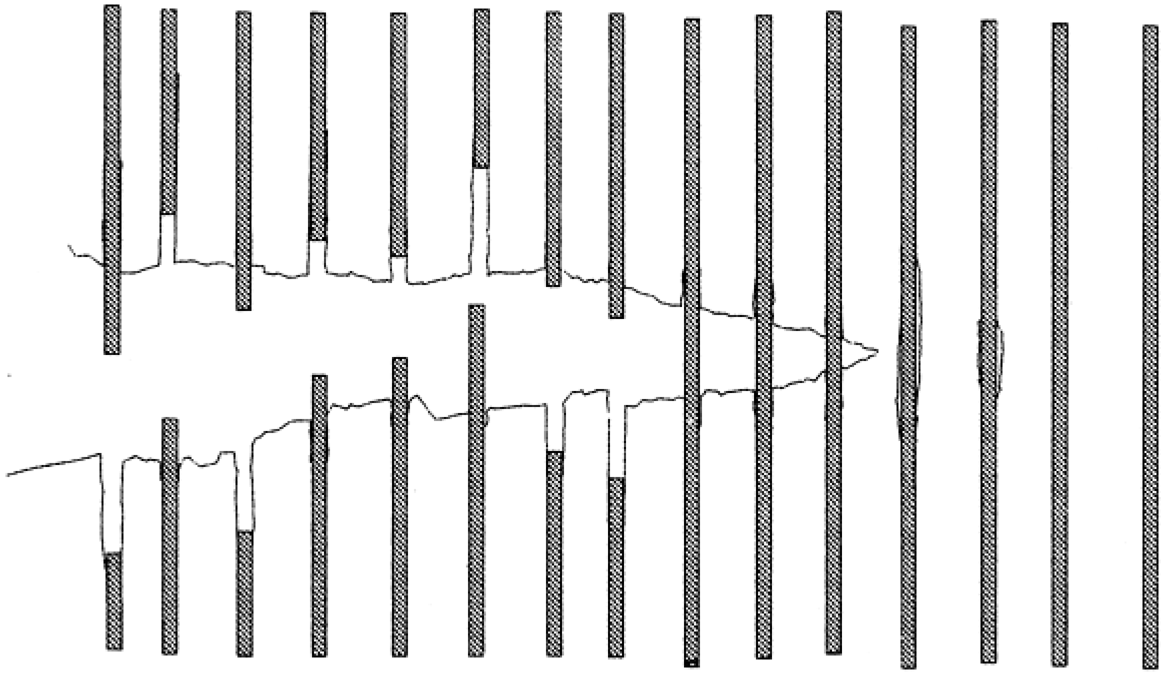

Fig. 2 Mechanisms of fiber debonding, crack bridging, and fiber pullout as a result of crack propagation within a continuous fiber ceramic composite. Source: Ref 35

The ways in which fiber-matrix interface strength influences the toughness of a CFCC is illustrated by the four stress-strain curves in Fig. 3. The first curve, labeled BSG, is that of an unreinforced glass in which the stress-strain behavior is purely elastic and failure is brittle. Curve A illustrates the stress-strain behavior of a fiber reinforced glass with a strong fiber matrix interface. Because the elastic modulus of the fibers is higher than that of the matrix, some strengthening of the composite is observed. However, because the fiber-matrix interface does not allow for debonding in the presence of a matrix crack, the potential toughening mechanisms of crack deflection and crack bridging are not activated, and both matrix and fibers fail in a brittle manner. The CFCC represented by curve B has a fiber-matrix interface that is engineered such that debonding occurs as the crack passes by the fiber, leaving the fiber intact in the wake of the crack to continue to bear load and to toughen the composite by crack bridging. Curve C represents the stress-strain behavior of a CFCC in which fiber pullout has been added as a toughening mechanism, in addition to crack deflection and crack bridging. Thus, through the addition of a continuous network of strong fibers, and well-engineered fiber-matrix interfaces, a normally brittle material can be designed to have improved tolerance to strain and reduced probability of catastrophic failure. The mechanics of fracture initiation and propagation is detailed and modeled in “Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites” in this Volume.

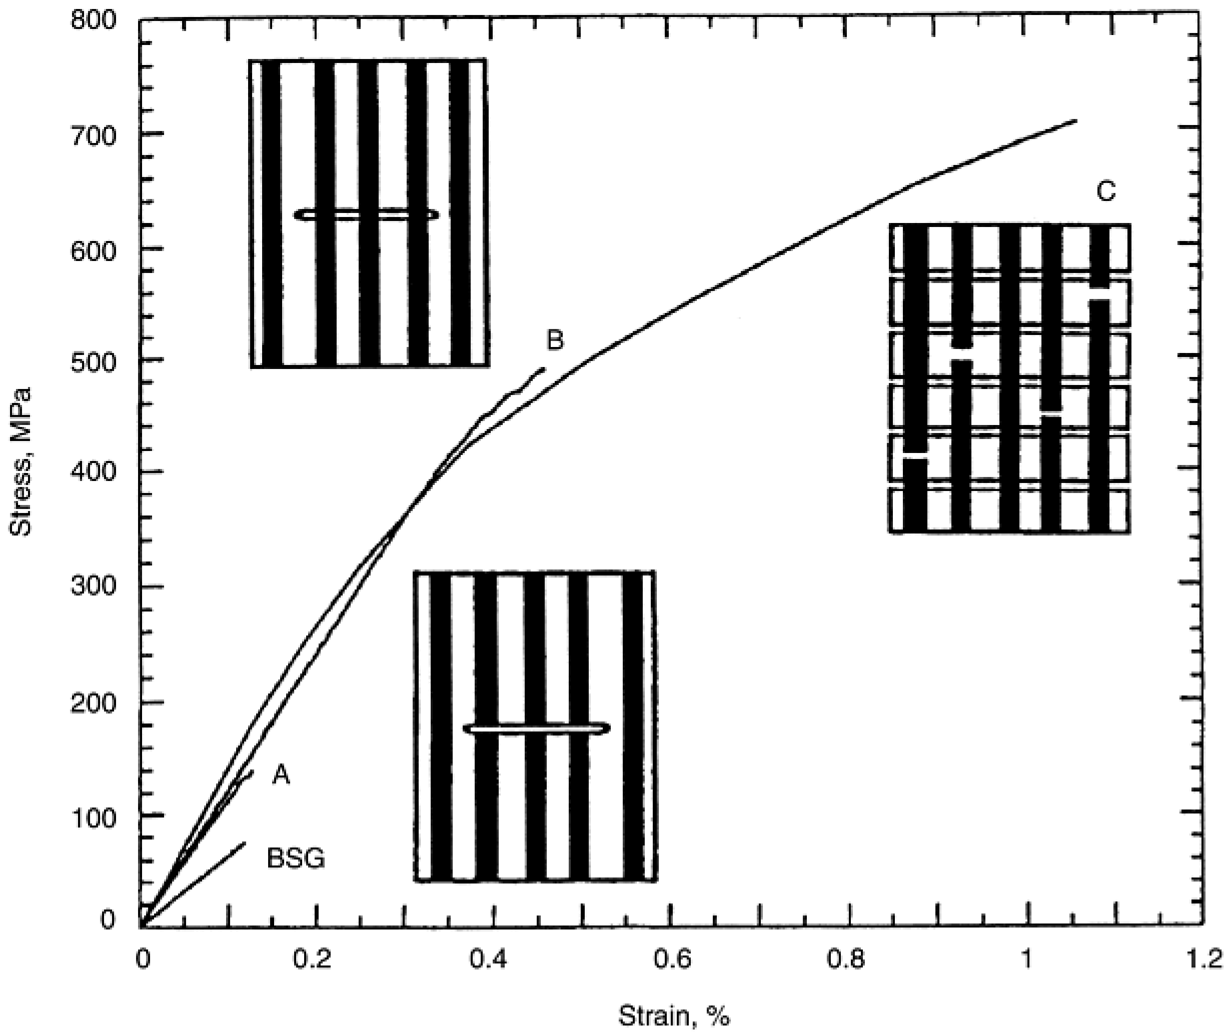

Fig. 3 Stress-strain curves for (a) unreinforced glass (BSG), fiber reinforced glass with a strong fiber matrix interface, (b) fiber reinforced glass with a relatively weak fiber matrix interface in which toughening by fiber debonding and bridging can occur, and (c) fiber reinforced glass in which the toughening mechanisms of debonding, bridging, and pullout are active. Source: Ref 36

Interface bonding is controlled either by selecting fiber and matrix materials that are thermodynamically stable at both the processing and the service temperatures, or by applying coatings that act as diffusion barriers and therefore prevent a strong bond between fiber and matrix. Currently, carbon and boron nitride are the coating materials most often used to control the interfacial properties of the CFCC because of their weak crystallographic orientations, which can preferentially delaminate. These coatings also serve to prevent mechanical damage to the fibers during processing. However, both carbon and boron nitride are susceptible to environmental degradation at elevated temperatures. As a result, a variety of alternative multilayer and oxide-base coatings are in the design/feasibility stage.

Mechanical and Physical Properties. In CFCCs, the principal driving force in adding a continuous distribution of fibers is to mitigate against the inherent brittleness of the ceramic matrix. Enhancement of other physical properties, such as strength, hardness, or conductivity, may be the result of the addition of reinforcement to the CFCC, but it is rarely the objective of their production. Table 5 provides a list of the room-temperature mechanical properties of several commercially available CFCCs, and Table 6 lists the thermal properties of the same suite of composites.

Table 5 Room-temperature mechanical properties of several commercially available CFCCs

Limitations to Current Technology. Although ceramic materials are noted for their high-temperature stability, characteristics of a polycrystalline ceramic microstructure make the current generation of materials susceptible to deformation and creep at temperatures as low as 900 °C (1650 °F). This is true both for the matrices and for the fibers that are used to produce CFCCs. This susceptibility results from the presence of grain boundaries and the tendency for relatively low-melting phases, which may be introduced either intentionally or unintentionally during processing, to reside there. When these grain-boundary phases begin to soften, the grains can slide relative to one another, resulting in the initiation of creep cracks and the deformation of the bulk material at temperatures much lower than the softening point of the matrix. Because of grain-boundary creep, current generation oxide fibers have a maximum-use temperature of approximately 1000 °C (1830 °F), rendering them unsuitable for many CFCC applications. Depending on the amount of oxygen present in the material, SiC fibers can also exhibit significant creep in the same temperature range. As a result, poor fiber stability is considered one of the major barriers to the high-temperature application of CFCCs, and research emphasis is now focusing on the potential of single-crystal oxide fibers as a possible reinforcement material.

In addition to high-temperature deformation, environmental susceptibility is a problem for many of the nonoxide matrix and reinforcement materials used in CFCCs. Both SiC and Si_3N_4 form a SiO_2 surface layer upon exposure to an oxidizing environment, which is protective to temperatures approaching 1200 °C (2190 °F). However, decomposition reactions at higher temperatures render the oxide coating nonprotective, and volatilization of the material can be problematic. This high-temperature decomposition occurs even in nonoxide fibers embedded within the composite matrix. In the case of fibers, cracks in the matrix can expose the reinforcement to an oxygen-containing environment. Alternatively, fast diffusion of oxygen along grain boundaries, or along interfaces, can cause internal volatilization of the reinforcement, resulting in cavitation, bloating, and/or blistering. Finally, oxidation of the protective boron nitride or carbon coating typically applied to fibers can result in the formation of a strong interfacial bond that will embrittle the composite.

As a result of these limitations, it appears that oxide-oxide CFCCs, which include single-crystal reinforcement, have the highest potential for structural applications at temperatures greater than 1400 °C (2550 °F). However, issues with grain-boundary creep of the matrix and thermal shock resistance have yet to be resolved, and thus it will be several years before these materials can be developed and commercialized.

Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites

Cynthia Powell Doğan, U.S. Department of Energy, Albany Research Center

---

Carbon-Carbon Composites

A number of advantages—including stable mechanical properties to temperatures greater than 2000 °C (3630 °F), high strength-to-weight ratio, high thermal conductivity, good thermal shock resistance, good abrasion resistance, and good corrosion resistance—make C-C composites a candidate material for virtually any application requiring structural integrity at very high temperature. In addition, C-C composites are biocompatible, and this characteristic, combined with the ability to tailor the directional properties of these materials, makes them attractive for use in various load-bearing prosthetic devices. However, C-C composites

have at least two drawbacks that prevent their widespread application. The first is that C-C composites are extremely susceptible to degradation by oxidation at temperatures as low as 350 °C (660 °F). As a result, the long-term use of these materials as structural components at high temperature in oxygen-containing environments is impossible without some form of protective coating. The second drawback is that production costs can be quite high, making C-C composites a prohibitively expensive solution for many applications. Because of these drawbacks, use of C-C composites to date has been limited primarily to military and space applications. However, C-C composites have also been successfully utilized as commercial aircraft brakes, where their superior performance outweighs their increased costs.

Carbon-carbon Composite Architecture. Carbon-carbon composites are composed of carbon fibers embedded in a carbon matrix. The microstructural characteristics, and therefore the physical properties, of the carbon matrix can vary widely depending on the starting materials used and methods of composite fabrication. For example, the matrix carbon can be approximately isotropic, composed of small, randomly oriented crystallites of poorly graphitic or turbostratic carbon. The matrix can also be strongly anisotropic, consisting of relatively large crystallites of highly graphitized carbon. More often, however, the matrix microstructure is a combination of these two extremes and includes some porosity and microcracking. The level of porosity is determined by the methods of manufacture, whereas the matrix microcracking most often results from the strong anisotropy of carbon in thermal expansion.

The carbon fibers within a C-C composite are most often continuous, with a variety of orientations. Available fiber architectures include unidirectional, bidirectional (two-dimensional) laminates, three-directional (three-dimensional) orthogonal weaves, or multidirectional weaves and braids. The fiber architecture selected depends on the properties desired in the composite. Multidirectional C-C composites containing reinforcing fibers in three or more directions are advantageous because their fiber architecture can be designed to accommodate the specific requirements of the final component. Unidirectionally reinforced C-C composites, on the other hand, tend to have very high on-axis strength and fracture toughness, but at the expense of their off-axis mechanical properties. In addition to fiber architecture, C-C performance also depends on the physical properties of the fibers themselves, as well as on the characteristics of the interface between fibers and matrix. The carbon fibers used in C-C composites range from the isotropic variety, with low elastic moduli and modest strengths, to highly oriented, high-performance fibers, with high elastic moduli and strengths between 3 and 5 GPa (0.4 and 0.7×10^6 psi). Most of these fibers are derived from polyacrylonitrile (PAN) resin, although petroleum pitch or rayon may also be used as fiber precursors. Table 4 lists the mechanical properties of several commercially available PAN- based carbon fibers.

In C-C composites, the strain-to-failure of the carbon matrix is typically much lower than that of the reinforcing fibers, and as noted earlier the matrix is frequently microcracked as a result of thermal expansion mismatch stresses created during processing. As a result, it is frequently the characteristics of the interfacial bonding between matrix and fiber that govern the mechanical properties of the C-C composite. When the bonding between fibers and matrix is strong, cracks that form in the matrix are propagated across the fiber-matrix interface, resulting in fiber failure. Brittle failure of the composite results, with the ultimate strength of the composite governed by the strain-to-failure of the matrix, as illustrated in the stress-strain curve of Fig. 4(a). Weak interfaces between fibers and matrix, on the other hand, allow matrix cracking to occur without crack propagation through the fibers. Intact fibers bridge the matrix cracks and maintain load-bearing capability until increasing load finally initiates fiber fracture and failure. This process results in a much tougher composite, as illustrated in the stress-strain curve of Fig. 4(b). A more complete discussion of the effect of interfacial strength on the mechanical properties of C-C composites can be found in the work of Fitzer and Hüttner (Ref 38) and Thomas and Walker (Ref 39).

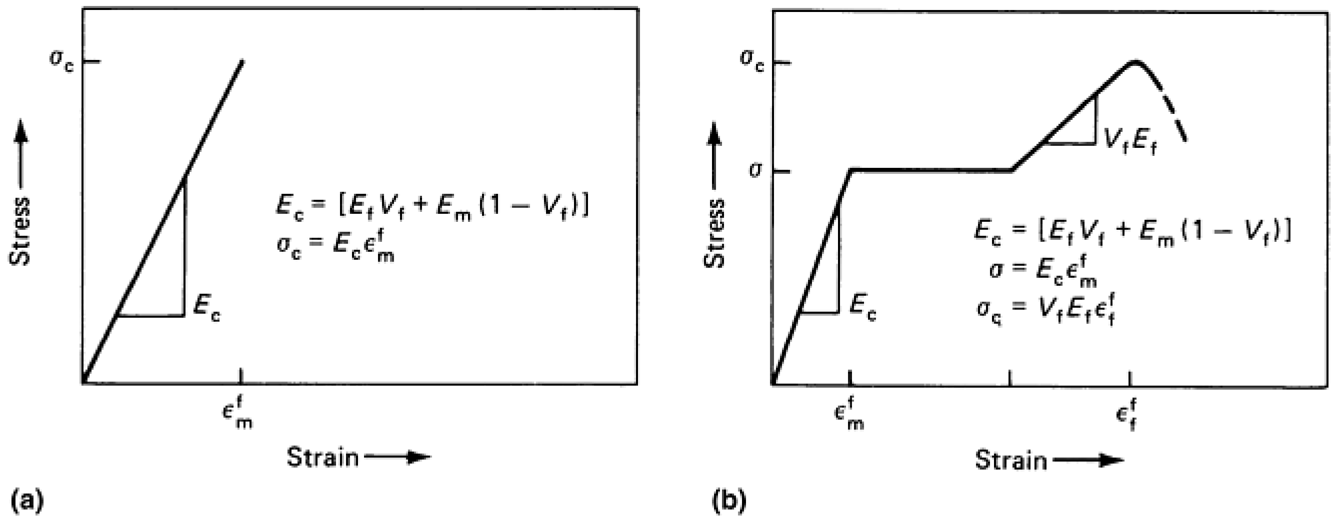

Fig. 4 Stress-strain curves for C-C composites. (a) Strong bonding between fibers and matrix and therefore little toughening of the composite. (b) Well-engineered fiber matrix interface in which significant toughening occurs

Although top mechanical performance depends on weak fiber-matrix interfaces, other physical properties are enhanced by strong fiber- matrix interfaces. As a result, fiber treatments and fabrication methods are varied to tailor the interfacial characteristics of the C-C composite to match the requirements of the specific application (Ref 40, 41). A number of theoretical models are available to predict composite behavior based on variables such as fiber volume fraction, fiber properties, matrix properties, porosity, degree of microcracking, and so forth (Ref 42, 43, 44, 45, 46, 47, and 48).

Thermal and Mechanical Properties. Fiber architecture, fiber type, matrix precursor, and processing methodology will all contribute to determine the physical properties of C-C composites. As a result of the large number of variables involved, C-C composites can be produced with a wide range of properties. Nonetheless, all C-C composites have the following basic characteristics in common: low thermal expansion that increases with temperature, good strength that increases with temperature in inert environments, and thermal conductivity that decreases with temperature. To illustrate the influence of carbon fibers and their architecture on the properties of the composite, Table 7 compares the room-temperature mechanical properties of a fine-grained monolithic graphite with unidirectional and three-directional C-C composites (Ref 49). Tables 8 and 9 list the mechanical and thermal properties of several C-C composites with different fiber architectures (Ref 50).

Table 7 Room-temperature mechanical properties of graphite and C-C composites

Material	Elastic modulus		Tensile strength		Compressive strength		Fracture energy,
	GPa	10^6 psi	MPa	ksi	MPa	ksi	kJ/m^2
Graphite	10–15	1.46–2.17	40–60	5.8–8.7	110–200	16–29	**0.01**
Unidirectional C-C composite	120–150	17.4–21.7	600–700	87–101	500–800	72.5–116	**1.4–2.0**

(a) Thermal expansion measured from room temperature to 1650 °C (3000 °F).
Source: Ref 50
(b) Thermal conductivity measured at 800 °C (1470 °F).

A comparison of the data in Table 7 clearly indicates the benefits of adding carbon fibers to the carbon matrix. All room-temperature mechanical properties are improved in the composites to a level that depends on fiber architecture. Unidirectional fibers provide dramatic increases in the strength of the material in the principal fiber direction. The addition of a three-dimensional network of fibers results in more modest increases in room-temperature strength, but a tremendous increase in fracture toughness. Tables 8 and 9 illustrate the directional nature of the mechanical and thermal properties. Room- temperature mechanical properties are many times higher when measured in the principal axis directions of both the unidirectional and fabric laminate composites. The woven orthogonal (three-dimensional) composite, on the other hand, has more isotropic mechanical properties.

Generally, the elastic modulus that is measured in the principal fiber direction of C-C composites reflects the fiber modulus according to the law of mixtures. Strength utilization of the fibers is typically between 25 and 50%, depending on how the composite is processed (Ref 50). However, as is common with fiber reinforced composites, the shear properties of the C-C composites tend to be relatively low and therefore will usually have a strong influence on materials selection and design. The same is true for the tensile properties of one- and two-dimensional composites in directions normal to the principal fiber directions. These low properties are the direct result of the weak fiber-matrix interfaces that are designed to prevent composite brittleness and low fracture strengths parallel to the fiber directions.

Carbon-carbon composites are unique in that their mechanical properties do not degrade with increasing temperature until 2200 °C (3990 °F). Increases in the tensile strength and decreases in the elastic modulus of the composites (measured in the principal fiber directions) as the temperature increases are typical of carbon fibers (Ref 51). However, it is the properties of the matrix, and of the matrix-fiber interface, that dictate the effect of temperature on the shear, cross-fiber tensile, and compressive strengths of the composites (Ref 50). Generally, these properties also improve with increase in temperature, a phenomenon that is attributed to the closing of matrix microcracks as the temperature is increased. Creep behavior has received only minimal attention to date; however, the steady-state creep rates of most C-C composites are predicted to be at least four orders of magnitude lower than that of most technical grade ceramics (Ref 52).

As with the mechanical properties in C-C composites, the bulk thermal expansion and thermal conductivity can be highly anisotropic in the unidirectional composite (reflecting the large anisotropy in these properties in single-crystal graphite), but approximately isotropic in the three-dimensional composite (Table 9). The thermal expansion of C-C composites tends to increase with increasing temperature, although the value remains low relative to other ionic and covalently bonded materials. The thermal conductivity, on the other hand, tends to decrease with increasing temperature. The combination of good strength, relatively high thermal conductivity, and low thermal expansion makes C-C composites very resistant to thermal shock.

Oxidation Resistance. The retention of mechanical properties to high temperature, combined with a resistance to damage by thermal shock, makes C-C composites an ideal candidate for many high-temperature structural applications. However, the lack of reliable oxidation protection for these materials has been, and continues to be, a serious limitation to their widespread application.

Depending on its crystal structure, carbon can become susceptible to oxidation at temperatures as low as 350 °C (660 °F), especially when the environment contains atomic oxygen. This susceptibility to oxidation increases with increase in temperature until approximately 800 °C (1470 °F), where the rate of oxidation is limited only

by the diffusion rate of oxygen to the carbon surface. Because the oxides of carbon are gaseous, oxidation results in significant material loss and serious degradation in material performance. As a result, some form of oxidation protection is essential to the long-term reliable use of C-C composites at all but the lowest temperatures. External coatings are the most direct, and to date the most effective, method of oxidation protection for these materials. However, the thermal expansion characteristics of C-C composites make establishing and maintaining coherent and adherent coatings extremely difficult. In addition, coating defects are unavoidable with current coating technology, and thus the addition of some mechanism for coating self-healing and/or internal oxidation protection is an absolute necessity for these materials.

The primary coating candidate for oxidation protection at temperatures below 1200 °C (2190 °F) is SiC, because it forms a surface layer of SiO_2 that is highly oxidation resistant, it is chemically compatible with carbon, and it has a relatively low coefficient of thermal expansion. The temperature limitation for SiC in oxidizing environments results from a reaction between SiC and SiO_2 that renders the SiO_2 nonprotective, and this leads to the rapid erosion of the SiC coating (Ref 53). Coatings of Si_3N_4 can also be used, but have essentially the same temperature limitations as SiC. Silicon carbide and Si_3N_4 are usually applied to the C-C composite surface in combination with a boron-containing inner coating to protect the carbon from the inevitable formation of coating cracks. Oxidation of this inner coating through the cracks results in the formation of a sealant glass that flows into and closes the cracks (Ref 54) and thus prevents the oxidation of the underlying composite.

Oxidation protection for C-C composites above ~1500 °C (2730 °F) requires the use of either a noble metal or a highly refractory ceramic coating as a primary oxygen barrier. The most attractive noble metal for carbon protection at high temperatures is iridium, which has a melting point of 2440 °C (4425 °F). In addition, iridium has a very low oxygen permeability to 2100 °C (3810 °F), is nonreactive with carbon below 2280 °C (4135 °F), and is an effective carbon diffusion barrier (Ref 55). However, there are also disadvantages to iridium, including a susceptibility to erosion by volatile oxide formation, a lack of adherence to carbon, and a thermal expansion incompatibility with C-C composites. The use of refractory ceramic coatings for high-temperature oxidation protection, on the other hand, is limited by the high oxygen permeabilities of the refractory oxides. All of the refractory carbides, nitrides, borides, and silicides oxidize rapidly at temperatures above 1750 °C (3180 °F), and most oxidize at significantly lower temperatures. As a result, refractory ceramic coatings cannot provide long-term oxidation protection to C-C composites without the identification of effective additives that can act as oxygen barriers. Problems such as chemical compatibility with carbon at high temperature and thermal expansion mismatch will also have to be solved.

Introduction to Product Reliability, Maintainability, and Repair

Michael J. Hoke, Abaris Training Inc.; Rikard B. Heslehurst, Australian Defence Force Academy

Introduction

THE RANGE OF APPLICATIONS of advanced composite structures is very broad. Operators of equipment that use structural composites must be well aware of the in-service implications with respect to maintenance, reliability, and repairs. These implications require a fresh approach to in-service operations and maintenance activities. Knowledge of the composite system is essential to provide adequate and effective in-service support of composite structures.

Facilitating Effective Repair of Composite Structures

This Section covers a range of topics that first include the general issues for reliability, maintenance, and repair of composite structures. Specific structural applications are also discussed, including marine, infrastructure, and aircraft related issues. The first article, "Designing for Repairability," discusses the need to begin by designing repairable structures. At the preliminary and detailed design stages, composite structures must be developed with the aim of reparability. Replacement of composite components is costly, particularly with the design requirements attempting to reduce parts by having large one- piece sections. The article "Repair Engineering and Design Considerations" provides comment and direction on designing simple repairs to composite structures. This article is aimed at the design of simple and effective repairs. Fabrication and application issues with respect to the repair scheme must be addressed for long-term justification of any maintenance activity. The quality-control and quality-assurance inspection requirements and their implementation provide for this reassurance. Practical methods in achieving quality repair schemes are provided in the article "Repair Applications, Quality Control, and Inspection."

Introduction to Product Reliability, Maintainability, and Repair

Repair Issues for Specific Applications

The next three articles provide detailed discussions on the repair issues and practices for marine vessels, civil infrastructure, and aircraft. While there are many common elements across all applications of composite structural repair, each application discusses in their respective articles the unique requirements of repair.

Composite materials are also a medium to achieve effective and structurally efficient repairs to existing structures. Using a composite repair patch to overcome structural deficiencies has been proven for many years. But the details of engineering design and practical application of composite repair patches are still considered a

unique field of engineering. The article “Bonded Repair of Metal Structures Using Composites” discusses the composite repair scheme as applied to metal structures, such as that found on aging aircraft. Civil infrastructure issues with respect to repairing concrete and steel-based constructions are covered in the article “Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites.” Repairs of marine craft are addressed in the article “Ship Structure Repairs.” Issues related to in- service maintainability of aircraft are discussed in the article “Maintainability Issues.”

Repair Standardization and Reliability Considerations

In today's climate of structural repair validation and verification, there is a need for the standardization of repair design, applications, and materials. The article “Worldwide Repair Standardization” provides an overview of these requirements and then discusses several of the key issues in detail. The final article, “Product Reliability, In-Service Experience, and Lessons Learned” looks at overall product reliability and the specific aspects that pertain to composite structures. A significant part of understanding the reliability of the composite components of today is based on the lessons learned for several aging composite structure applications.
Composite structures are here to stay! Their applications and general uses are growing steadily. Operators of equipment employing composite structures in primary load applications must understand the issues with respect to maintenance and repair action. This Section looks at a significant portion of these requirements. The authors have provided the current state-of-the- art in composite structure reliability, maintenance, and repair. However, this area is a very dynamic engineering system. New materials, fabrication methods, and design and analysis approaches are being developed. It is imperative that the in-service equipment operators keep up- to-date with the latest trends and maintain their own skills and those of their employees.

Designing for Repairability

Introduction

DESIGN is typically a compromise of conflicting requirements. This is particularly so with the design of composite structures. On one hand, there is the ability to produce very efficient structures that are lightweight and cost-effective with respect to manufacture. On the other hand, in- service maintenance and repair often require a structure that does not have the best strength-to- weight ratio or stiffness-to-weight ratio and could be more complex and costly to fabricate. The final structure needs to be both production and structurally efficient and simple to maintain and repair. This article discusses the requirement for designing repairable composite structures by providing general and specific design guidelines. Several examples are used to illustrate how this can be achieved. This article is largely based on the content of Ref 1, 2 3, and 4. While these reports may seem dated, the content is still regarded as significant in the design of composite joints.

Introduction to Designing for Repairability

The de Havilland DH-98 Mosquito “Wooden Wonder” or “Mossie” fighter-bomber of World War II is an excellent example and source of very valuable information about the design of composite aircraft structures, in particular, the principles of structural joints in composite materials. The most important lesson for designers today is that the wood (a natural composite) in the Mosquito was used only to carry in-plane loads. Metal fittings were used for all triaxially loaded components—the landing gear, engine mounts, control surface mounting brackets, wing-to-fuselage junction, and so on. Such a policy of avoiding triaxial or interlaminar loads on composite structures makes even more sense today, because the resin matrix is far weaker compared to graphite fibers, for example, than the cellulose was compared to the wood fibers.

Another key feature of the Mosquito was the extensive use of adhesive bonding throughout the primary and secondary structures, even though the early casein adhesives used survived only in the cold environment of Europe and not in the tropical environment of the Far East. Later production models used formaldehyde adhesives instead. The extensive use of adhesive bonding on the Mosquito is in sharp contrast to the widespread malpractice today of bolting together thin, lightly loaded composite components that would be far better suited to bonding. Bolting should be reserved for thicker, more heavily loaded composite structures, as it was on the Mosquito. This reluctance to make greater use of adhesively bonded advanced composite structures is particularly difficult to fathom, because the adhesives of today are much stronger than the resin matrices that hold the fibers together.

The BAe/Boeing AV-8B Harrier II uses approximately 25% composite materials in its structural weight. The distribution of composite materials includes wing, empennage and fuselage skins, and the substructure of the forward fuselage and wing. Figure 1 illustrates the material use. The all-composite wing on the AV-8B Harrier is an excellent example of composite structure where repair and maintenance were considered during the initial design phase rather than as the more customary afterthought. The fiber pattern is near quasi-isotropic throughout. The strain levels are sufficiently low to permit U.S. Marines to perform quick bolted repairs anywhere without first having each specific repair reviewed by the manufacturer. A slightly orthotropic fiber pattern would have been more appropriate for some other wings with higher aspect ratios, but the structural efficiencies would not have been much greater than with the quasi-isotropic pattern.

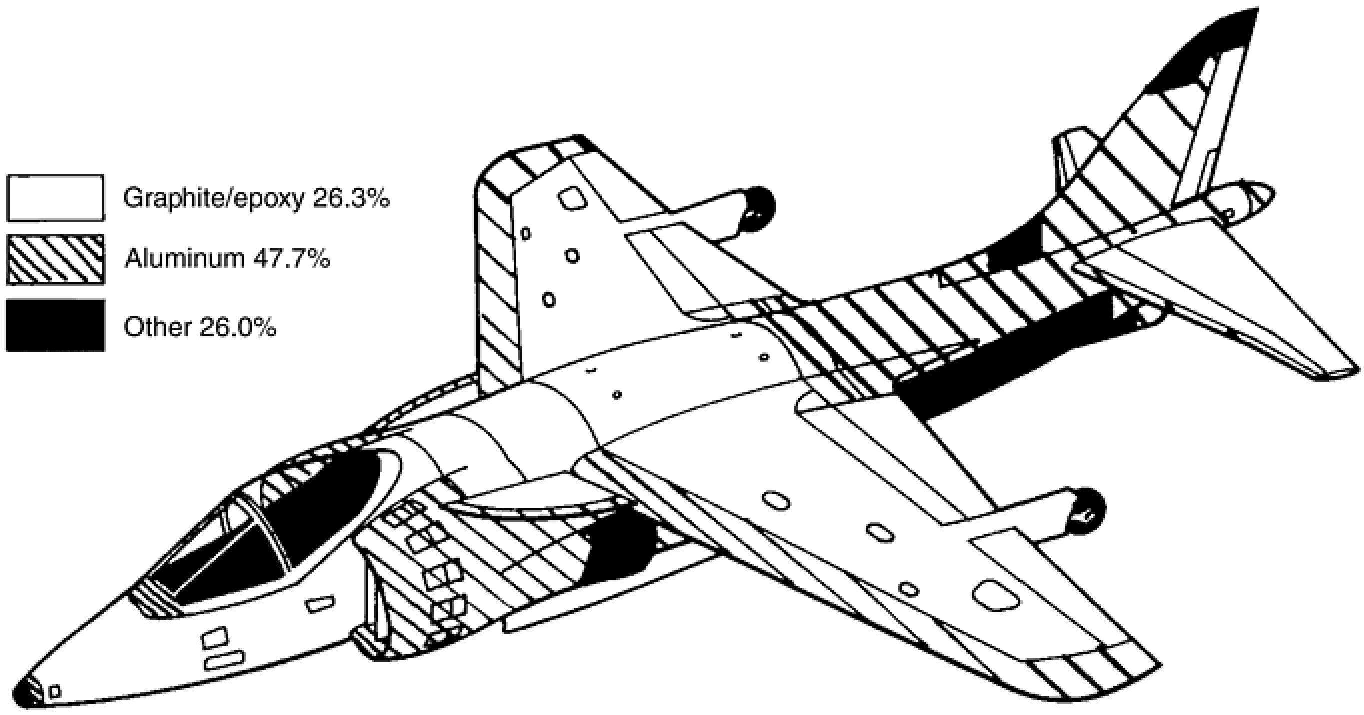

Fig. 1 AV-8B material breakdown. Courtesy of Boeing

On the other hand, in the Bell/Boeing V-22 Osprey (Fig. 2), which has a more orthotropic fiber pattern for strength-to-weight and stiffness- to-weight advantages, bolt holes and cutout develop a higher stress concentration. Because the Harrier wing contains no major splices, being continuous from tip to tip, the design of the bolted joints could be performed according to a simple design procedure.

Review of Joining Methods. The choice between mechanical or bonded repair of advanced composites is often dictated by the nature of the component. For instance, minimum gage control surfaces are lighter if bonded than bolted, because there is no need for locally thickened seams to allow for countersunk fastener heads. Very thick primary structures, on the other hand, are best made by bolting or riveting together simple details that do not have the critical weaknesses due to laminate wrinkling that seems to be inherent in many integrally stiffened co-cured panels (Fig. 3).

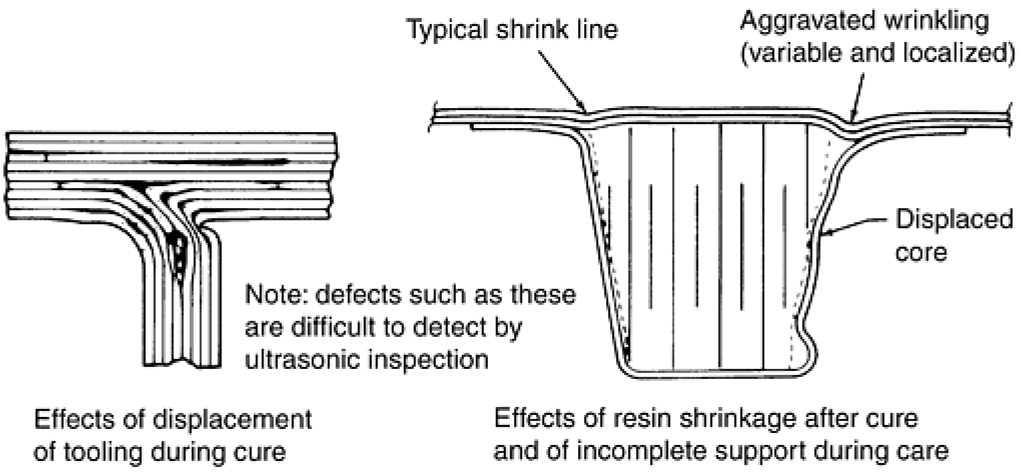

Fig. 3 Internal wrinkling of co-cured composite structures

Bolted or riveted composite repairs may be preferred to bonded repairs, because they take less time, can be done with fewer skills and special equipment, and because some structures lend themselves to mechanical repairs with no loss of static strength. In any event, it is important to plan and to use a laminate pattern that is compatible with bolted holes.

Bolted Joint Failure Modes. The failure modes of mechanically fastened joints are illustrated in Fig. 4. The individual mode of failure is dependent upon the joint geometry as well as the lay- up pattern. The strongest joint usually fails by tension through the hole at a particular width-to- diameter (w/d) ratio. The width is the strip width or bolt pitch distance, and the diameter is that of the hole or fastener. Bearing failures occur at lower total loads per unit width and at greater w/d ratios, where the bolts are further apart. Shear- out failure is controlled by near quasi-isotropic laminate patterns and sufficient edge distances; whereas fastener-type failure is restricted by appropriate fastener diameter-to-component thickness ratios. It suffices here to state that in both original structure and repairs, the strongest joints are developed only by keeping the fastener loads low in comparison with both the rated shear strength and the laminate bearing allowable.

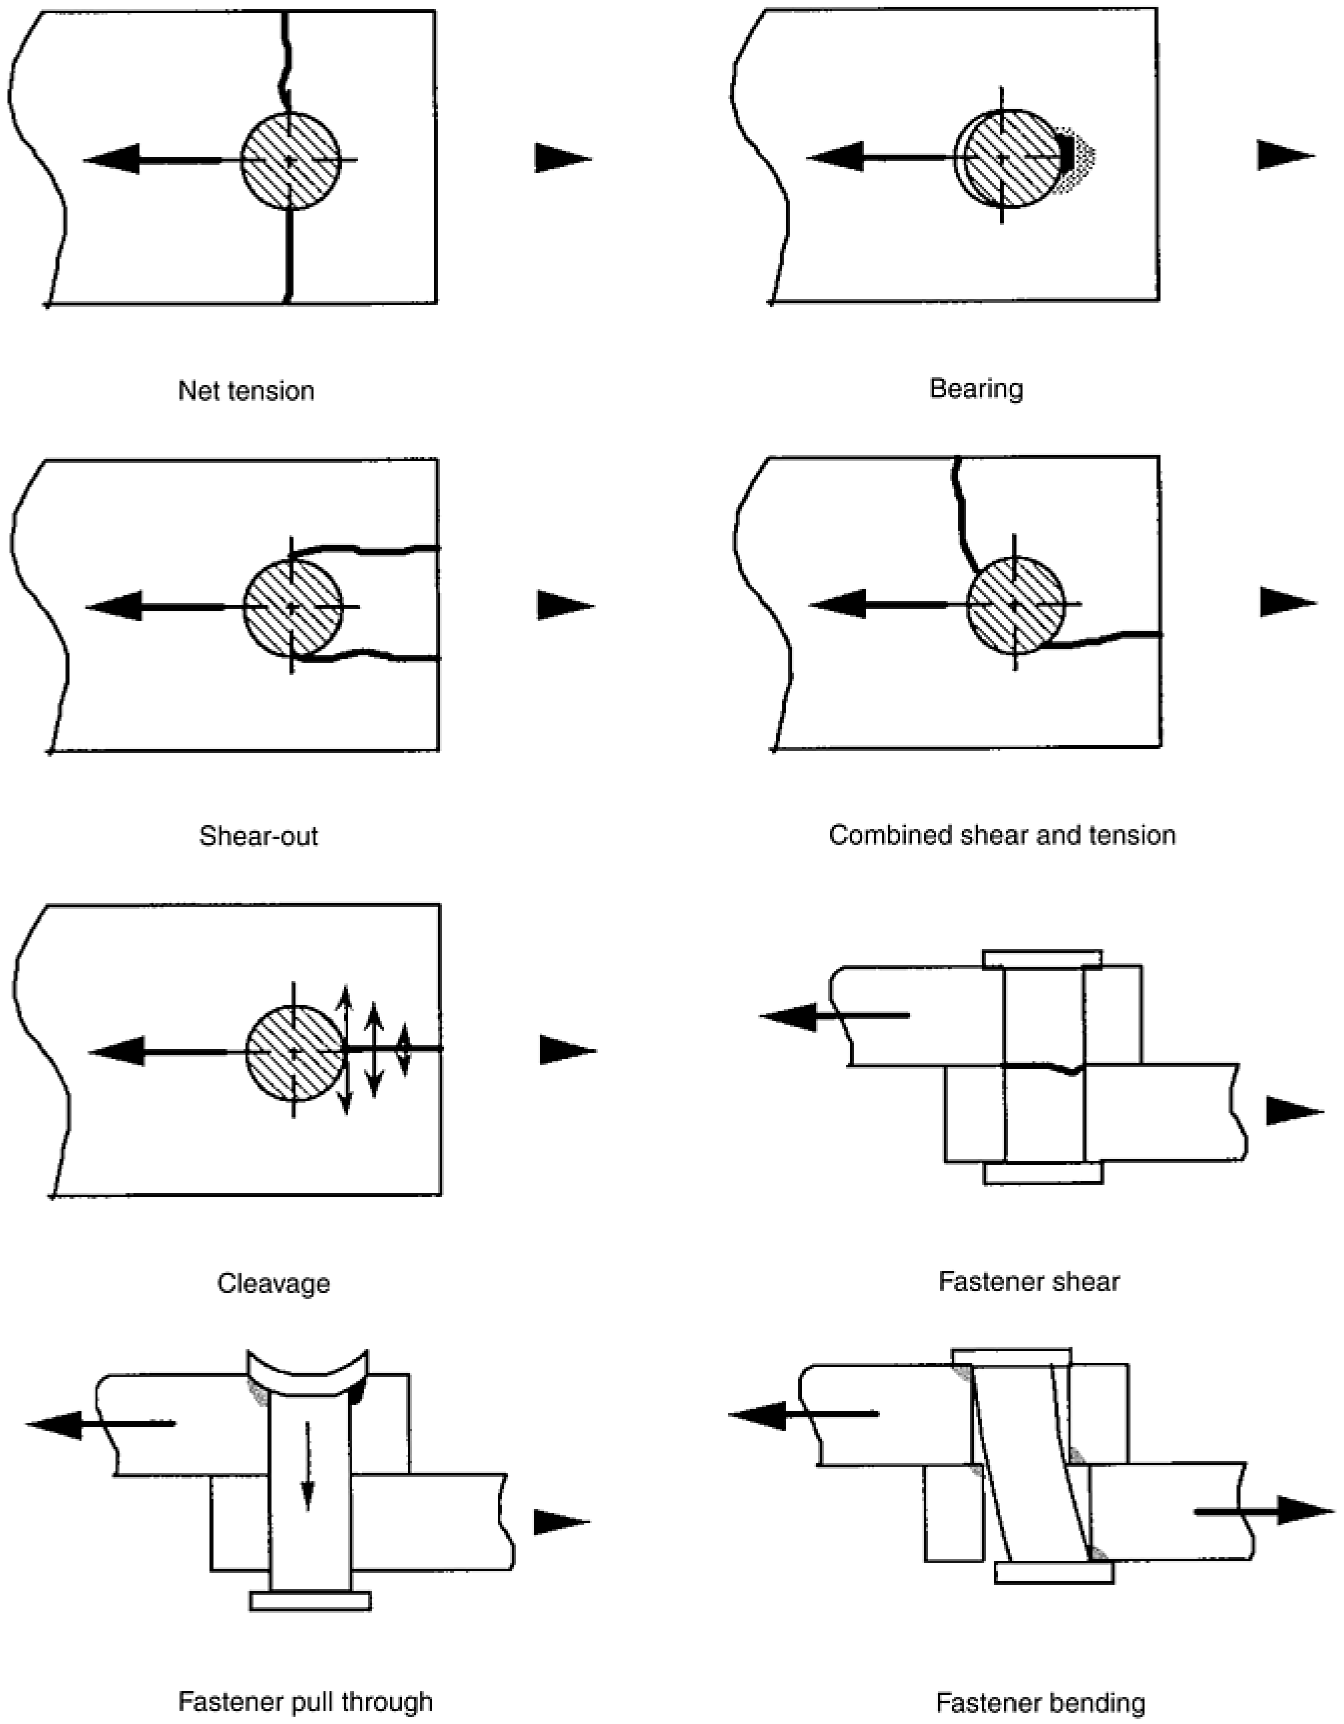

Fig. 4 Failure modes of mechanically fastened joints

Adhesively bonded repairs are needed for advanced composite structures that have already been manufactured and were not designed for bolted repairs. They are also needed for the very thin skins used on fairings and control surfaces. However, despite the need, many of today's composite designs contain areas in which no structural repair at all is possible.

The understanding of what can be adhesively bonded and what cannot starts with an assessment of the relative strengths of the bonded joints themselves and the laminates that are to be bonded together. That assessment is best performed in terms of the local load intensity (load per unit width) rather than of the stresses (load per unit area) in either the adherends or adhesive. As a rule, light loads are resisted by thin structure and heavy loads by thick structure, so the thickness of the laminate is the most appropriate independent variable here. For thin laminate, it is always possible to design an adhesively bonded joint that is inherently stronger than the adherends being bonded together (see Fig. 3 in the article "Bolted and Bonded Joints" in this Volume). For this discussion, it is sufficient to recognize that the simplest joint configurations are applicable to thin bonded structures, while thick structures need more complex joints, as shown in Fig. 5.

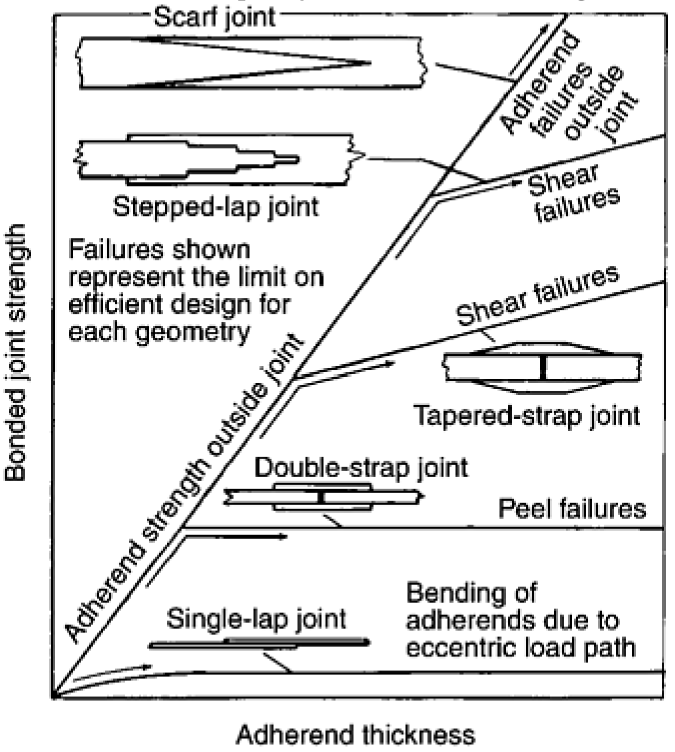

Fig. 5 Relative uses of different bonded joint types

Adhesively Bonded Joint Failure Modes. The failure modes of adhesively bonded joints are illustrated in Fig. 6. Adherend failure is the preferred failure mode, and the strength of the adhesive in cohesive shear must be designed to be at least half as much stronger than the adherends. Adherend and cohesive peel failure mode are controlled by detailed joint end design. Adhesive failure is excluded by specific and detailed attention to surface preparation.

Design Guidelines

Some proponents of advanced composite structures claim that the main weight savings are attained because fiber patterns can be tailored to be orthotropic, thereby uncoupling the materials needed for the bending and torsion requirements of wings, for example. Actually, the converse is closer to the truth. Composite monolayers have so little strength in the transverse fiber direction that it is necessary to include fibers in every direction for which some load condition exists. In contrast, for adhesively bonded laminated metal alloy structures, each laminate can perform double or triple duties, because the same layers can react to different loads that do not occur simultaneously.

The need for fibers in every direction in a composite laminate is most pronounced around bolt holes. (The distribution of hoop and bearing stresses is shown in Fig. 24 in the article “Bolted and Bonded Joints” in this Volume.) It is not surprising that the quasi-isotropic pattern (0°, ±45°, 90°) with one quarter of the layers in each of the four directions lies in the middle of a plateau (of bolt bearing strength) on the plane of varying fiber patterns. Excessive deviation from that pattern involves substantial loss of bolted joint strength. The preferred fiber patterns for bolted or riveted composite structures are shown in Fig. 7 for the family of laminates based on the 0°, ±45°, 90° directions.

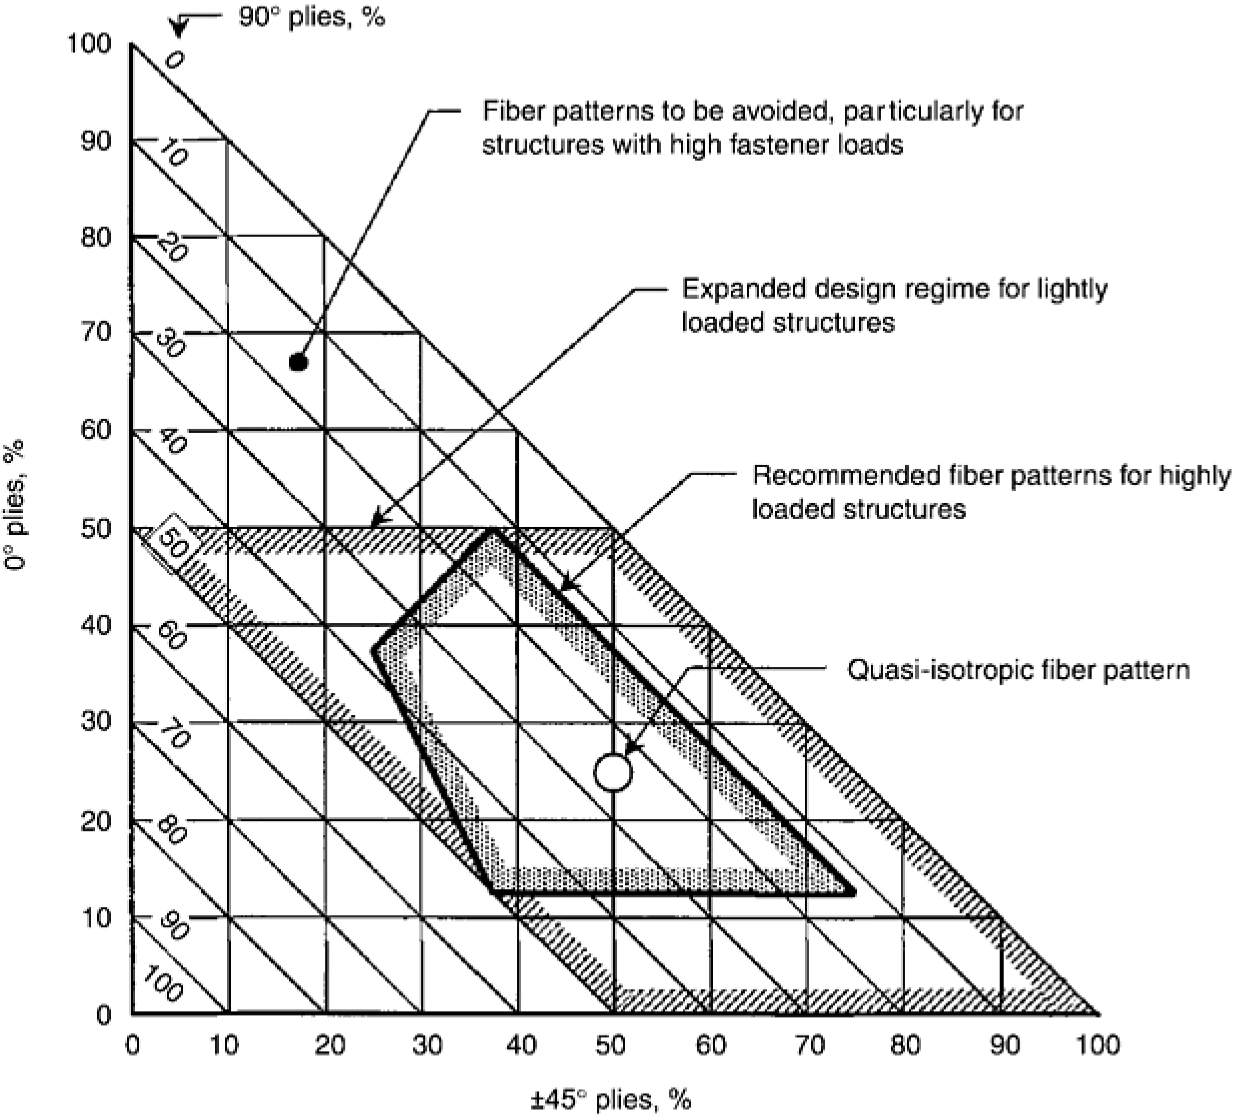

Fig. 7 Selection of lay-up pattern for carbon-fiber-reinforced composite laminates

It should be noted that there is a minimum requirement for about 12.5% of the fibers in each of the four directions. In addition, a good balance of strength around the circumference of the bolt bearing area is achieved with a maximum 37.5% of the fibers in any one direction. Figure 8 shows a larger regime than Fig. 7, limited by no more than 50% of the fibers in any one of the four directions, that is suitable for the mechanical repair of lightly loaded, minimum gage composite structures. Those laminates will not split longitudinally provided that the applied loads are restricted. However, for the heavily loaded primary composite structures, the fiber patterns should be confined within the area shown in Fig. 7, not Fig. 8.

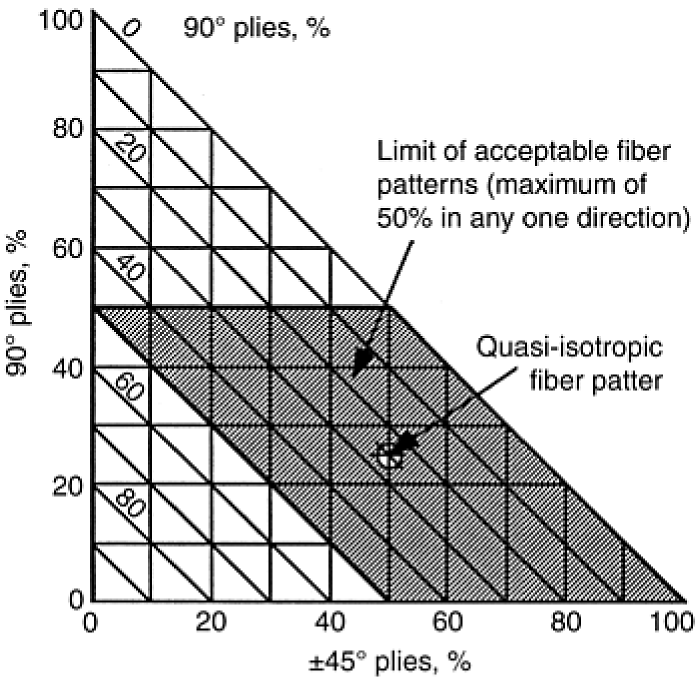

Fig. 8 Selection of lay-up pattern for bolted repair of lightly loaded fibrous composite laminates

Adhesively bonded repairs are most suitable for thin, lightly loaded structures for two reasons. The first reason is the complexity of the joints needed for the transfer of large bond loads. The titanium-to-composite stepped-lap joints are difficult enough to make as original structure, let alone as an after-the-fact repair. Second, an adhesively bonded joint must never be allowed to be weaker than the members it is joining; otherwise, it does not tolerate damage and could act as a weak link fuse. Another powerful reason for not using bonded repair of a small hole in thick laminates is the large amount of undamaged material that is removed for a scarf repair. For the majority of structural adhesives used, the scarf angle is limited to 3°.

Bolted or Riveted Repairs. The few keys to successful bolted or riveted repairs of advanced composite structures can be expressed as follows:

- The original laminate must have no location where the stresses are so high that drilling repair holes will result in an unacceptable loss of ultimate strength. Typical stress limits are given in Fig. 9; they indicate a need to design to no more than about 50% of the unnotched material allowable strengths. More such design information is given in Fig. 10, in terms of the more customary design strain levels. It should be noted, however, that these strains are not as independent of fiber pattern as was once believed.
- The bearing stresses must be kept much lower than the single-hole bearing allowables, if efficient bolted joints are to be designed. The need to restrict the design bearing stress is indicated in Fig. 10, which relates the interaction between bearing and bypass stresses to the strengths of the laminate. These load increments also apply at each bolt in a multirow joint.
- The original laminates must not be excessively orthotropic. A minimum of 12.5% of the fibers in each of the 0°, ±45°, and 90° directions is desirable, along with a maximum of 37.5%, as shown in Fig. 7. The need for such a restriction on fiber patterns is often overlooked, if the original structure is all bonded or co-cured.
- Optimal bolted joint geometries can be computed, as in Ref 5 and 6. Nonoptimal geometries can easily result in joints far weaker than anticipated.
- Neither fully plastic nor perfectly elastic bolted joint analyses are suitable for advanced composites. This is evident from Fig. 11, which shows that the two-straight-line designs, akin to typical metal structural analysis, are inappropriate and often dangerous for composites. That two-straight-line method is based on a uniform bearing allowable applied to the hole and a fictitious universal tensile strength applied to the net section. Linear finite-element analysis of bolted composite joints is unduly conservative, unless some fudge factor is used. Actually, designing bolted composite joints is not very difficult, as explained in Ref 6 and 7, unless one seeks the maximum efficiency for a splice.

- The need for repair should be recognized at the time of the design, and the use of laminate optimization programs that ignore such practical considerations as repair should be resisted, even if doing so results in a reduction in the weight saved.

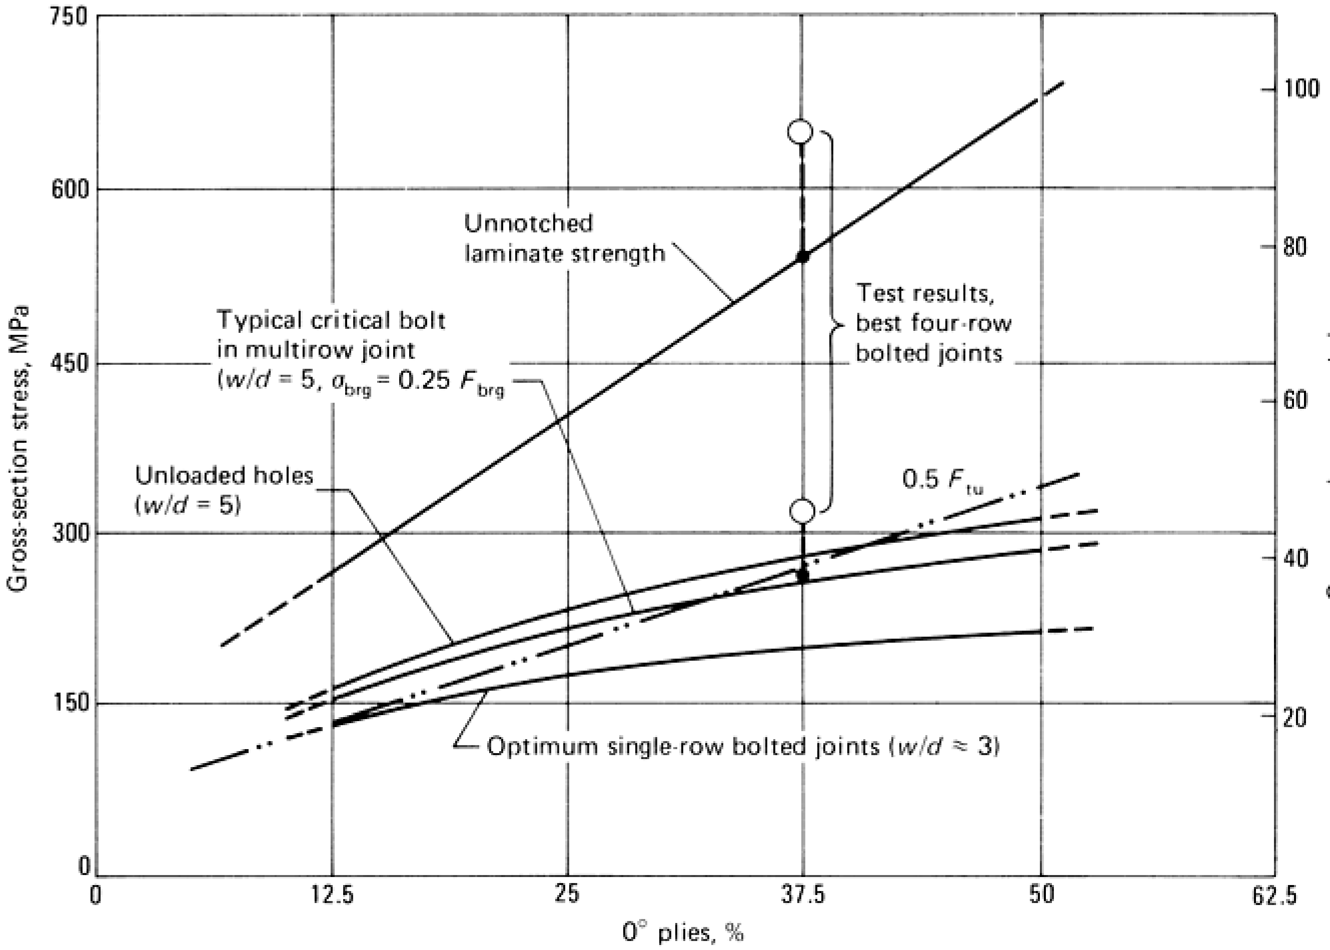

Fig. 9 Gross-section design stresses (*B*-basis allowables) for bolted composite structures (graphite/epoxy laminates). Chart is applicable for bolts up to 9.5 mm (0.375 in.) in diameter. Larger bolts are associated with progressively lower laminate stresses. σ_{brg}, bearing stress ($\sigma_{brg}=P/dt$, where *P* is the load, *d* is the bolt diameter, and *t* is laminate thickness), F_{brg}, composite ultimate bearing strength; F_{tu}, composite ultimate tensile strength parallel to the applied loads.

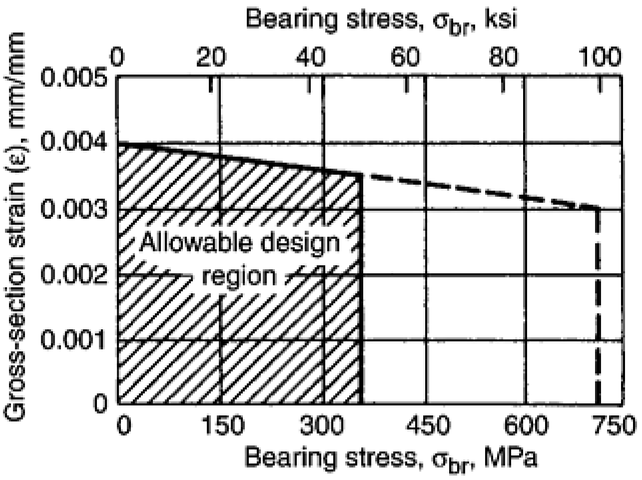

Fig. 10 Design strain levels for bolted graphite/epoxy structures

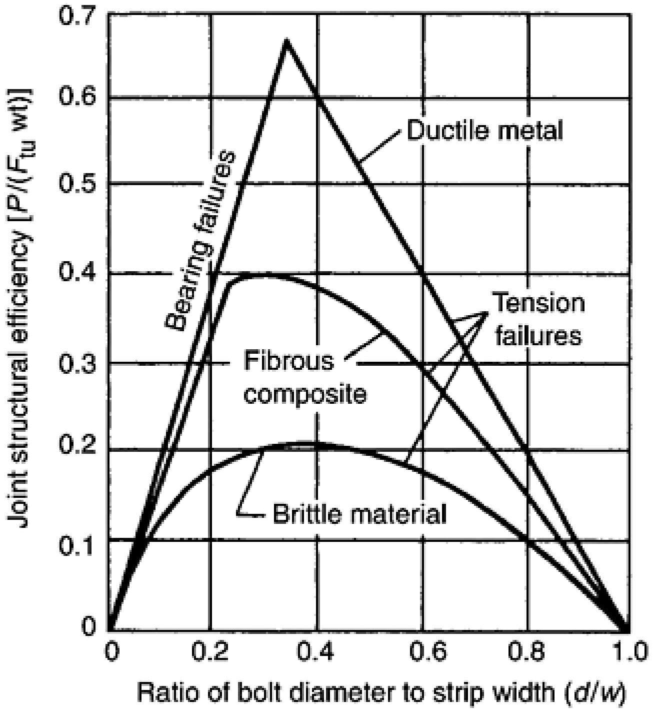

Fig. 11 Relationship between strengths of bolted joints in ductile, fibrous composite and brittle materials

Adhesively Bonded Repairs. The few keys to successful adhesively bonded repairs of advanced composite structures are as follows (but are based on good initial design):

- Only lightly loaded structures are considered practical for bonded repairs. The limits are the equivalent of 3.2 mm (0.125 in.) thick aluminum alloy for a two-side bond or 1.6 mm (0.063 in.) if only a one-side bond can be accomplished.
- An effective surface preparation technique is of paramount importance, especially if a metallic adherend is involved (in which case a chemical surface treatment may be essential).
- Patches should be precured wherever possible to avoid overheating the basic structure or joggling the fibers in the patch, even though such precured patches would usually not permit flush repairs to be made.
- Particularly for a co-cured repair, it is imperative to slowly and carefully dry out any absorbed moisture in the laminate or free water in honeycomb cells. Some honeycomb parts have been known to have so much water in the cells that the weight of the parts has been increased to as much as three times the dry structural weight. More closely monitored inspection of this past problem in sandwich panels limits this occurrence today. However, moisture ingress into honeycomb cells through thin porous (usually co-cured) face sheets remains a potentially serious problem with many such structures in service today. When the resin was not subject to autoclave pressure during the cure cycle, but to the vent pressure (i.e. atmospheric pressure at the most, or some level of vacuum at the least) higher than usual levels of porosity exist in such structures. Consequently, it is imperative not to use bare aluminum cores in such structures, but to use phosphoric acid anodized (PAA) cores instead. Even Nomex cores soften appreciably when immersed in standing water. For this reason, more recent structures have included surfacing layers of adhesive film (akin to gel coating on marine vessels) to minimize the occurrence of pin holes in the outer face sheets. Many have impervious Tedlar sheets cured on the inside of the parts to act as a barrier there, where the skins are often even thinner. (Some such structures now use pre-cured outer face sheets, cured at autoclave pressure, before the remainder of the structure is co-bonded to them.) The added structural weight is far less than that of the water that would otherwise have been absorbed which has, on occasions been far greater than the original structural weight. Nevertheless, when this additional weight needed to keep the water out is accounted for properly in the initial design trade-off studies, it is usually found that the multirib postbuckled thin-skin design, such as the DC-10 composite upper aft rudder, is lighter. Such designs can also be less expensive to build as well as easier to maintain than equivalent honeycomb designs. The same cannot be said for designs involving a

combination of honeycomb sandwich cores, in which water collects, and ultrathin composite facesheets, through which it passes.
- The design of bonded repair splices is straightforward—unless one has to adhesively bond a thick, damaged laminate that had been designed to a high strain level that will not permit the use of a bolted or riveted repair.

Honeycomb Sandwich Panel Construction. Honeycomb sandwich constructions have been used extensively for lightly loaded control surfaces, access doors, and fairings on large commercial transport aircraft; however, it is questionable whether this represents an improvement over the sheet metal components they replaced. Paradoxically, there has been a dearth of honeycomb composite structures in applications where slightly greater load intensities would make them more appealing. This is explained at length in Ref 3.

Leaving aside the difficulties associated with manufacturing fibrous composite honeycomb panels, there are service problems that become acute when the facesheets contain less than three layers of woven fabric. Because of high tensile residual thermal stresses in the resin matrix for autoclave-cured graphite/epoxies and aramid/epoxies, through-cracks grow easily in the middle of each bundle of fibers, and the components fill up rapidly with water. While actually a design problem, this situation is often misinterpreted as a Kevlar/Nomex (DuPont) material problem. (With graphite/epoxy, so far the cracks have not penetrated right through the facesheets; there is not any sign of water accumulation, mainly because most graphite fabrics have a finer weave than is customarily used with Kevlar.) There was no counterpart to these problems with the earlier oven-cured fiberglass/epoxy components because the residual stresses were lower and the resins were tougher. (Curiously, 20 years of satisfactory service with resins cured at 120 °C, or 250 °F, has been overridden by laboratory test- coupon results showing that 175 °C, or 350 °F, cures are needed to ensure durability in the service environment.)

The obvious solution to the moisture-ingress problem is to add more layers of composites to the facesheets, because the locally thickened areas where the fastener seams are located do not develop through-cracks. Weaves with smaller fiber bundles would also help. However, adding extra plies creates an apparent weight problem. The water absorbed through the minimum-gage facesheets is only in the part and not called out on the drawing; whereas the added plies would be counted as part of the weight even though they would weigh less than the water eventually transmitted through thinner and lighter facesheets.

Perfectly satisfactory metal control surface skins can be made from 0.4 mm (0.016 in.) thick aluminum alloy sheet, with adhesively bonded metal doublers to thicken the skin locally where the rivets are installed and to enhance the resistance to sonic fatigue. A structurally equivalent postbuckled design was used in the DC-10 graphite/epoxy rudders made at Douglas Aircraft Company under contract to National Aeronautics and Space Administration (NASA)-Langley. The composite skin was only 0.76 mm (0.030 in.) thick, and the entire structural box weighed only about two-thirds as much as the highly efficient metal design, even though during both initial testing and retesting of a composite rudder examined for possible deterioration in service, the rudder withstood 400% of design limit load without failure.

Despite concerns in some quarters about delaminations in postbuckled skins, more than 10 years of flight service on about 15 rudders has not revealed any such problems, mainly because the thin skins were not reinforced to delay the onset of buckling. Instead, they were allowed to deflect out of the way to relieve themselves of as much load as possible. Highlights of this technically very successful DC-10 composite rudder program are recorded in Ref 8.

This good application of composites to lightweight aircraft structures has not often been emulated, perhaps because most of the research into postbuckled composite structures has concerned thicker structures. In those cases, there is a very real possibility that any skin wrinkling would delaminate the structure at the stiffeners. The induced peel stresses are proportional to the fourth power of the thickness of the members being bonded together. Consequently, excessively thick postbuckled co-cured or bonded composite structures will delaminate, and moderately thick structures will need to be stitched together to prevent such delaminations. Another result of that same power law is that very thin composite structures can be allowed to buckle with impunity, because the induced peel stresses will be trivial, if the flange widths are adequate.

Honeycomb sandwich designs simply cannot compete with postbuckled designs of composites or metal. The 0.76 mm (0.030 in.) of graphite/ epoxy, which alone is structurally adequate when bonded to stable rib caps and spar caps, can be compared with the combination of a typical (nonbuckling) minimum gage exterior facesheet 0.63 mm (0.025 in.) thick, an interior facesheet 0.43 mm (0.017 in.) thick, a honeycomb core of 12.7 mm (0.5

in.), and four layers of film adhesive, each 0.125 mm (0.005 in.) thick. The smaller number of ribs in the honeycomb designs does not make up for the heavier skins. Worse, that sandwich skin is very prone to impact damage by debris thrown up from the runway and by hailstorms. The authors are concerned that the high incidence of minor damage to thin-skinned honeycomb structures in service will become a black mark against all composite structures. They fear that people might change back to metal structures, rather than admit that the problem was really caused by an inappropriate design concept. Such a reaction has already occurred in relation to Kevlar/Nomex construction, with a reversion to heavier fiberglass/epoxy facings to solve the problem of entrapment of water in the honeycomb core. An alternative solution of retaining the Kevlar skin because of its high impact resistance and eliminating the honeycomb has not been adopted, presumably because doing so would have added to the redesign and tooling costs. Yet, the microcracks in the Kevlar would never have been of concern if there had not been cavities in which water could collect.

A further undesirable feature common to many advanced composite control surfaces is the use of mechanical fasteners instead of adhesive bonding. This practice is particularly undesirable for mass-balanced control surfaces. There is a widespread irrational aversion to the use of secondary adhesive bonding with advanced composites. Because the fasteners must be countersunk and the minimum-size threaded fastener used is 4.76 mm ($\frac{3}{16}$in.) in diameter, whereas 3.2 mm ($\frac{1}{8}$in.) diameter rivets are permitted in the metal structure, the composite panels include thickened seams over all rib caps and spar caps that are not needed for structural reasons, but merely accommodate the greater countersunk head size. That weight penalty is compounded by replacing 3.2 mm ($\frac{1}{8}$in.) diameter rivets with 4.76 mm ($\frac{3}{16}$in.) diameter threaded fasteners on an almost one-for-one basis and by the need for additional balance weights.

In the DC-10 rudder design philosophy, the unreinforced skins would be bonded directly to the rib caps and rear spar caps in the future. The 20 rudders made under the flight service evaluation program were co-cured as complete boxes in a single operation, but because the design remains an object lesson for the future, the manufacturing method used needs to be improved. Hart-Smith first saw such work in Europe early in the 1980s, by which time it had already been developed to include preheating both the flat lay- ups and the rubber bag to enable even thicker sections to be flanged. Suggested design and manufacturing improvements for subsequent work on lightly loaded composite structures are given in Ref 8. Any such future designs would be bonded together from individual, uniformly thick details. The only thickening for fasteners would be along a removable front spar, where the moment arm with respect to the hinge line is small and so is the effect on the balance weights.

It is noteworthy that the key to the considerable excess strength of the DC-10 composite rudders was between 0.11 and 0.23 kg ($\frac{1}{4}$and $\frac{1}{2}$lb) of conservatism at the bolted joints attaching the hinge and actuator fittings to the composite structure; the remainder of the structure was almost all of minimum gage. The judicious decision to not seek the last possible ounce of weight saving was directly responsible for an uneventful and quick series of certification tests.

The use of honeycomb construction for fairings, such as at the wing roots, is also not an optimal solution. Unfortunately, it has been used extensively, because it is the quickest to draw and the cheapest to tool, due to the small number of parts. Consequently, such designs can also maximize the return on investment for subcontractors by minimizing their up-front costs. The higher recurring costs are passed on to the customer.

Apart from the weight and moisture absorption problems discussed earlier, honeycomb panels present one other serious potential problem. If they warp out of shape during manufacture, they require tremendous force to make them fit on assembly to the basic structure or line up properly with similar adjacent panels. Such problems were not as severe with the older fiberglass panels, because of the low modulus of those facesheets. When co-cured as a single assembly, the panels also tend to suffer from pinholes on the surface, and these must be filled and glazed before the panels can be painted. An alternative design concept that is torsionally soft and easy to assemble is a hollow-hat stiffened single-skin arrangement, as shown in Fig. 12. If a secondary adhesive bonding process were used instead of co-curing, spare parts would be available to facilitate repairs. In addition, repairs would not often be needed, because the single solid skin would be less prone to impact damage than today's minimum-gage skins on each side of a honeycomb or foam core.

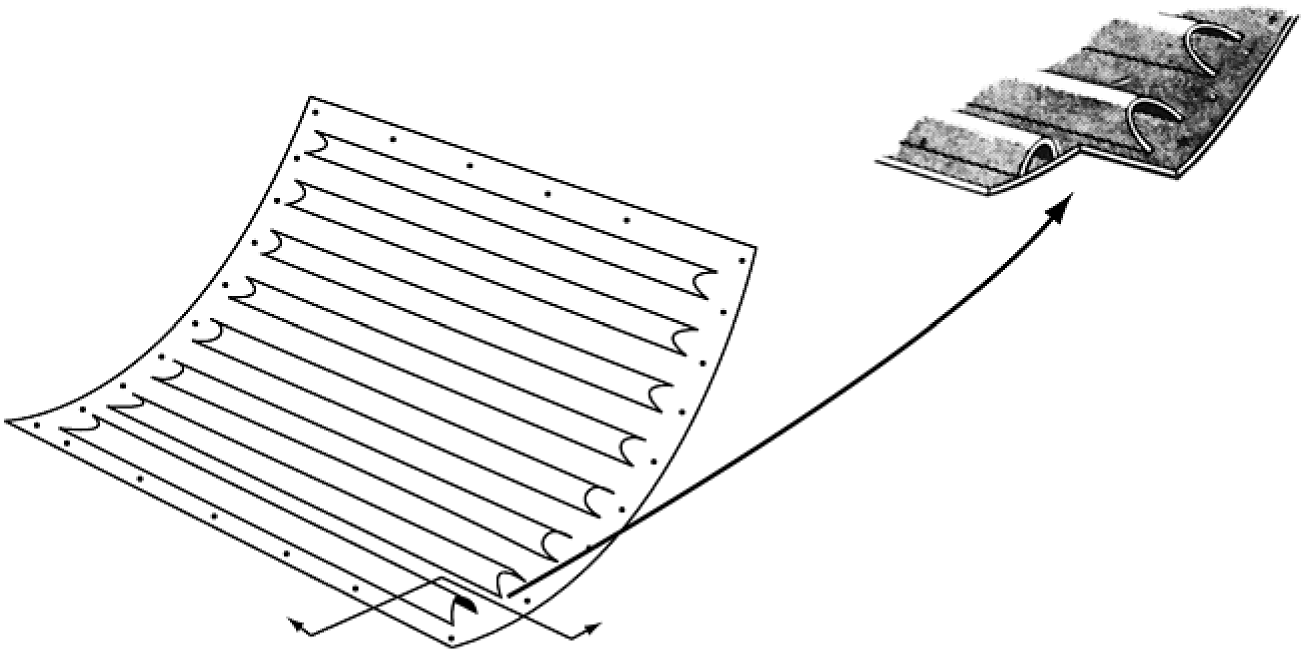

Fig. 12 Hollow-hat stiffened composite panel

Skin tools for such fairings can easily be made by stretch forming a metal sheet over a numerically machined wooden master model. Such woodwork is common for automobile prototyping. The Lear Fan spar masters were made from wood in a most successful subcontract. Stiffener tools can be made by draping long sections of flexible rubber mandrels (made in simple straight tools) inside the skin tool, if only a few panels are needed. Machined metal tools would be preferable, if many components are needed.

Designs of the type shown in Fig. 12 are easily adaptable to low-cost manufacture using thermoplastics by designing components, such as the trailing-edge panel in Fig. 13, as two uniformly thick panels subsequently glued or fused together. One panel defines the exterior shape, while the other provides the stiffening elements and local doublers. Each component is formed from a fully cross-plied flat pattern to avoid the internal bridging and wrinkles associated with a layer-by-layer hand lay-up directly on the tool.

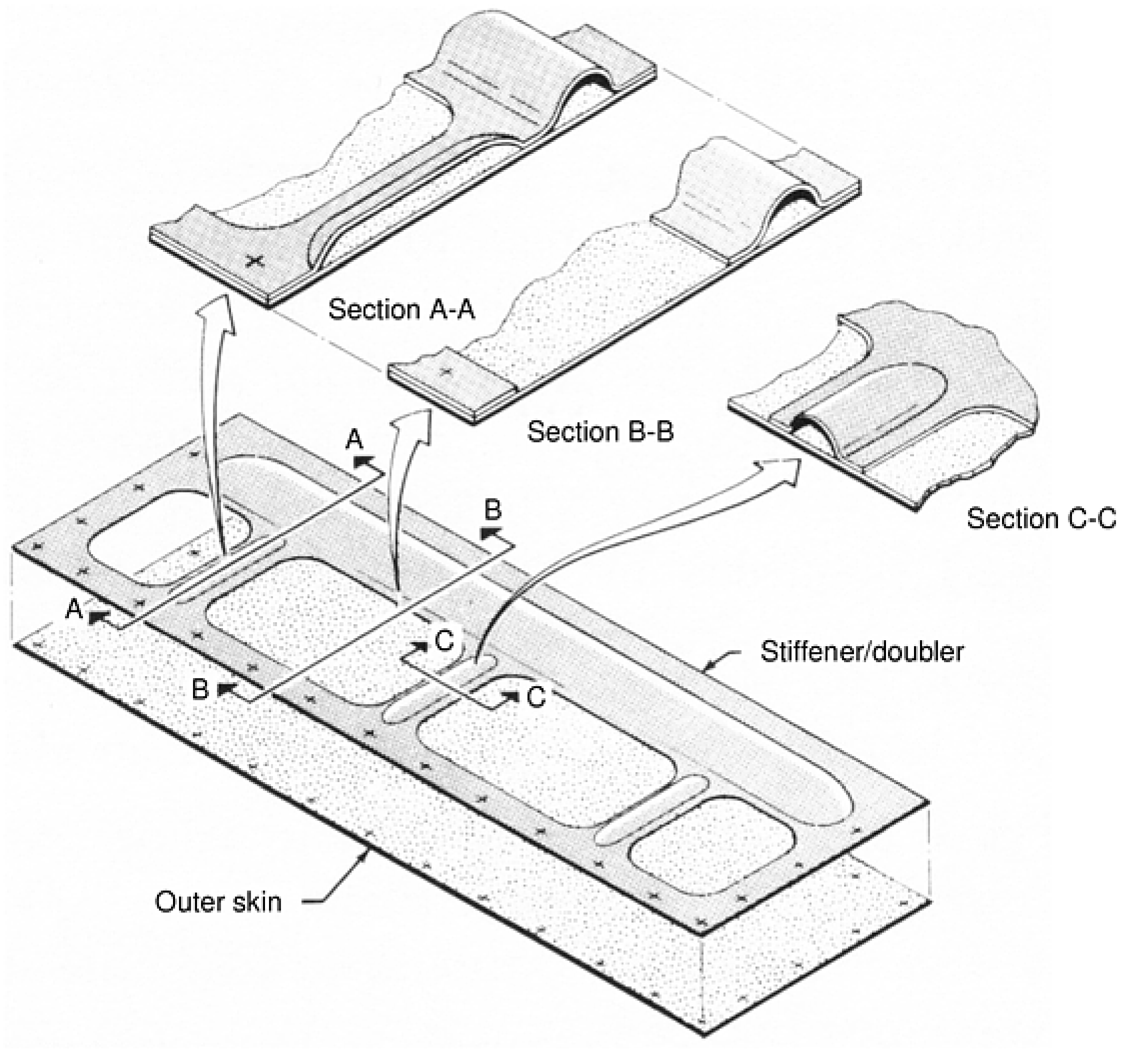

Fig. 13 Construction of two-piece thermoplastic composite access panels. Exploded views (not to scale). Section views show outer skin bonded to reinforcement.

It is noteworthy that the skin and stiffener tools are each complete in a single component, without any removable details of the type needed to co-cure integral blade stiffeners, for example. The design concept in Fig. 13 is actually a development of an earlier idea for making such panels out of thermoset resins in a single operation. Figure 14 shows the arrangement of the first such panel built.

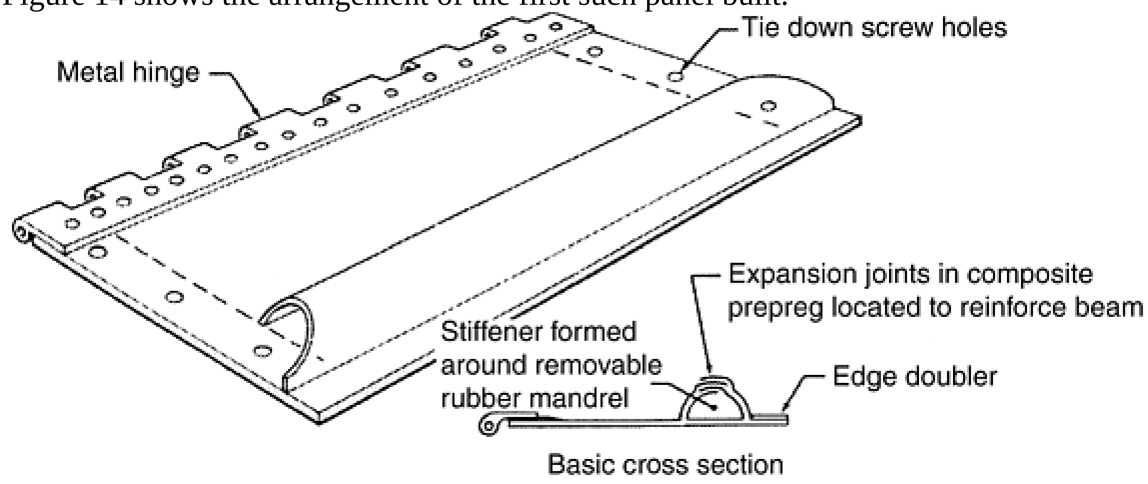

Fig. 14 Integrally stiffened co-cured composite trailing-edge panel

The rational use of honeycomb sandwich construction with fibrous composites requires that applications with higher load intensities be found to justify the necessarily thicker facings than have been used on aircraft control surfaces and fairings. Figure 15 shows how the optimal structural geometry varies with load intensity; honeycomb is best only for a limited range between thin postbuckled single-skin structures and thick discretely

stiffened structures that are resistant to buckling without the need for a continuous second skin. Alternatively, as on the wing of the round-the-world Voyager and modern composite sailplanes, sandwich construction can be justified by the greatly improved control of the wing section profile, leading to a dramatic reduction in drag. Similar special cases include the passenger floors of large aircraft; it would be virtually impossible to wheel the food and drink carts around on a spongy, discretely stiffened single-skin floor.

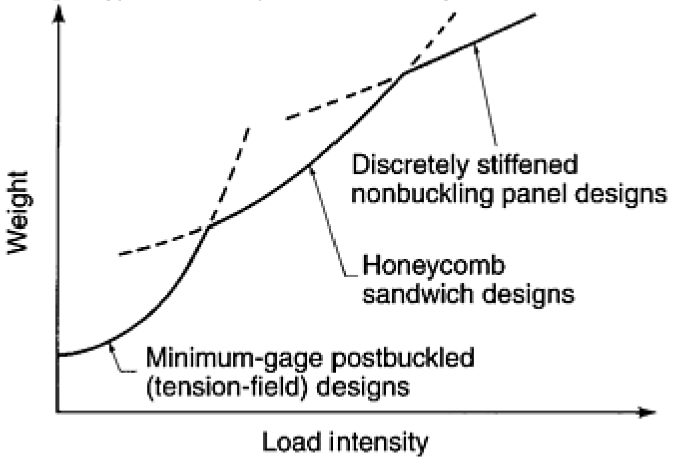

Fig. 15 Relative weights of different structural configurations

Integrally Stiffened Co-cured Composite Structures. Many of today's advanced composite structures contain integrally stiffened co- cured panels or assemblies. These are used to save on tooling costs, but there is also a desire to strengthen composites by eliminating bolt holes. This improves the fracture toughness by alternating hard and soft areas to prevent any initial damage from spreading catastrophically under subsequent loads. The reason for this latter technique is that basic uniformly patterned composites have specific fracture toughness only about half as high as that of today's pressurized metal fuselages. By alternating stiff and soft strips, where the stiff strips are stronger than the soft strips, damage to either is confined or will not spread beyond the adjacent strips. While that technique has been shown by test to control the spread of damage, neither the stiff nor the soft areas lend themselves to bolted or riveted repairs. The stiff areas, being rich in 0° fibers, tend to split or delaminate longitudinally. Indeed, that is how the spread of damage is confined. The soft areas, having very few 0° fibers, cannot develop substantial strength, because the strains there are limited by the bolt holes in the adjacent stiff areas. These different strains-to-failure for each fiber pattern are explained in Ref 5.

This technique of attaining damage tolerance at the cost of repairability is obviously unsatisfactory. A careful study of the manner in which damage tolerance is achieved in metal aircraft structures and an appreciation of the behavior of bolted joints in different composite fiber patterns indicate that other approaches could achieve both goals simultaneously. Integrally stiffened machined metal planks are known to provide the least damage tolerance of all, in the sense that a crack, once started, will continue to grow across skin area and stiffener alike. In built-up metal structures, on the other hand, neither a slow- growing fatigue crack nor a fast fracture needs transfer from one member into another. In thin adhesively bonded structure, the glue layer provides the flexibility and the unbroken member the alternate load path to arrest the crack. The rivets or bolts in light or heavy built-up metal structures achieve the same purpose.

In short, damage tolerance in metal structures relies upon the absence of one-piece integrally stiffened structures, which are used mainly in the compression skins of wings, which are not fatigue-critical, and on horizontal tails, where the normal operating stresses are only a small fraction of those experienced with an extreme design load.

There is no reason to expect that the use of discrete members in fibrous composite structures would be any less effective in providing damage tolerance than in metal aircraft structures. Likewise, depending on the thickness of the members involved, adhesive bonding, rivets, or bolts should be used, as appropriate, for joining. For example, consider a composite wing skin. Determinable amounts of spanwise bending and torsion material are needed, along with a compatible amount of chordwise material. All of this material could be co-cured together in the scheme at the left of Fig. 16. Alternatively, the structure could be created by bolting together the elements shown at the right, where the skin would typically be of a quasi-isotropic (25, 50, 25) pattern to provide the torsional material. The stiffeners and doubler would be made from the (50, 37.5, 12.5) pattern and would provide the bulk of the bending material. All of these patterns could be bolted together, or, if the structure were thin enough, they could be adhesively bonded.

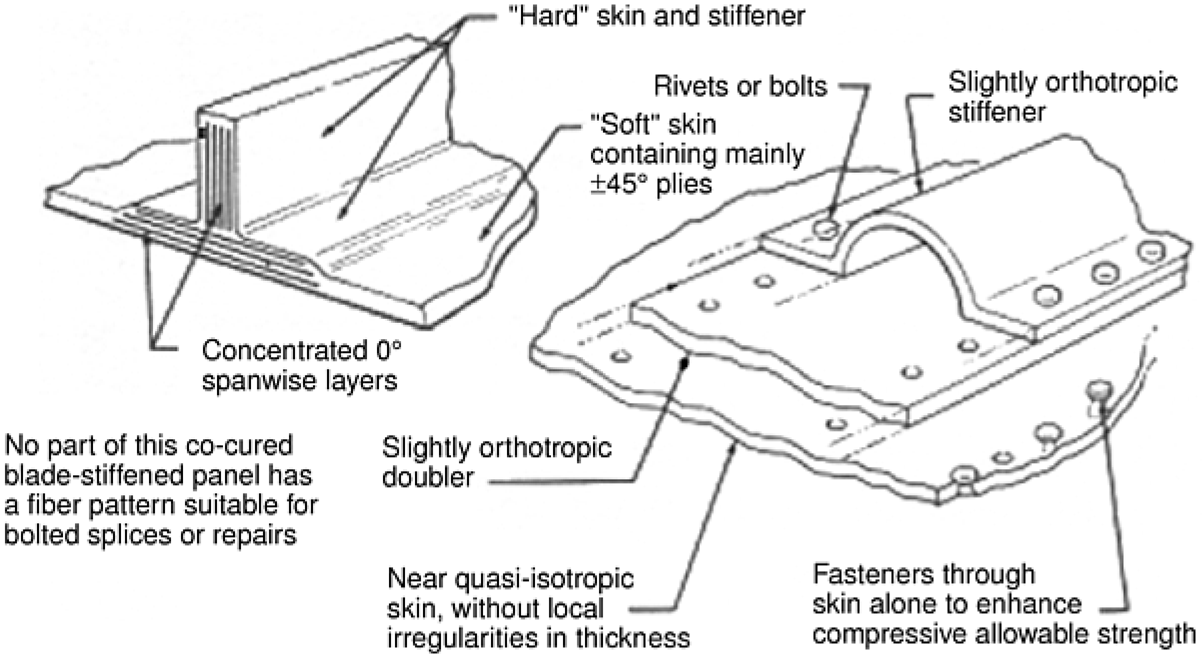

Fig. 16 Merits of not co-curing primary composite structure

Now, this built-up composite structure obviously has good damage tolerance as well as inherent repairability. Moreover, it also has some very powerful manufacturing advantages. The difficulty in manufacturing parts is roughly proportional to the maximum thickness of the parts. It is not at all unusual to have to consolidate complex lay-ups every 0.76 mm (0.030 in.) or so during the lay-up to eliminate trapped voids and to minimize wrinkling of the plies. The three simple detail parts to the right of Fig. 16 are far easier to lay-up than the complex assemblies on the left and involve far fewer bagging cycles. The reason for the doubler, rather than a thicker stiffener, is that the two individually thinner parts are easier to lay-up and to fit together for final assembly. The choice of a hat stiffener is based on three considerations: its structural efficiency, the ease of forming it from a flat lay- up, and the way it can be flattened out for easy splicing at manufacturing breaks in the wing skins. The integrally stiffened constructions need not have any advantage in terms of compressive allowables; the built-up assemblies can be bonded and bolted just as easily as they can be bolted and sealed.

The price paid for these superior laminates is having a large number of fasteners. However, those fasteners may be needed anyway to arrest the spread of delamination. They can be looked upon as giant stitches, performing the same role that fiber stitches do in thin composite structures. The effectiveness of such fasteners in controlling the spread of delaminations in thick composite structures is analyzed in Ref 9 and 10.

There is another often-overlooked reason for avoiding highly loaded, integrally stiffened composite structures. Were a designer to advocate adhesive bonding the stringers to the wing skins in a C-5, 747, DC-10, or L-1011 instead of drivematic riveting, he would be quickly reassigned to another task. The same fate would befall him, and deservedly so, were he to advocate adhesive bonding alone for a large all-composite wing. Thin layers of structural adhesives are simply not strong enough to provide damage tolerance in such cases, even if they could transfer the running shear loads in a carefully designed structure with no discontinuities. Yet when some other designer advocates leaving that layer of adhesive out of such a composite wing structure and relying instead on a single layer of resin to connect the skin and stiffeners together, few people understand that such an integrally stiffened structure is weaker than an equivalent adhesively bonded one. (Actually, the adjacent layers of resin would fail prematurely and prevent the development of the full strength of such an adhesive layer.)

Unfortunately, integrally stiffened laminated designs are usually perceived as equivalent to integrally stiffened isotropic metal structures, with total disregard of the weak interlaminar strength of the composite. A more appropriate comparison would be with adhesively bonded metal structures in which someone replaced the layer of adhesive with a layer of wet paint primer.

To be fair, it should be acknowledged that a few of the integrally stiffened composite panels have been designed in such a way that the fibers, rather than the resin, transfer most of the load between the stiffeners and the skin. The criticism in the preceding paragraph was not intended to refer to these design concepts. The following comments, however, do refer to all integrally stiffened panels.

Perhaps the greatest difficulty associated with integral stringers on large composite wing structures is in transferring massive loads into or out of the stringers at manufacturing breaks. For typical average wing skin load intensities of 207 MPa (30 ksi), it is usual to have individual stiffener loads of 220 to 440 kN (50 to 100 kips) at the nacelle or the side of the fuselage. In most panels tested thus far, such loads have been applied with block compression into potted ends of the composite structure. Transferring such loads through a bolted or adhesively bonded splice is no easy task. Most major aerospace manufacturers in the United States and abroad have experienced catastrophic failures of large composite structures that resulted from single overloaded bolt holes. This was true for the A-4 horizontal stabilizer failure from the front spar fitting and the Falcon 10 lower wing skin near the landing gear cutout. The DC-10 vertical tail failed through a rear spar access hole, because of insufficient structural deformation for bolts in clearance holes to pick up load. Each component was redesigned and retested before being shown to have adequate strength.

One is reminded of the difficulties encountered when trying to use 7079 aluminum alloys that were once supposed to be superior to 7075 material for aircraft structures. They presented so many problems that they are no longer used. Highly orthotropic composite laminates present much the same kind of problem, both in the original designs and for repairs—it is very difficult to design reliably for very high loads in any very brittle material, and the material is very unforgiving of any error in design or analysis.

There is another powerful reason for preferring to secondarily bond precured composite skins and stiffeners instead of co-curing them together. The bonding approach avoids the highly visible exterior mark-off associated with co-curing. As shown in Fig. 3, the locally excessive resin buildups in the co-cured structures contract during the cool-down period after cure. That mark-off even occurs around the perimeters of honeycomb panels at the edge of the core. Because the remainder of such co-cured panels is usually visually perfect, the mark-off needs subsequent filling and sanding before painting to enhance the cosmetic appearance of the panels. Those subsequent operations tend to negate the original savings from co-curing.

In summary, it can be stated that experience has shown that the manufacturing economies sought by co-cured integrally stiffened constructions are often illusory for large panels. More importantly, the co-curing has frequently led to designs that cannot be repaired. The authors suggest other ways of achieving desirable goals in terms of manufacturing costs and damage tolerance without sacrificing repairability, such as bonding or mechanically fastening separate precured details.

Design for Supportability

It is possible to extract valuable lessons about what to do and what not to do in the future from the many composite aircraft components that have been built since the 1980s. Perhaps the most valuable conclusion is that it is vital to start with a well-conceived plan that coordinates the concurrent activities of various participating groups, rather than allowing work to pass from group to group sequentially. Success can be achieved only when good use is made of the preliminary design phase to uncover and solve potential problems before the majority of the budget has been committed. Failure to confirm that the tooling and manufacturing approaches will work before the formal design commences is an invitation to disaster. Experience has also taught that success is unlikely if the assigned personnel do not include a core of proficient experts; composites are too unforgiving for learning on the job. Perhaps the greatest trap is a feeling of complacency that composites are such wondrous materials that nothing can go wrong.

The Dos and Don'ts of Composites Structural Design.

Some technical and managerial lessons learned include the following:

- Don't design for primary loads being transferred by interlaminar shear; also, avoid secondary induced interlaminar loads.
- Do plan the tooling and manufacturing approach during the preliminary design phase to ensure that all three are compatible. Don't complete the design in isolation and then worry afterward about how to build it at a specified production rate.
- Don't begin the formal design drawings until after the first part has been completed. Do the drawings last to ensure that they are in conformity with the part.
- Don't design integral co-cured stiffening without expecting to pay for the more-expensive tooling needed to avoid hidden internal wrinkles. While seeming to be rather expensive, the metal-block tooling techniques developed at Messerschmitt-Bolkow-Blohm for Airbus tail surfaces and spoilers are appropriate for such components.
- Do thoroughly intersperse the different fiber directions and avoid having more than two 0.125 mm (0.005 in.) thick unidirectional plies adjacent when the angle change to the next direction is 90°, or more than four such plies when the angle change is 45°. (It should be noted that this imposes a limit on the maximum permissible percentage of fibers in any one direction.)
- Do require a minimum content of about 12.5% of the fibers in each of the four standard directions, 0°, +45°, 90°, and–45° (see Fig. 7).
- Don't permit in excess of 37.5% of the fibers to be oriented in any one direction, if the structure is mechanically fastened.
- Do be aware of abrupt internal ply drop-offs. Drop off plies in small increments, not all together; otherwise, the transitions in thickness will cause wrinkling of the fibers and possibly delaminations under load.
- Don't trust computer strength analysis or optimization programs that advocate the use of highly orthotropic fiber patterns.
- Don't design the basic structure first and the joints last—design the joints first, to maximize the structural efficiency, and fill in the gaps in between afterward.

- Do allow for the presence of loaded bolt holes, cutouts, or both in establishing the design strain levels that will be, in nearly all cases, appreciably less than those of unnotched laminates.
- Do not adhere blindly to original plans when difficulties arise. If three cure cycles are needed to manufacture a design that was supposed to be made in one shot, it is time to change to a different optimal design for two- stage manufacture.
- Do beware of subscale testing and proof-of- tool demonstrations. Many effects can be simulated only in actual size.
- Do understand the reasons behind historical precedents before following them in the future. What is optimal for one set of circumstances is often quite unsuitable for others.
- Do use secondary adhesive bonding extensively for thin, lightly loaded composite structures, restricting the use of mechanical fastening mainly to thicker, more heavily loaded structures.
- Don't be afraid to let thin composite skins wrinkle or buckle, but beware of allowing thick structure to do the same. It is wrong to add reinforcement to a structure merely to delay the onset of buckling; doing so just reduces the ultimate strength.
- Do consider the required production rate when deciding between a subassembly approach and fabrication of an essentially complete co-cured structure in one tool. The latter is best only for very low production rates, because, otherwise, it requires more replicates of the largest and most-costly tools.
- Don't be a slave to fashion. Understand the merits and limitations of past design and manufacturing techniques thoroughly before deciding on an approach for some given application.
- Don't repudiate 50 years of experience in designing metal aircraft structures as being of no value in composite construction. There is no real reason why composite structural arrangements should be fundamentally different from equivalent metal ones.
- Do take advantage of the greater dimensional control of composite detail parts made on metal tooling to integrate into one simple component what would normally have been made from several adjustable pieces in pressed or bent metal.
- Do understand that optimal design solutions are not generic. They vary, in particular, with load level, with the production rate, and with the need, or otherwise, for repair.
- Don't treat repairability and damage tolerance as afterthoughts once the static ultimate- strength design has been accomplished. All conditions need to be treated simultaneously.
- Don't complicate designs by seeking the last ounce of weight saving. Doing so will add unreasonably to the design and manufacturing costs.
- Don't be reluctant to design conservatively in local critical areas. The weight penalty for doing so is insignificant, while the savings in time during the development program can be enormous. Don't design to excessive bolt bearing stresses; doing so reduces the structural efficiency of the composite laminate.
- Don't ever design an adhesive bond to be the weak link in a structure. The bonds should always be stronger than the members being joined.
- Do be wary of induced peel stresses, both in adhesive layers and in the composite laminates.
- Don't be blind to the possibility that, for some structures, metals may be better or more cost- effective than fibrous composites.
- Don't standardize by using only one fiber and one resin for all applications. Follow metal practice that uses different alloys and heat treatments, as appropriate.
- Do remember the need to put fibers in every direction for which there is some significant load. When there are multiple load conditions, it is not permissible to optimize for only the most severe load on its own.
- Do remember to allow for expansion and contraction of the tools and composite material at different times during the cure cycle.
- Do be wary of unacceptably slow heat-up rates whenever the tooling (particularly rubber) has an excessive heat sink.
- Do be cautious about oversimplified cure cycles with no feedback control. Quality is often improved and inspection and rework costs reduced by extended consolidation periods prior to cure, by relating the pressure profile in the autoclave to the thermal profile and by temperature dwells within the cure cycles.
- Do provide slip joints within complicated lay- ups to ensure proper compaction and to ensure that there are no voids, bridges, or resin- rich buildups in the finished article. The same is true for the installation of bagging and breather material. Once verified by initial production, such details should be included in

the drawings. Reference axes at one location of a compound-curved panel are not sufficient to define the lay-up.

- Do remember that composites are very brittle. There is no yielding to provide forgiveness for mistakes about internal load distributions or underestimated stress concentrations.
- Don't be overawed by the mystique of the composites. With well-thought-out load paths and a sensible manufacturing plan, good composite structures are not difficult to design.

Designing for Repairability

L.J. Hart-Smith, The Boeing Company; R.B. Heslehurst, Australian Defence Force Academy

Specific Examples

Several typical skin repairs for the graphite/ and Kevlar/epoxy components on the MD-80 are described in this section. The same techniques can be applied to the Kevlar/ and fiberglass/epoxy fairings on this and other aircraft. The techniques are applicable to such components on virtually all subsonic aircraft, except for those in proximity to the engines.

Consider the MD-80 composite spoiler. The basic exterior skin consists of four layers of unidirectional AS4/3501-6 tape aligned in the ±45° directions with respect to the 0° reference of the leading and trailing edges of the spoiler. It has a full-depth honeycomb core of 4.8 mm ($\frac{3}{16}$in.) hexagonal cell size. Most of the in-service damage is expected to consist of small punctures to the 0.51 mm (0.020 in.) facings or dings in the trailing edge that will cause local delaminations. There also might be some surface bruising that crushes the honeycomb core without damaging the facesheets. If any damage is not too close to the fitting or front spar, there is no limit to the size of the damaged area that may be repaired structurally.

Co-cured repairs using the original composite material are not encouraged, because of the high probability that the 450 K (350 °F) cure would react adversely with any moisture that may have been absorbed by the laminate or collected in the cells. No repairs should be performed above 394 K (250 °F), and the range of 355 to 366 K (180 to 200 °F) is preferred.Those restrictions leave the options of repairing by using either a patch of precured tape made to the original specifications or a wet lay-up with three layers of 0.21 mm (0.0083 in.) thick 3PW AS4 woven graphite fabric impregnated with a resin (e.g., EA-956 or Ciba-Geigy 1300) that cures at room temperature, but is usually postcured at 355 to 366 K (180 to 200 °F). The initial cure may also be accelerated at the same temperature to reduce the elapsed time for repair. These repairs are illustrated in Fig. 17 and 18.

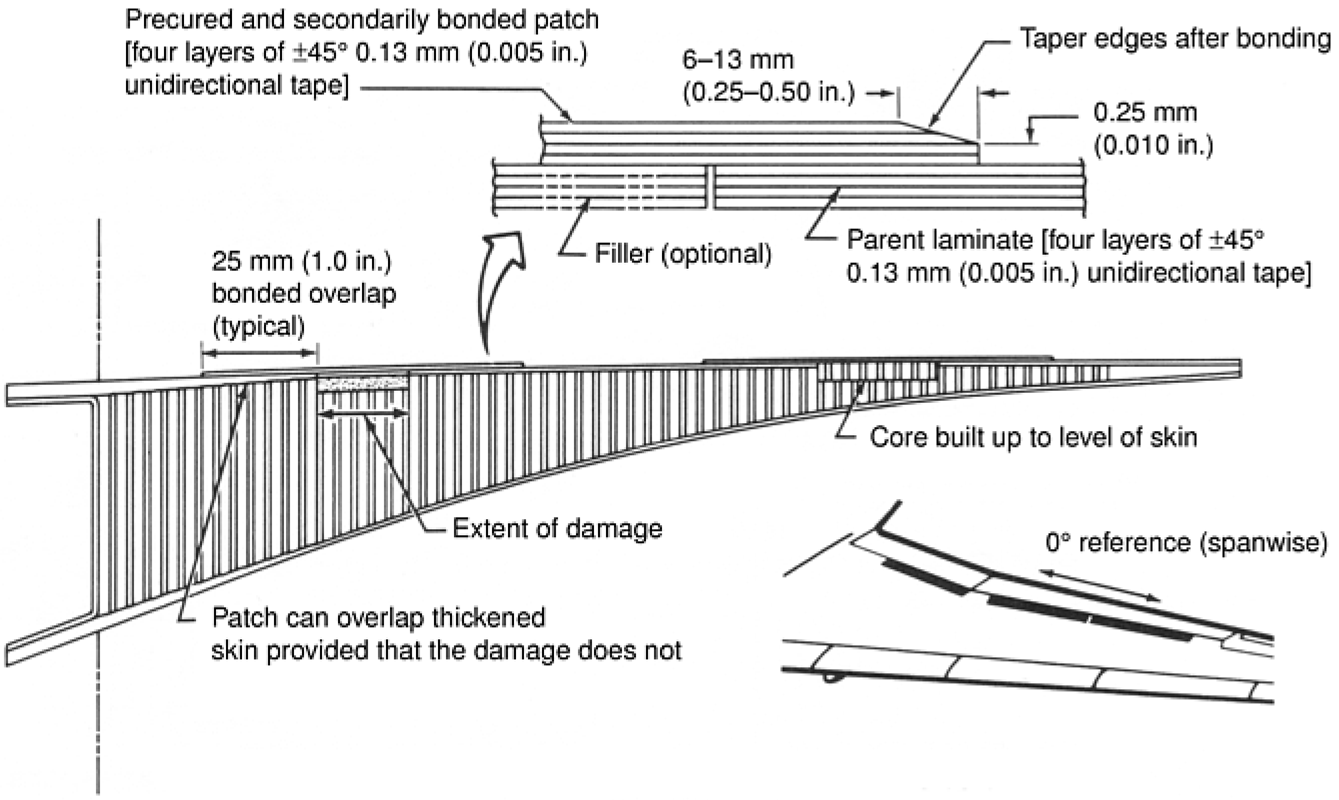

Fig. 17 Precured composite skin repair for MD-80 spoiler

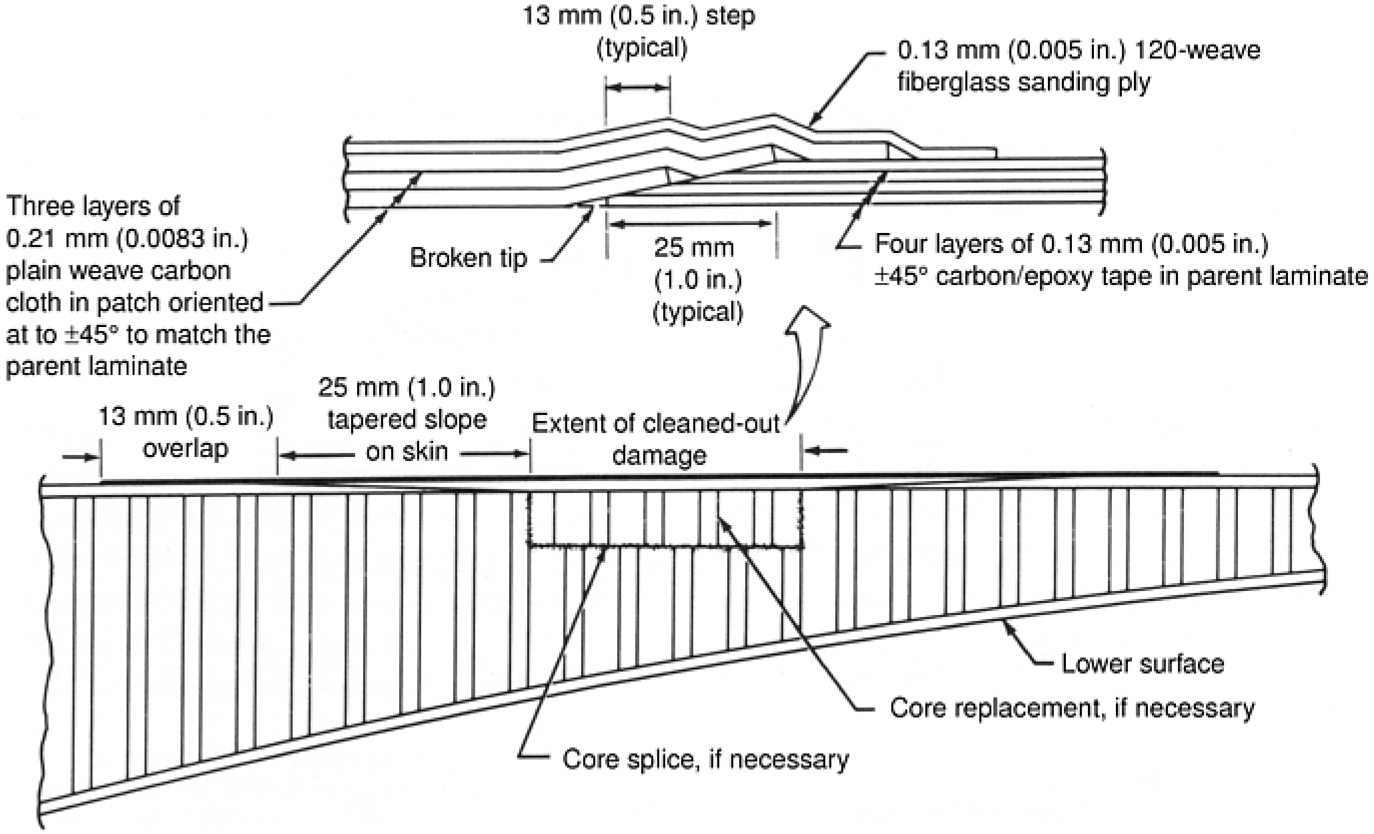

Fig. 18 Co-cured composite skin repair for MD-80 spoiler

The precured patch could be used for any size damage; whereas the wet lay-up patch would be preferred only when cosmetic considerations are important. Large co-cured patches tend to be very heavy, particularly if potting compound is used to fill the core cells. The compound would not be necessary, however, if the spoiler was removed from the aircraft and the patch cured with the repaired skin facing down. The mechanical properties of co-cured composite facesheets are inherently inferior to those of precured facesheets, even on a per-ply basis that allows for the additional resin needed to prevent pinholes; therefore, two layers of 0.25 mm

(0.010 in.) graphite cloth would not suffice in this case. Naturally, the repair fibers would be oriented in the same ±45° directions as in the parent laminate. The technique of using a thin 0.13 mm (0.005 in.) 120-weave glass surfacing ply to facilitate sanding and painting is shown in Fig. 18.

While on the subject of sanding, it is appropriate to remind the reader of the difficulties associated with sanding Kevlar fibers. Kevlar tends to break up into fuzzy balls, rather than break off smoothly the way glass and graphite fibers do. For that reason, and because of the difficulty of impregnating Kevlar fabric, it is customary to use fiberglass repairs for Kevlar panels.

The execution of a structurally adequate, perfectly flush repair for honeycomb skins is shown in Fig. 19. With the appropriate overlaps, this repair would work for either the MD-80 spoilers or the MD-80 rudder skins. Obviously, such a repair would be used infrequently, because of the complexity, and would not be used at all on the (full-depth honeycomb) aileron for which there is no unexposed surface on which to conceal the buildup on the other skin. Its greatest applicability would seem to be for the repair of large- area damage suffered by a compound-curved wing/fuselage fillet, tail cone, or radome for which no reference shape is available other than a plaster splash taken from a spare part. Even for those shapes, if the inner skin is undamaged, it is common for airlines to reconstruct the damaged part from the inside out and to tolerate the substantial additional finishing required, rather than create an exterior mold surface.

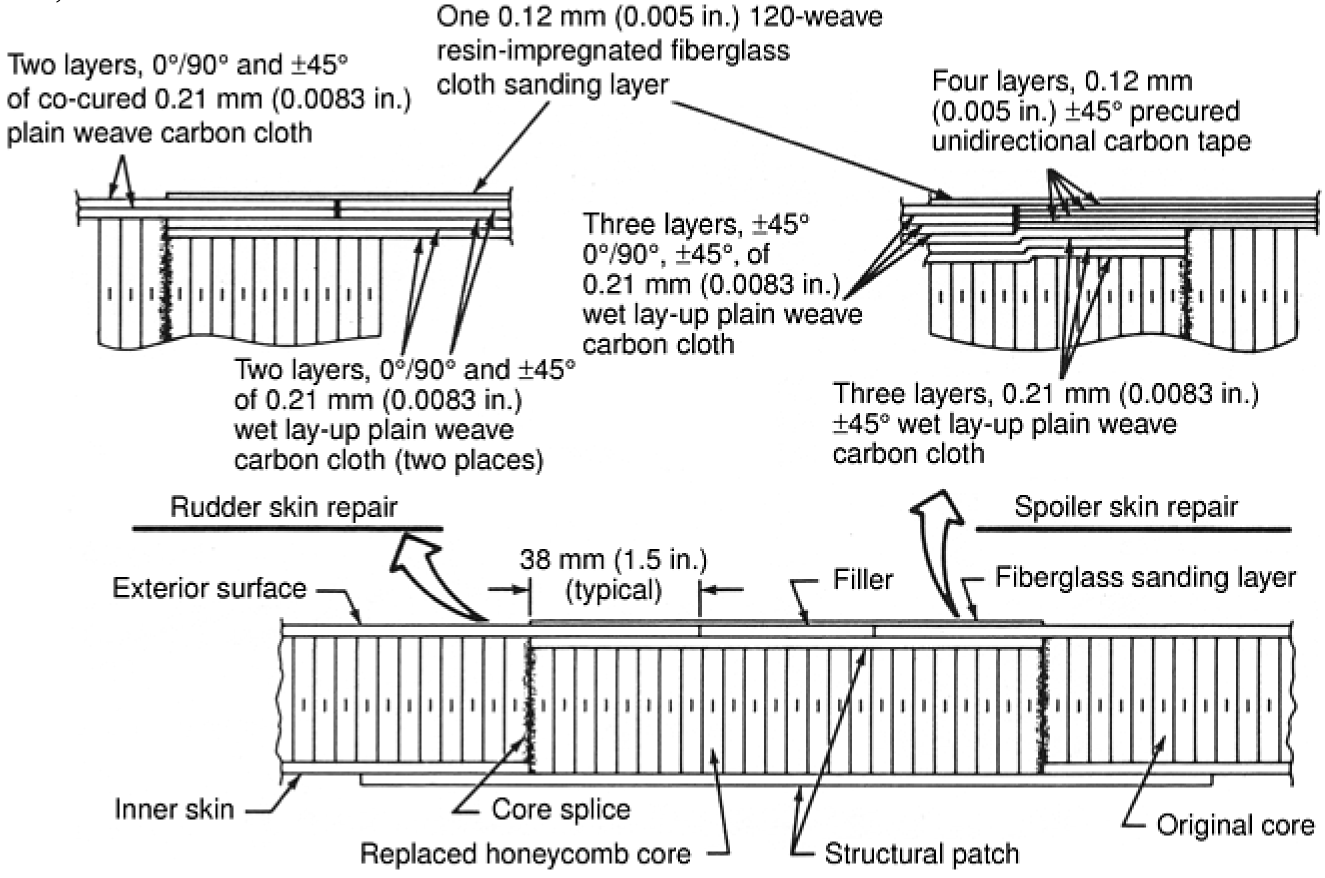

Fig. 19 Flush co-cured repairs for MD-80 spoilers and rudder

The skin of the MD-80 graphite/epoxy rudder is a double-skin, Nomex-honeycomb-cored panel having two layers of 0.21 mm (0.0083 in.) thick plain-weave AS4/3501-6 graphite/epoxy woven fabric on each side. One layer has a 0°/ 90° orientation, and the other is at ±45° to the 0° spanwise reference axis. The composite skins are thus quasi-isotropic, and a repair of the same kind could be oriented in any direction, provided that the two individual layers are rotated 45° with respect to each other. Nevertheless, it is customary to match the original fiber orientations, particularly for large repairs.

There is a possibility that the outside skin will be covered by a thin fiberglass layer, as part of a flame sprayed lightning-strike protection system. This is not shown here, because it would not be considered structural.

Because the sides of the MD-80 rudder are essentially flat, it would also be possible to perform repairs using two-ply (0°/90° and ±45°) precured skins bonded with a room-temperature curing adhesive that would subsequently be postcured. The details of such a repair are shown in Fig. 20. Even though the panel appears to be thermally unbalanced, it will not warp, because each cloth layer is symmetric about its midplane, and the thermal characteristics are identical in all in-plane directions. Figure 20 shows repairs performed to both skins,

not because it is mandatory for precured repairs, but because precured repairs are more likely to be used for large areas of damage, and they, in turn, are likely to be associated with the puncture of both thin and thick skins.

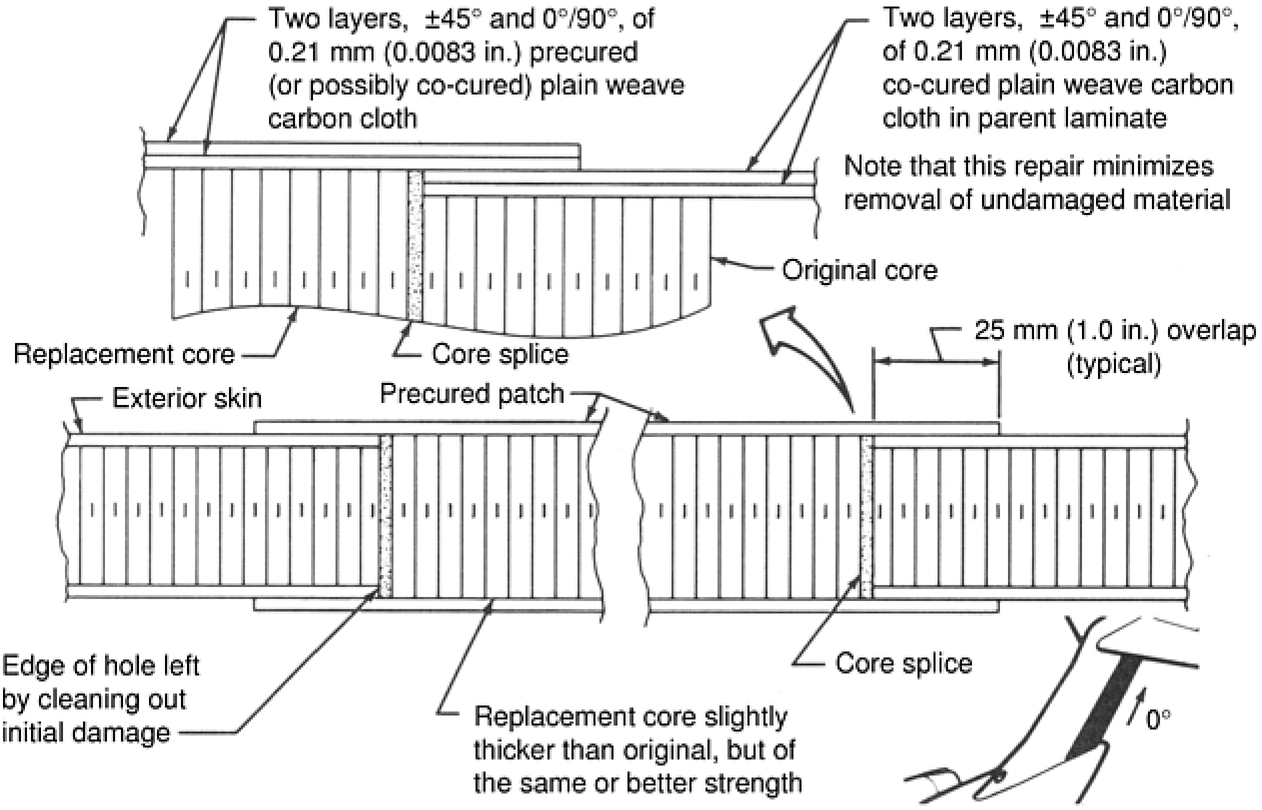

Fig. 20 Precured patch repair of MD-80 rudder skins

The extent of such precured patch repair work is limited only by the possibility of its intruding into the reinforced areas around the spars and rib caps. Were a relatively large area (more than about 0.3 m, or 12 in., in diameter) to be repaired using the wet lay-up technique, it would be prudent to add one additional layer of graphite fabric—in the ±45° direction, because the primary load is in torsion due to the fact that the mechanical properties of such laminates will be inferior to those of the original laminate manufactured in an autoclave. The extra layer could be omitted, if justified by an examination of the stress levels in any area of specific concern, with a stronger case for doing so existing near the top of the rudder rather than near the bottom where it is actuated.

The composite ailerons on the MD-80 are of full-depth honeycomb construction, except for the inboard end that is unreinforced skin in the area through which the push-rods pass to the inboard tab. (The push-rods to the outboard tab are contained in hollow external fairings.) The facings on the skin consist of three layers of AS4/3501-6 graphite/epoxy 0.21 mm (0.0083 in.) thick plain weave cloth in the (±45°, 0°/90°, ±45°) directions, with the 0° reference being spanwise. Both wet lay-up and precured patches could be used to repair these skins, with typical dimensions shown in Fig. 21. Note that in this case, the skin facings are not quasi-isotropic, and it is important that the patch fiber orientations match those in the parent material. Perfectly flush repairs are not desirable, except possibly for small cosmetic fiberglass repairs of the form shown in Fig. 22. The corresponding cosmetic (and waterproofing) repairs on the thinner facings of the rudder and spoiler should have one 0.13 mm (0.005 in.) layer of fiberglass outside the loft surface to ensure adequate bonding. Even for the aileron skin, the semiflush nonstructural repair is structurally preferable.

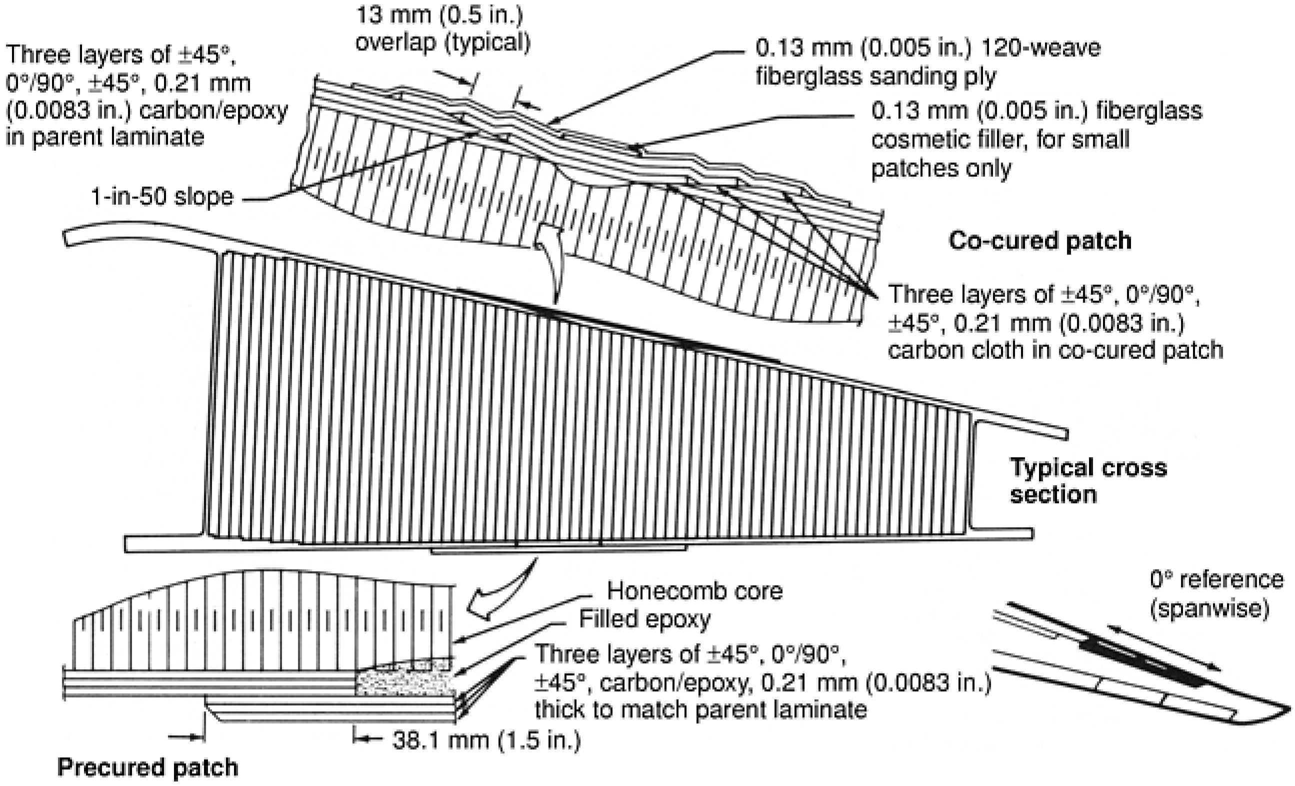

Fig. 21 Repair of MD-80 aileron skins

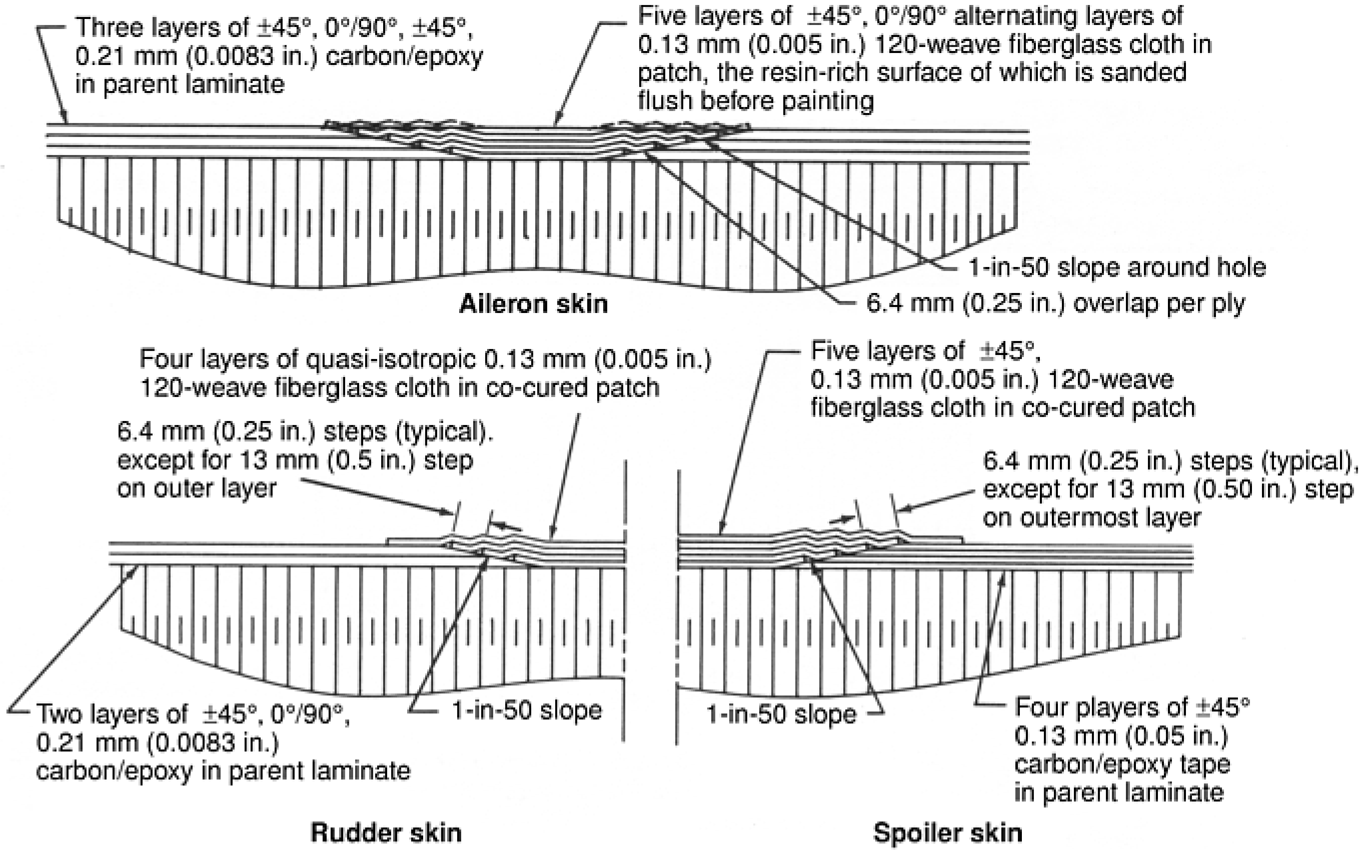

Fig. 22 Cosmetic repairs of minor damage to MD-80 composite control surfaces

If a composite elevator is produced for the MD-80, it will have much the same multirib, postbuckled (tension-field) skin design that has given such trouble-free service on about a dozen DC-10 rudders in flight-service evaluation. With tail-mounted engines, it is very important to maximize the weight savings associated with any redesign of the elevator. In addition, nonhoneycomb designs are preferred for mass-balanced control surfaces, because they preclude water from collecting in undrainable cavities. The ribs would be located on a 125 to 150 mm (5 to 6 in.) pitch, and the skin would be made of seven layers of 0.13 mm (0.005 in.) graphite/ epoxy

unidirectional tape in a [0°, +45°,–45°, 90°,–45°, +45°, 0°] pattern, with the 0° reference again being spanwise. The DC-10 upper- aft-rudder skins are the same, except that the chordwise (90°) layer is not distributed uniformly, but concentrated in a narrow double layer as part of each rib cap.

The relatively few repairs actually performed on the DC-10 rudder skins have been made with slightly thicker patches of quasi-isotropic wet lay-up graphite fabric, using a semi-flush exterior patch over a 1-in-50 scarf slope. A steeper- than-normal slope could be justified by the proximity of a spar cap containing bolt holes and, therefore, operating at a reduced strain level. Test samples proved satisfactory at a slope of 1-in- 50, as reported in Ref 11, but similar trials with a 1-in-30 slope failed unacceptably in the bonded joint. Larger damage could easily be repaired by using a properly oriented precured patch made from unidirectional tape and having a uniform bonded overlap of 38 mm (1.5 in.) all around.

The low-drag extended flap hinge fairings for the MD-80 are simple solid laminates made from basically five layers of Kevlar/epoxy cloth sandwiched between fiberglass/epoxy outer and inner faces. The fairings have co-cured local buildups serving as edge reinforcements and transverse stiffeners; all attachments pass through locally reinforced areas. The compound-curved shape renders the use of precured patches impractical, although both scarfed and uniform co-cured patches could be suitable. A repair concept for the unreinforced skin areas of this component is shown in Fig. 23. It should be noted that not only should the outer surface be smooth for low drag, there are some areas on the inner surface that cannot be built up excessively, because they would interfere with the metallic flap support structure.

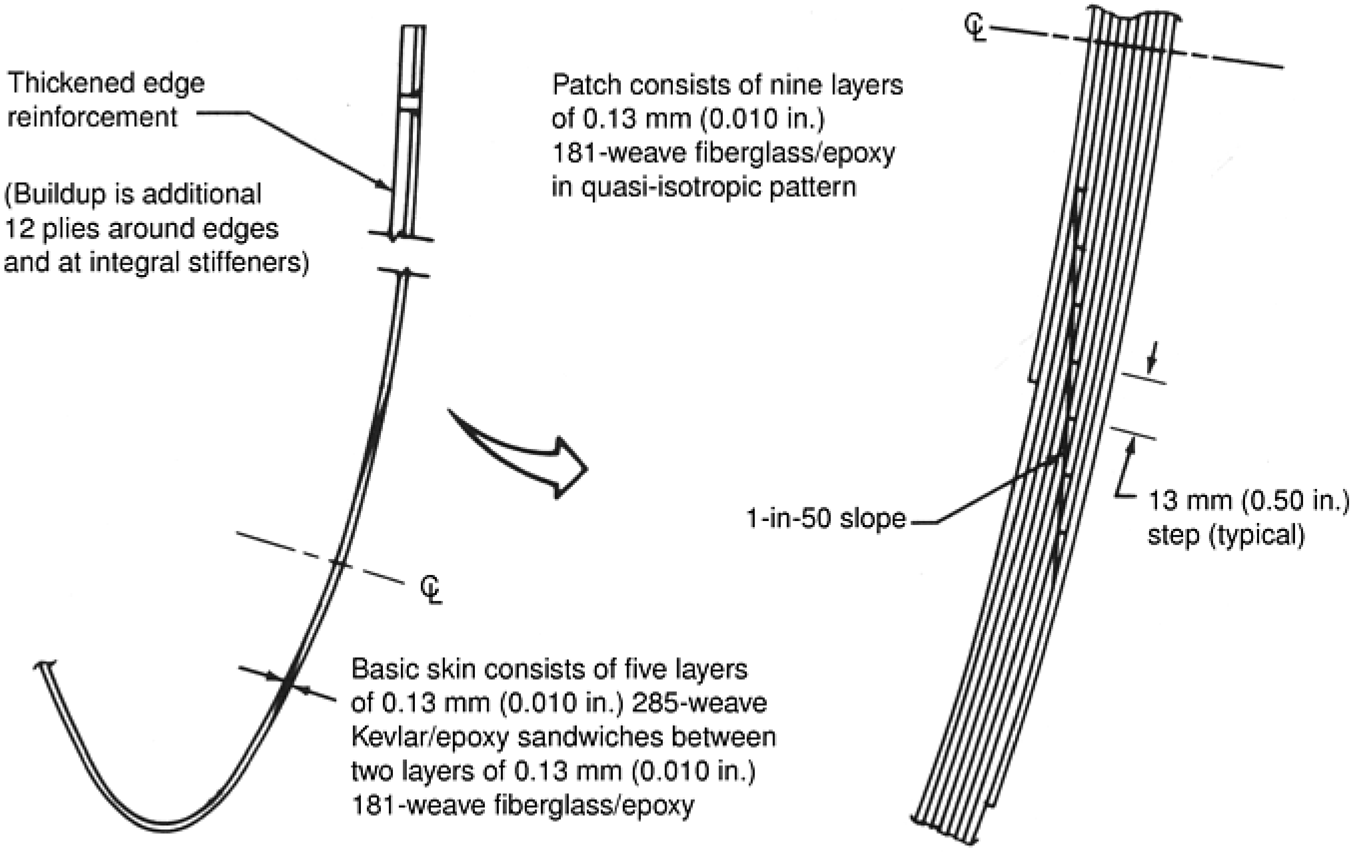

Fig. 23 Repair of MD-80 extended flap hinge fairings

The more-recently delivered MD-80s have had many of the older fiberglass/epoxy fairings replaced by Kevlar/epoxy ones, particularly on the wing trailing edges and the wing root fillets. The typical wing trailing-edge panel construction consists of three layers of 0.25 mm (0.010 in.) 285-weave (4-harness) Kevlar cloth on the outside and two layers on the inside of the Nomex honeycomb cells. Because the direction of the fibers is not controlled on the drawings for these lightly loaded covers, reference must be made to the actual part in the area surrounding the damage. Typical basic repairs for such components are shown in Fig. 24. The greatest problem with repairing in this manner is in sanding the scarf angle accurately. A simple exterior three-ply patch, while not as aesthetically pleasing, may be considered far more practical.

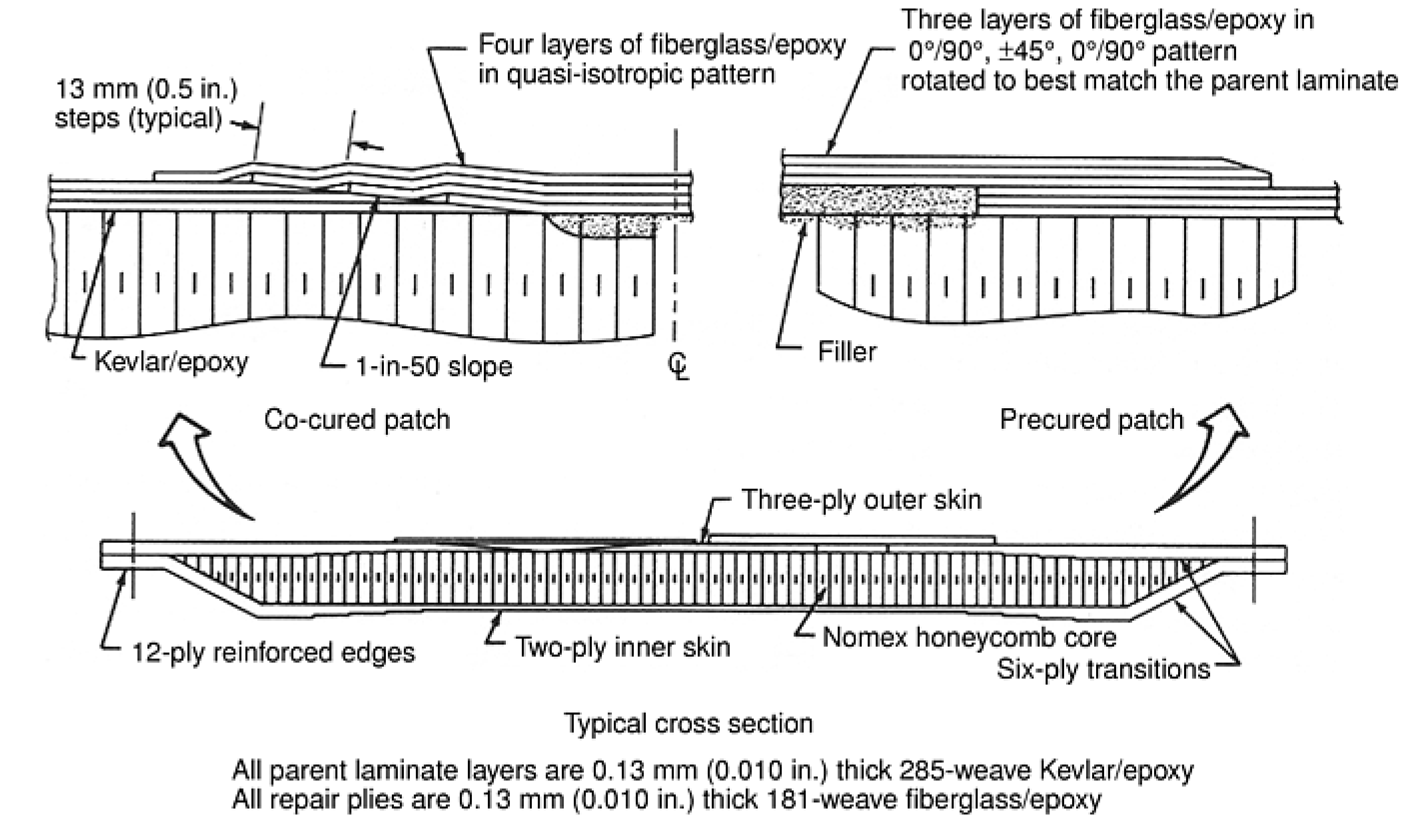

Fig. 24 Repair of MD-80 Kevlar/epoxy wing trailing-edge panels

In an attempt to avoid the problem of sanding Kevlar, the original MD-80 composite engine cowl repair uses a stepped-lap patch of the type shown in Fig. 25. This requires that the parent material be peeled apart and cut back ply-by-ply, without ever cutting into the underlying layer(s). Such an operation is felt to be risky for normal use, and the second nacelle design (with syntactic core) is to be repaired using the simpler double-lap patch shown in Fig. 26. This also permits the repair of larger skin damage than would the more restrictive method shown in Fig. 25 which requires the removal of a considerable amount of previously undamaged material without the patch spreading too close to hinge or latch areas. Unfortunately, because of regulations requiring that engine cowls withstand specific burn tests, it is not possible to authorize the structurally improved repairs retroactively without first verifying that they meet other requirements also.

Repair Engineering and Design Considerations

Rikard B. Heslehurst, Australian Defence Force Academy; Mark S. Forte, U.S. Air Force Research Laboratory

Introduction

Repair of advanced composite structures is a relatively new area of engineering design and analysis. Repair engineering requires a thorough understanding of composite structural mechanics and structural joining of composites and metal structures. These two aspects, in combination with other considerations, such as damage removal, surface preparation, and repair fabrication, require a clearly defined engineering process. The level of repair will be determined by such factors as damage criticality, operational requirements, and repair station capabilities. All of these add up to a unique repair for most composite structural damage restoration.

Figure 1 illustrates an example of the repair application steps for a composite sandwich structure. The damaged region is mapped out in Fig. 1(a). Then the damage is removed and the surface is prepared for a scarf repair scheme; Fig. 1(b) shows the removed core plug and scarfed skin. The replacement core plug is installed (Fig. 1c) and the repair plies are cured in place (Fig. 1d).

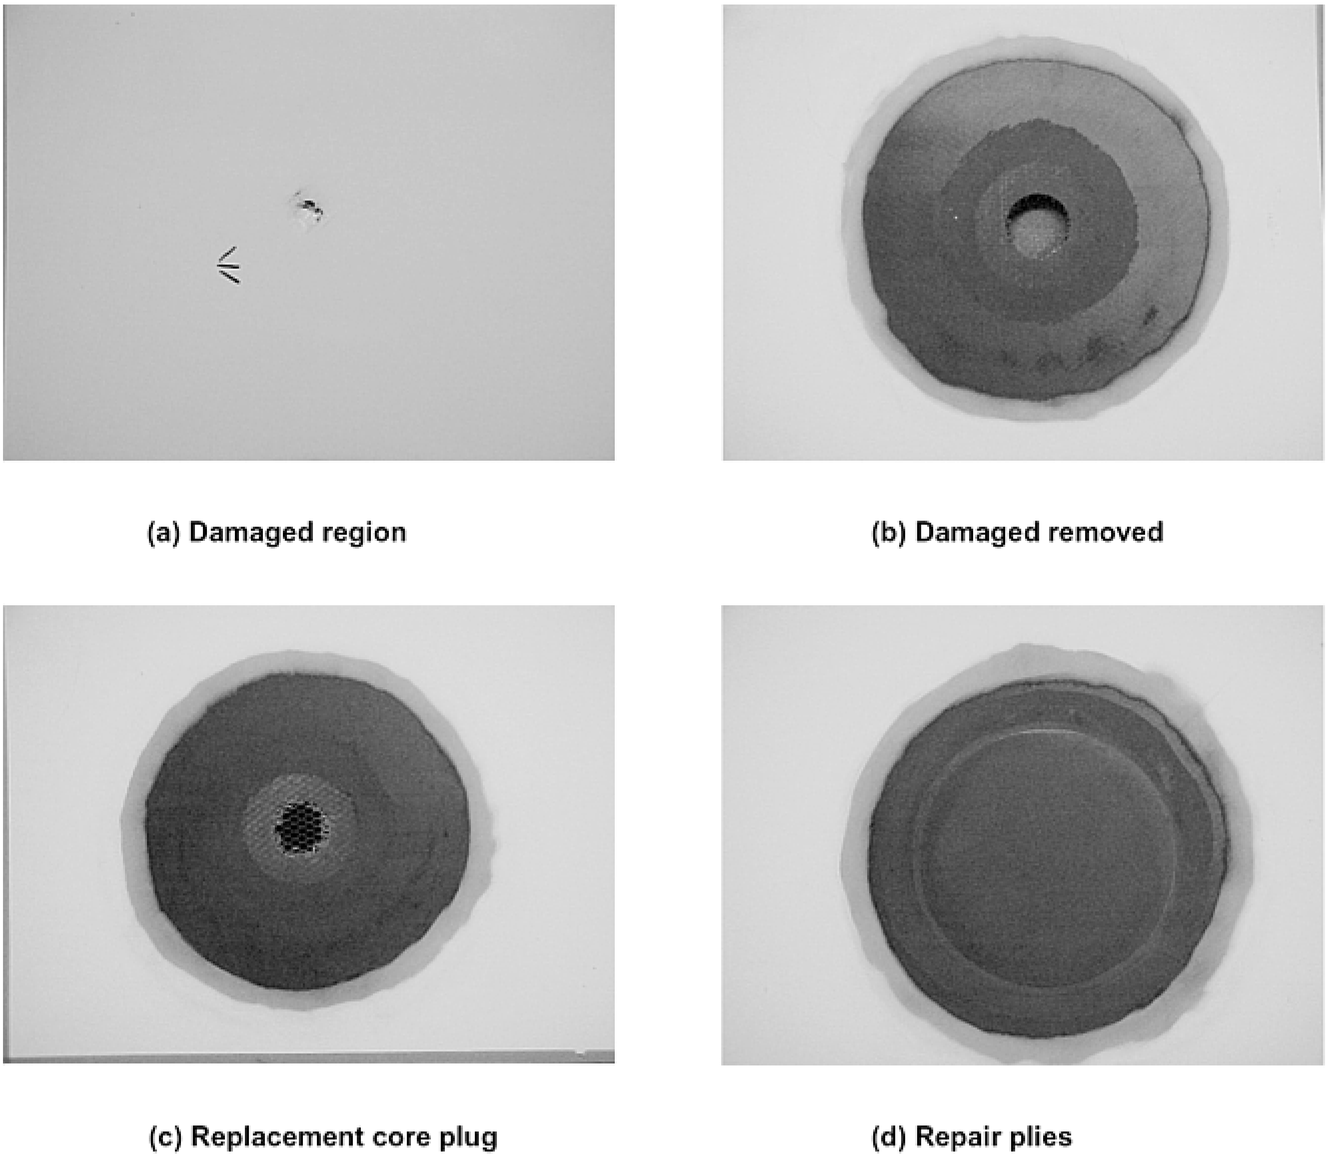

Fig. 1 Example of a repair to a sandwich structure. See text for discussion.

Repair Engineering and Design Considerations

Types of Repairs to Composite Structures

There are three typical repair types for composite structures. The first is a temporary repair that essentially maintains aerodynamic smoothness or prevents the damaging environment from entering the damaged site. For relatively thin structures, adhesively bonded repair patches are likely to be used because they are structurally efficient. Where thick, primary structures are to be repaired, bolted repair patches are likely choices. Although they are not necessarily structurally efficient, bolted joints are economical for repair over all size constraints. An example of each repair type is shown in Fig. 2, 3, and 4.

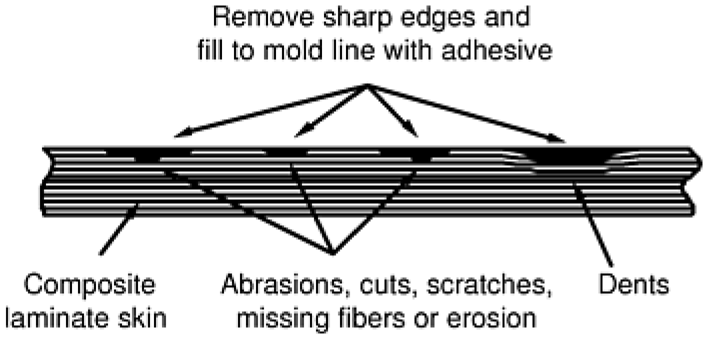

Fig. 2 Temporary or minor repair to a composite laminate

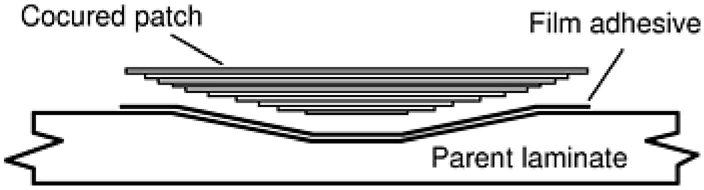

Fig. 3 Adhesively bonded repair to a composite laminate

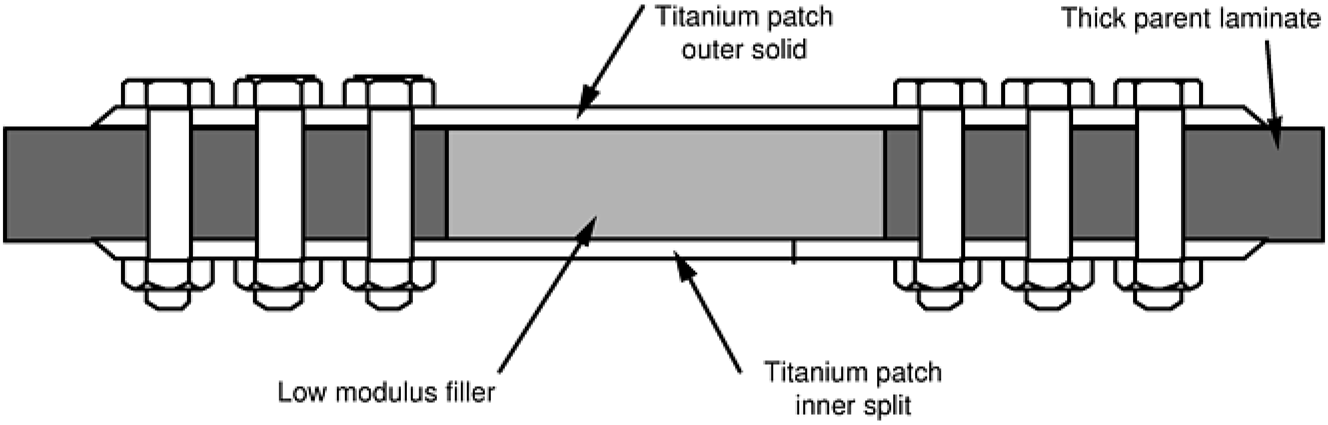

Fig. 4 Bolted repair to a composite laminate

Repair design in each of the three design schemes is based on the specific requirements of the repair medium. The fundamental analysis for each type is summarized as follows:

Temporary Repairs. Temporary repairs do not specifically require substantial analysis. The design requirements are based on minor structural damage. The temporary repair should be designed so that it does not attract load into itself; therefore, it should be made from a material with a relatively low stiffness.

Adhesively Bonded Repairs. Adhesively bonded repairs are designed so the adhesive shear and peeling strengths and interlaminar strengths of the composite are not critical. Special attention is directed to surface preparation in the design application. However, for the design analysis of adhesively bonded repairs, complete adhesive material properties are required.

Bolted Repairs. The analysis of mechanically fastened repairs in composite structures will require specific information on the composite laminate material structural or orthotropic properties for both on-axes and off-axes. The need to develop bearing-strength properties for the composite laminate is of particular interest.

Repair Engineering and Design Considerations

Repair Requirements

Table 1 lists general design requirements and considerations for the repair of composite structures. Several of these are described subsequently in greater detail.

Table 1 Requirements and considerations for repair of composites

Repair requirement or consideration	**Important factors**
Static strength and stability	Full versus partial strength restoration Stability requirements
Repair durability	Fatigue loading Corrosion Environmental degradation
Stiffness requirements	Deflection limitations Flutter and other aeroelasticity effects Load path variations
Aerodynamic smoothness	Manufacturing techniques Performance degradation
Weight and balance	Size of the repair Mass balance effect
Operational temperature	Low and high temperature requirements Temperature effects
Environmental effects	Types of exposure Effects to epoxy resins
Related on-board aircraft systems	Fuel system sealing Lightning protection Mechanical system operation
Costs and scheduling	Downtime Facilities, equipment and materials Personnel skill levels Materials handling
Low observable characteristics	Radar cross sectionLaser cross section

Static Strength and Stability. Any repair must be capable of supporting the design loads applied to the original structure. There are two major aspects:

- *Strength Restoration:* The first question to ask is if full strength restoration is required. The answer is determined from the results of damage stress analysis.
- *Stability Requirements*: The greatest concerns in many of the damaged structures are instability under compressive loading and restoration of structural stiffness. The damage analysis will indicate where structural instability exists. The repair design is then focused on how to overcome this instability.

Repair Durability. Any repair designed to restore aircraft to flying condition is generally expected to remain an integral part of the airframe for the remaining service life of the craft (exceptions are rapid-action or battle-damage type repairs). Durability of the repair scheme must consider the following in its design phase:

- Fatigue loading of the structure and its effects on bolted and bonded joints, damage growth, and monitoring for airworthiness
- Corrosion of components where dissimilar materials have been used in the repair and maintenance of corrosion protection precautions
- Environmental degradation of resin-system- based repairs, particularly via moisture absorption and hot or wet environments.

Stiffness Requirements. In aircraft where lightweight structures are an essential design requirement, stiffness is often more critical than strength. Likewise, repaired structures must maintain the integrity of structural stiffness. The following requirements must be considered in a stiffness-critical repair design:

- Deflection limitations of flying surfaces, such as wings and flight controls, are based on aerodynamic and performance requirements of the aircraft, repair should not unduly alter the flying characteristics of the aircraft.
- Flutter and other aeroelasticity effects limit the design of a repair so that the repair scheme stiffness should be essentially equal to that of the parent structure.
- Load path variations are undesirable in any structure. As a general rule, the repair area stiffness should match that of the parent structure, so as not to change the load path significantly.

Aerodynamic Smoothness. Aerodynamic smoothness is an important consideration when maximum speed or fuel efficiency is required. Those parts of the aircraft that require good aerodynamic smoothness, that is, leading edges and locations where the boundary layer is laminar, must have flush or very thin external patch repair schemes. These repair types are based on local capabilities in manufacturing techniques, the effects of performance degradation, repair size, and the possible effects of multiple damage sites.
Weight and Balance. The size of the repair and the local changes in weight can be insignificant to the total component weight, but in weight-sensitive structures such as flight controls, the effect on the mass balance can be highly significant. The effective change in local weight must be controlled and kept within defined limits; in some cases, component rebalancing may be necessary.
Operational Temperature. The operating temperature influences the selection of repair materials, particularly adhesives and composite resins. Materials that maintain adequate properties within the required operational temperature range must be selected. The combination of extreme temperatures with environmental exposure, the hot and wet condition, is the critical design condition for the repair.
Environmental Effects. Composite and adhesively bonded joints are prone to property degradation when exposed to various environments, in particular, to fluids and to thermal cycling. Absorbed moisture is known to have major long- term concerns. Durability of the repair design must consider environmental aging.
Related On-Board Aircraft Systems. The repair design must also be compatible with onboard aircraft systems. Such onboard aircraft systems include the following:

- *Fuel System*: In many aircraft, the fuel is carried within the wing structure as a “wet wing.” Therefore, any repair to wing skins, which are in direct contact with the fuel system, must seal the fuel tank, cater for out-of- plane fuel pressure forces, and not contaminate the fuel system during the repair process.
- *Lightning Protection*: If electrical conductivity of the parent structure is required for lightning protection, then the repair must also incorporate the same degree of electrical conductivity.
- *Mechanical System Operation*: Any component that is required to move during aircraft operations or is in close proximity to a moving component that is subsequently repaired must not impede component operation; for example, repair of a retracting flap must provide adequate retraction clearance.

Costs and Scheduling. Repair and repair design result in aircraft downtime and increased operating expenses. However, experience has shown that it is less expensive to repair than replace, given that appropriate facilities and adequate personnel skilled to do the repair.

Low Observable Characteristics. An important attribute for military aircraft is reduced radar cross section (RCS), which is a major contributor to low observable characteristics of the aircraft. If the aircraft is a stealth type by design, then repairs must be designed to maintain the mold line and not have reflective corners.

Repair Engineering and Design Considerations

Rikard B. Heslehurst, Australian Defence Force Academy; Mark S. Forte, U.S. Air Force Research Laboratory

Considerations Prior to, During, and After Repair Action

The recommended engineering approach to more effectively restore structural integrity to damaged composite components entails a ten- step methodology. This methodology is based on the current level of damage stress and the damage tolerance required in structural strength and stiffness restoration of a repair scheme. The ten steps are described below.

Step 1: Find the Damage. The location of the composite structure damage is found by either a visual inspection of the external surface of the component or through the inadequate performance or structural behavior. This step has significant implications for the damage tolerance of the composite structure. Internally hidden damage to a composite structure does not show itself readily on the surface (Fig. 5). Nonvisible or barely visible impact damage can result in little evidence on the structural surface but significant internal damage in the form of delaminations. A good understanding of the likely sites of potential damage is essential in locating such damage. The common tap hammer test provides an acceptable method for finding near-surface damage.

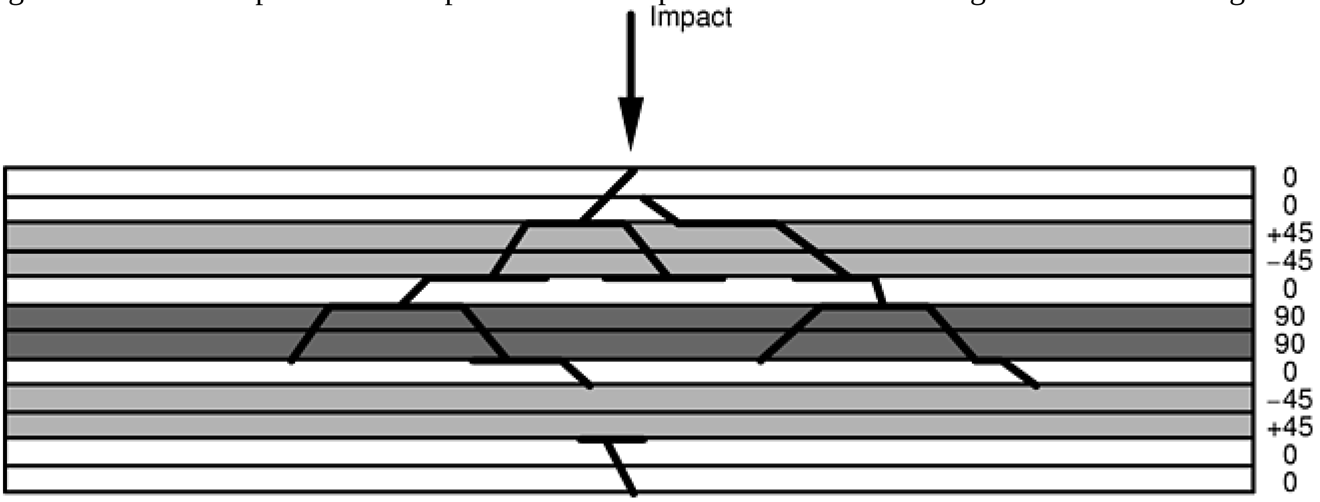

Fig. 5 Impact damage barely visible on the surface but showing extensive subsurface delaminations

Step 2: Assess the Extent of Damage. Following the visual inspection or observation, a more sophisticated nondestructive inspection (NDI) technique is used to determine the physical geometry of the damage state (see the article “Nondestructive Testing” in this Volume). The appropriately selected NDI technique will determine the size, shape, and depth of damage. Because composite laminates are known to have damage hidden beneath the surface, the NDI techniques applied will exhibit the true extent of the damage. A typical C-scan result is shown in Fig. 6. In this figure, the details of delaminations around fastener holes can be scrutinized.

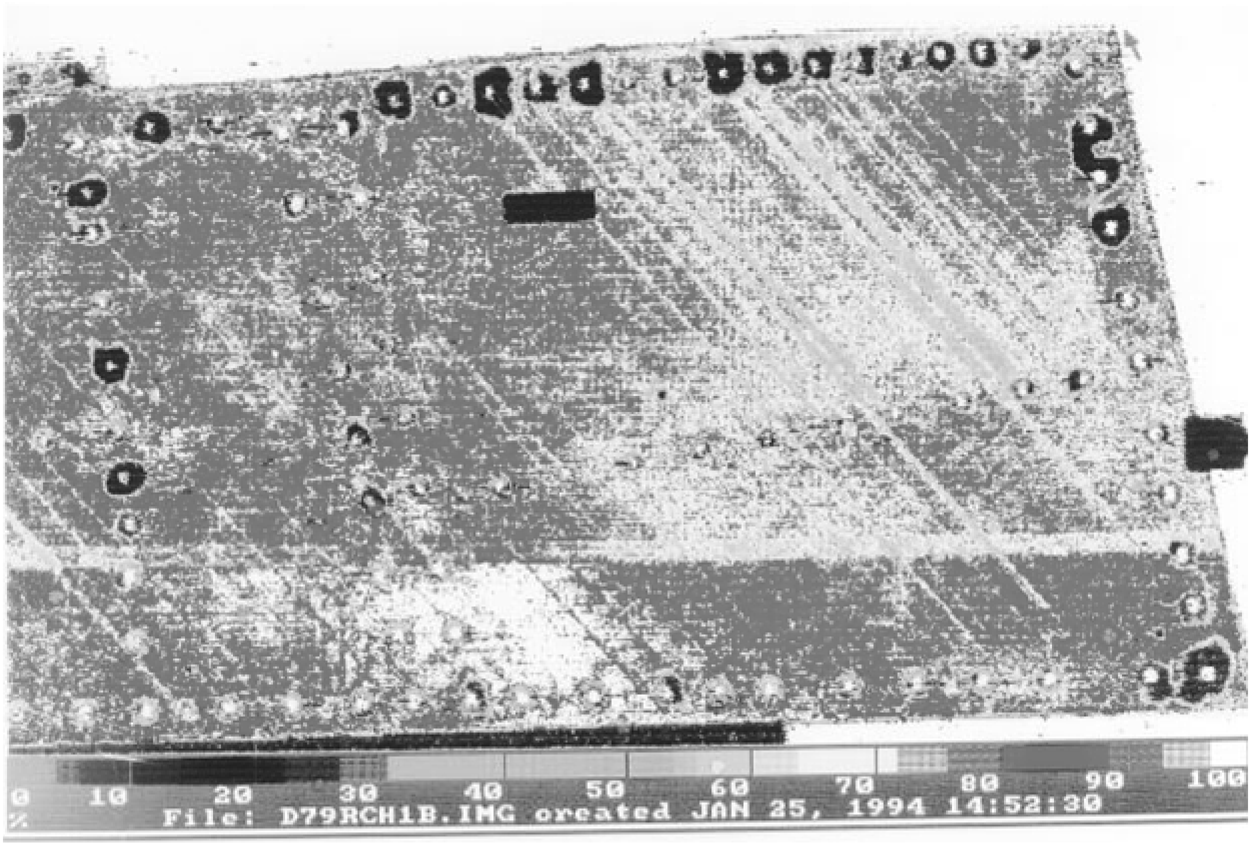

Fig. 6 C-scan of a composite panel with fastener hole delaminations

Step 3: Analyze the Damage Stress State. Before the most effective repair scheme can be designed, the damage stress state must be evaluated. This analysis will determine the type of repair scheme to be designed for the damage. From the calculated stress state, the residual structural strength can be compared against the design allowable or ultimate strength. Hence, the structural integrity or the loss of damage tolerance can be ascertained. The details of the damage stress analysis are discussed in Ref 1, 2, 3, and 4. A brief summary is provided later in this article.

Step 4: Design the Repair Scheme. The repair-scheme design is typically one of three generic repair design categories. The generic repair categories are non-structural, semi-structural, or full-strength repair schemes. Each of these three generic repair schemes is illustrated in Fig. 7, 8, and 9, respectively. The various repair designs are generically the same, but each design should be analyzed to determine its adequacy. The design variables are the repair-ply configuration and thickness and the overlap length. Simple repair design techniques are discussed in Ref 5, 6, 7, 8, and 9.

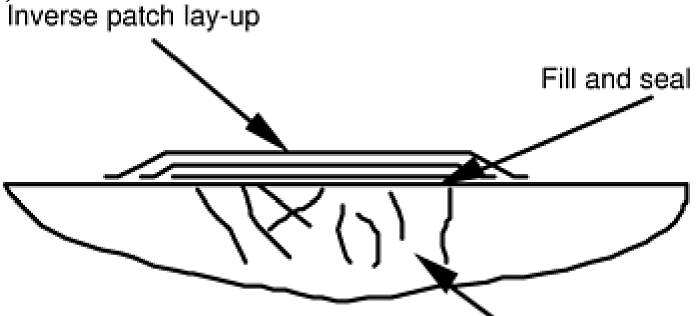

Fig. 7 Doubler patch installation over matrix cracking for non-structural repairs

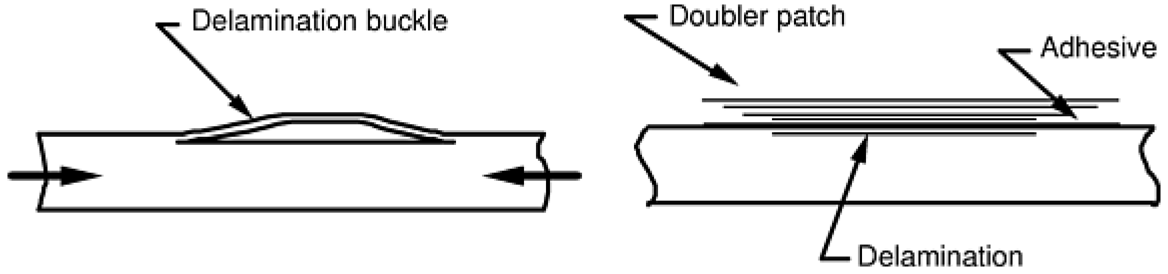

Fig. 8 Doubler patch installation over delamination for semistructural repairs

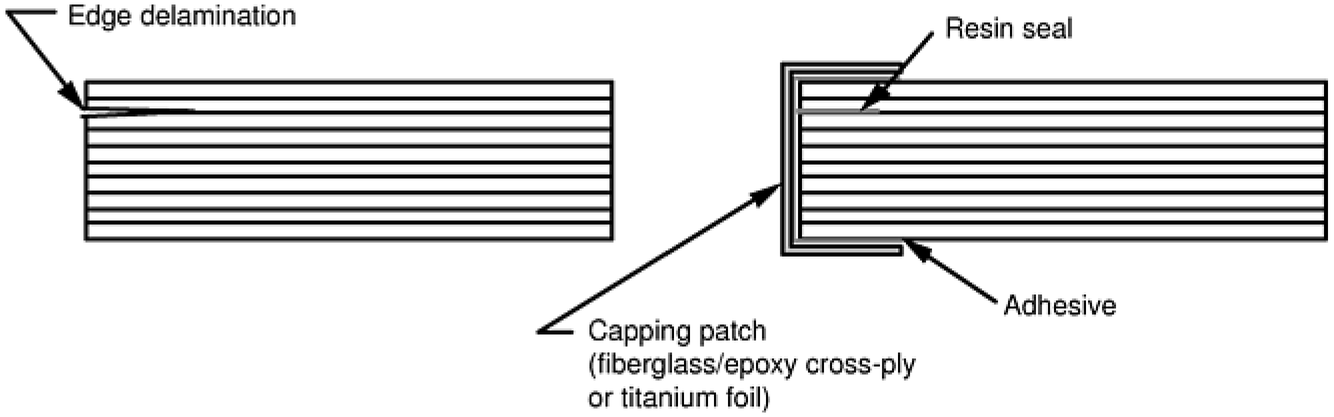

Fig. 9 Out-of-plane reinforcing capping patch over edge delamination

Step 5: Remove the Damage and Prepare the Component for Repair. Using standard composite machining techniques, the damage is removed (Fig. 1b). If a hole is produced, then simple geometric shapes should be used, such as holes or rounded rectangles. The preparation of the structure for repair application involves moisture removal and surface preparation for repair patch bonding. Both of these steps are crucial to ensure complete repair scheme structural integrity.

Step 6: Fabricate the Repair Scheme. To ensure that the repair patch meets material property specifications, the materials and fabrication process used must be to the appropriate engineering standards. Precured autoclave patches are preferred; however, if a vacuum bagging technique without positive pressure cures the patches, strength properties must be reduced accordingly.

Step 7: Apply the Repair Scheme. Whether the repair scheme is cured in place (co-bonded) or secondarily bonded, three aspects are critical. First, surface preparation is most important for bondline structural integrity; also, cure temperature and time of cure must be within specified limits. The cure profile requires careful understanding, as improper curing can have major consequences.

Step 8: Conduct a Post-Repair Inspection of the Repair Scheme. A quality assurance check by an appropriate NDI method will identify any apparent repair scheme deficiencies. At the least, a visual inspection of adhesive fillet flow and an acoustic-hammer tap test should be done to indicate gross defects.

Step 9: Document the Repair Scheme. Repair documentation is required of repair management and design-certification procedures. Flight-critical structural repairs must have supportive documentation to verify repair structural integrity and mass-balance effects. Multisite- damage concerns necessitate engineering management of the component repair history.

Step 10: Monitor the Repair Zone. Due to material and fabrication anomalies and/or unknown stress states around the repaired region, the repair scheme and parent structure should be regularly monitored for ongoing validation.

Validation and Certification of Repairs

The relative infancy of composite-material application in aircraft structures and the growing use of adhesive bonding in primary structures have caught most aircraft operators by surprise. Design and manufacturing techniques for advanced composite structures have advanced by leaps and bounds, but, unfortunately, corresponding repair and maintenance techniques have lagged behind.

Because of this sudden increase and the importance of the maintenance and integrity of composite structure repair, management activities have to take a new thrust. All areas of the repair activity need detailed managing. This is particularly true with a developing composite structural repair capability. However, because of rapidly growing technology, ongoing attention for the improvement of current capabilities needs a concerted management effort.

Certification and structural worthiness of composite structures in the manufacturing area is still developing, and only a few rules have been formulated by the structural-worthiness authorities. In the repair and maintenance fields, there are no defined requirements to certify repairs or define what constitutes structural worthiness. The following discussion is a general review of certification and structural worthiness requirements for manufacture and design of composite structures. These requirements are directly related to the repair and maintenance of composite structures.

Management

Requirements for an Effective Repair Capability. The development of an effective composite structural repair capability needs to address the following requirements:

- Engineering damage assessment, analysis, and repair design skills
- Engineer and repair technician training, which includes maintaining learned skills
- Repair station quality control and assurance

- Repair station facilities
- Repair management and certification procedures
- Personal safety and environmental health policy

Some of these requirements are discussed in more detail in the following paragraphs. The article "Maintainability Issues" in the Section "Product Reliability, Maintainability, and Repair" of this Handbook also discusses these repair requirements.

Engineer and Technician Training. The training of engineers and technicians in repair of composite structures is of the utmost importance. Both engineers and technicians must understand the issues in the structural mechanics, limitations and influencing factors of composite materials. They are also required to have a very thorough appreciation of the repair process issues discussed earlier. Other issues that are necessary for engineers and technicians to understand are as follows:

- Materials handling
- Damage removal and surface pretreatment requirements and methods
- Repair fabrication requirements
- Repair application methods
- Quality control and assurance of the repair process and finished product
- Continuation training to keep pace with the rapidly changing technology
- Regular work in the repair procedures to maintain learned skills

Repair Station Facilities. The requirements of any composite structure repair station depend on the level of repair to be undertaken. The three typical levels of repair activity, operation-level maintenance (OLM), intermediate-level maintenance (ILM), and depot or deeper-level maintenance (DLM), have different composite-structure repair requirements, outlined as follows:

Operation-Level Maintenance. Limited repair action is typically undertaken at the OLM facility. Such activities would include preliminary NDI and simple cosmetic repairs. Minimal equipment, material storage, and infrastructure facilities are required.

Intermediate-Level Maintenance. A significantly greater level of repair activity is expected at ILM. Vacuum sources for full-flow and local- vacuum extraction of contaminants and air supply for tools and breathing equipment are required in the damage removal process. In a separate clean room with temperature and humidity controls as well as positive pressure, vacuum bag/heater blanket curing equipment are required. Cold-storage facilities for prepreg and adhesive materials are essential. Prior to repair, some composite structures may need to have absorbed moisture removed; a drying room may be required. More sophisticated NDI equipment is required for ILM than for OLM.

Depot Level Maintenance. In addition to the requirements of an ILM facility, DLM facilities also require autoclaves and/or heated platen pressing, honeycomb profilers, prepreg cutters, anodizing process tanks, and C-scan facilities.

Repair Validation

To ensure that the repaired composite components are structurally sound, repair validation is required. The driving needs for repair validation are the rapid technological changes that occur in composite structure design, design capabilities, and new materials substantiation. Furthermore, composite components in primary loaded structures have only had a limited life cycle, so repair tracking is critical in the ongoing validation of repair methods and techniques. Finally, multisite damage is only beginning to be understood in metal structures; in composite structures, the interaction with neighboring repairs is not yet well understood. The monitoring of damage growth will also provide a better understanding of repair limits and damage criticality.

Certification

Structural Design Certification. The issues in structural design certification are static loads and margins of factors, static-strength substantiation, cyclic loading, impact resistance and damage development, repair design and strength restoration, erosion resistance, stiffness variations, and damage-inspection capabilities.

Elements of Certification for Composite Structures. The elements for certifying composite structures and their subsequent repairs are as follows:

- Design criteria (stiffness, strength, or other)
- Analysis requirements and capabilities
- Design allowables, including static, fatigue, and damage tolerance with environment and scatter factors
- Design/configuration development
- Quality control and quality assurance from receipt of materials through to completed task
- Verification testing for static, fatigue, and damage tolerance properties
- Other considerations, including lightning, flammability, individual component tracking, inspection, and repair

Structural Worthiness Considerations

The main concerns here are the proper allowance for environmental effects (moisture and temperature) on the static and fatigue properties of composite structures and their repair, and the data scatter, which is greater than that of metals (improving for static properties). The use of A- allowable or B-allowable properties is defined for a limited number of structural composites in MIL-HDBK-17. A significantly extensive testing program is called for to allow for new structural composites to become structurally certified. Included in the certification requirements are the curing conditions and other process variables.

Repair Engineering and Design Considerations

Design Guidelines

Designing a repair first requires analyzing the damage and then analyzing possible strategies for making a repair.

Damage Analysis

The repair scheme developed for a damage- stress state can be based on the loss of structural integrity. The damage-stress state can be examined by generalizing the damage into one of four categories. Table 2 provides a summary of these generalized damage types and how they typically affect the structural integrity of the composite component. The size of the damage does play a key role in the degree of degradation.

Table 2 Effect of local damage on residual strength and stiffness

Damage type	**Production error**	**Low-energy impact**	**Puncture**	Effect on	
				Residual strength	Residual stiffness
Core damage	Minimal	Moderate	Significant	Limited	**Small**
Cut fibers	Few	Minimal	Significant	Significant	**Significant**
Matrix cracks	Few	Many	Many	Limited	**Small**
Delaminations	**Minimal**	**Significant**	**Moderate**	**Moderate**	**Significant**

Core Damage. Damage to the core material must be very substantial to result in a significant loss of structural integrity. The skin material is usually damaged with fiber fracture. The fiber fracture will become the dominant damage type. Core-to-skin separation can be more common. The resulting disbond will cause concern under compression or in-plane shear loading. Loss of stiffness integrity due to a disbond can be analyzed by the same method as that used for delaminations.

Intralaminar Matrix Cracks. Intralaminar matrix cracks in composite structures are confined to those cracks within a ply or lamina. These intralaminar cracks tend to be transverse to the fiber direction and terminate at the ply boundaries. Crazing and heat damage are examples of matrix cracks. Local stiffness loss is attributed to intralaminar matrix cracks. Local loss of stiffness can easily be evaluated by using a degraded value of the matrix stiffness and strength properties of the individual ply effect. This value, generally about a 60 to 80% reduction, can be applied directly to the ply transverse properties or used in micromechanics analysis and then used in any of the structural analysis techniques. If the effect of stiffness reduction is severe, particularly under compressive loads and fatigue cycling, then delaminations may be initiated. If matrix cracks are present with delaminations or fractured fibers, their influence becomes insignificant. Repair of matrix cracks is done by using a low-viscosity resin to fill the surface cracks and then applying a surface patch to prevent moisture absorption and restore any loss of local stiffness (Fig. 7). Always ensure that the repair patch has a stiffness that is less than or equal to that of the parent laminate. A stiffer patch will attract load to the damaged area. The repair region should be inspected at each major service or at regular intervals to determine if the crack density has grown and/or delaminations have been initiated. Removing the matrix cracks by cutting out the damage and therefore removing the fibers will do more damage and can cause more degradation to the repaired structural integrity.

Delaminations. Delaminations are also a form of matrix cracking, but they lie in the plane of the laminate and between plies. The delaminations typically grow from transverse intralaminar matrix cracks. Structural instability under compressive loading is of greatest concern in the presence of delaminations. Linear elastic fracture mechanics (LEFM) has been used to determine the delamination propagation. However, LEFM methods require determination of basic material property values relating to each method. These material properties have been difficult to obtain for composite structures. Under compressive loading, the delamination generally grows after sublaminate buckling. After an initial estimate of potential delamination crack growth, the stability of the sublaminate under design loading conditions can be determined. Several methods of determining the loss of buckling stiffness are found in the literature. A modification to laminated plate theory for a sublaminate (the delamination) allows for evaluation of the critical buckling load. This critical buckling load is then compared to the design loads in the laminate. Repair of delamination damage (Ref 10) can be accomplished by four principal methods:

- *Resin Injection*: The injection of a low-viscosity resin into the laminate has been a commonly used delamination repair method for many years. However, there are several concerns about the effectiveness of the repair method, such as complete infusion of resin and the cut fibers, which result from drilling the holes. The method is best used on lightly loaded structures.
- *Doubler Patch*: The bonding of a doubler patch over the delaminated region, as shown in Fig. 8, to increase the critical buckling loads has been suggested in several reports. This allows the delamination to remain in the structure but restores the structural integrity of the damaged region. The repair region should be monitored at regular intervals to ensure that the delamination does not grow. The basic principle behind this method is the same as that for the crack patching technology used to restore metal-structure fatigue integrity. The structural stiffness of the doubler must be matched to that of the parent laminate, so that it will not attract additional load to the damaged region.
- *Damaged Removal*: Removing the delaminations by cutting out the material results in a partial through-the-thickness hole, which can be treated as a fiber-fracture (hole) damage type.
- *Edge Delaminations*: Edge delaminations require special attention, as it is very difficult to restore out-of-plane structural integrity without cutting out the damage. Another suggested repair method is to fill the edge damage with a low-viscosity resin and support the out-of-plane properties with a wrap-around patch (Fig. 9).

Fiber Fracture (Holes). In the event that fibers are fractured, the damage removal process will result in the drilling of a hole with circular ends. The stress state can be determined by calculating the stress concentration factor for the hole. The stress state is then evaluated against the structural design allowables.

There are several methods of calculating the stress concentration factor for a hole in a composite structure. The most common methods are the point stress failure criteria (Ref 11) and a stress-field model (Ref 12); a more detailed method exists where the hole is elliptical in shape and the far-field in-plane loads are complex (Ref

13). Generally, there are only two methods of restoring the structural integrity in the presence of a hole. The repair scheme will either be an adhesively bonded patch or a mechanically fastened patch.

Repair Design Analysis

When developing the repair scheme, the stress analysis will be based on whether the repair is a core replacement, an adhesively bonded patch, or a mechanically fastened patch. These three repair schemes are discussed briefly.

Core Replacement. The replacement of the core material (Fig. 1b) is relatively straightforward. There are a few simple rules:

- The replacement core ribbon direction should match so that the core stiffness/strength properties remain directionally consistent, and the cell densities are the same.
- When bonding the replacement core to an existing lower skin, the adhesive should fillet to the core cell walls (Fig. 10).
- Use a foaming adhesive to lock the replacement core to the existing core.
- Ensure that the top of the replacement core allows the replacement skin to lie flat.

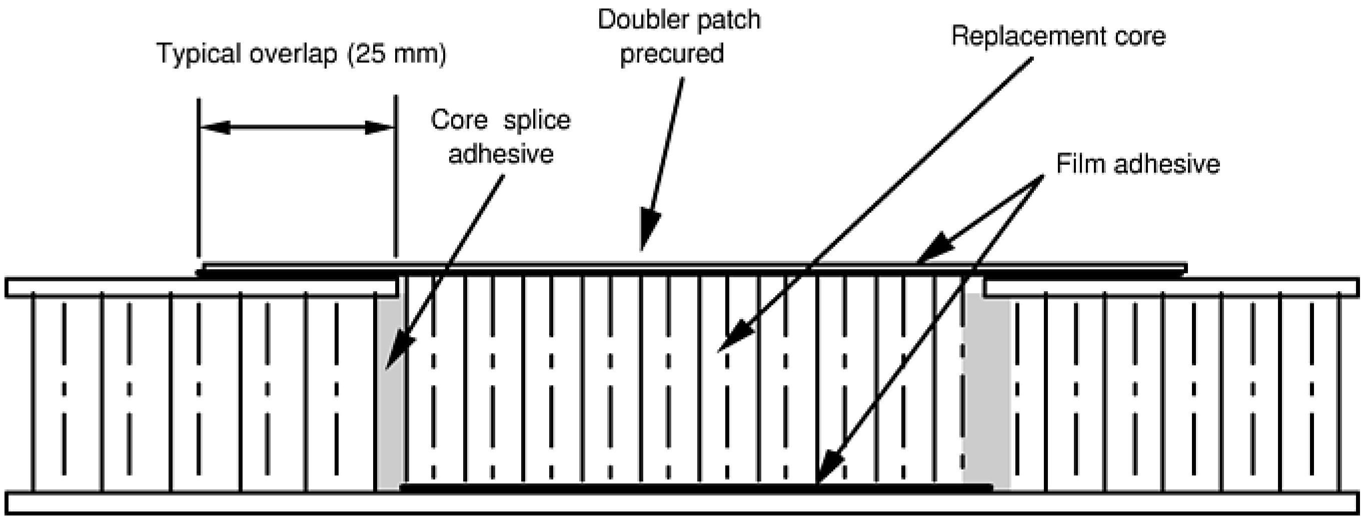

Fig. 10 Structural doubler and plug repair

Adhesively Bonded Joints. There are two methods of adhesively bonding repair patches: doubler repair patches and scarf, or stepped, repairs.

Doubler Repair Patch. This is the simplest of the adhesively bonded repair patch schemes (Fig. 10). However, the bonded-joint overlap length here must be sufficient to allow for an elastic-load trough to develop in the adhesive. Also, the ends of the repair must be checked for peel stresses. Tapering the joint ends will reduce peel stresses substantially. Standard practice is to taper the repair laminate, with the largest ply placed last (Fig. 11). Based on the idealized adhesive stress/strain curve (Fig. 12), the load carrying capacity of the joint (*P*) is as follows:

$$P = 2\sqrt{\eta\tau_p\left(\frac{\gamma_e}{2} + \gamma_p\right)Et}$$

where η is the adhesive thickness (nominally 0.13 mm, or 0.005 in.), τ_p is the peak adhesive shear stress, γ_e and γ_p are the adhesive elastic and plastic shear strains, respectively, and *Et* is the effective stiffness of the patch or parent laminate. The allowable load per unit width of the patch is given by:

$$P_{all} = E\varepsilon_{all}t$$

where nominally ϵ_{all}= 4000 microstrain. (Microstrain is the strain over a gage length comparable to the material's interatomic distance.)

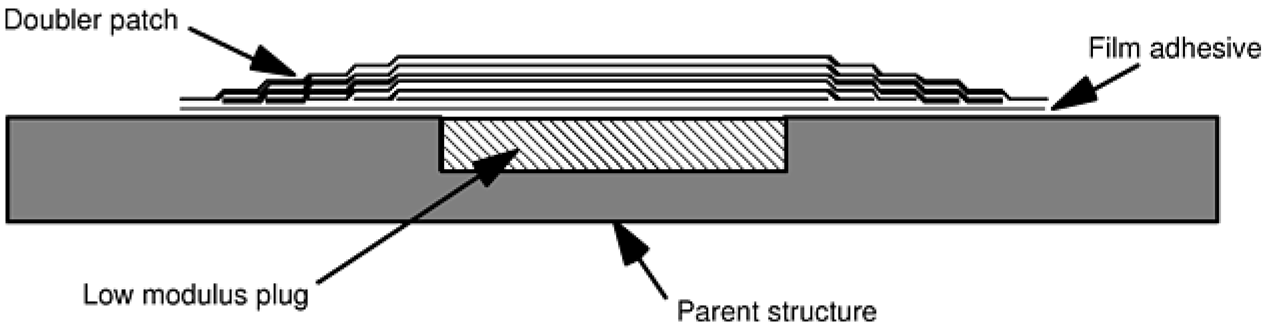

Fig. 11 Inverted doubler and plug repair

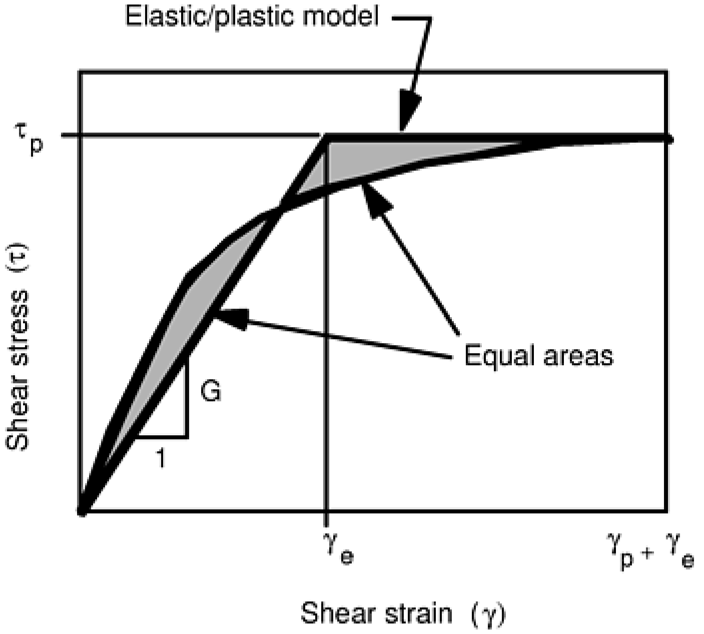

Fig. 12 Idealized adhesive stress-strain curve

The patch overlap length is:

$$l_{\text{overlap}} = \left[\frac{P}{\tau_p} + \frac{2}{\lambda}\right] FS$$

where $\lambda = \sqrt{2G/\eta Et}$, $G = \tau_p/\gamma_e$, and *FS* is the factor of safety.

Scarf or Stepped Repair. When higher loads are to be transferred through the repair region or a smooth surface contour needs to be maintained, an adhesively bonded scarf repair is recommended (Fig. 1). A flush repair to a thin laminated section will be either a scarf joint or stepped-lap joint. Generally the damage removed results in a scarfed section, and the replacement plies are stepped (Fig. 13). For preliminary design purposes, a scarf joint analysis is used. In the simple analysis, try to maintain stiffness and thermal coefficient of expansion balance; therefore, if the load is acting over a scarf angle of θ°, the shear and normal stresses (Fig. 14) are:

$$\tau = \frac{P\sin(2\theta)}{2t}$$

and

$$\sigma = \frac{P\sin^2\theta}{t}$$

As θ gets smaller, the normal stress will approach zero. By letting $\tau = \tau_p$, the allowable load carrying capacity of the joint is:

$$P = E\varepsilon_{\text{ult}}t = \frac{2\tau_p t}{\sin(2\theta)}$$

where E_{ult}= nominally 4000 microstrain.

Therefore, the scarfing angle is given as:

$$\theta = \frac{\tau_p}{E\varepsilon_{ult}} \text{ (in radians)}$$

For the majority of structural adhesives and adherends, the scarf angle θ is limited to 3°. This gives a repair scheme length expression of:

$$l_{patch} = \frac{2t}{\tan\theta} + D_{hole}$$

where t is laminate thickness and D_{hole} is the hole diameter. As a function of the laminate thickness for a hole size of 50 mm (2 in.), Table 3 indicates the increasing patch size if a 3° scarf joint is used and clearly shows that this repair design is limited to thinner structures.

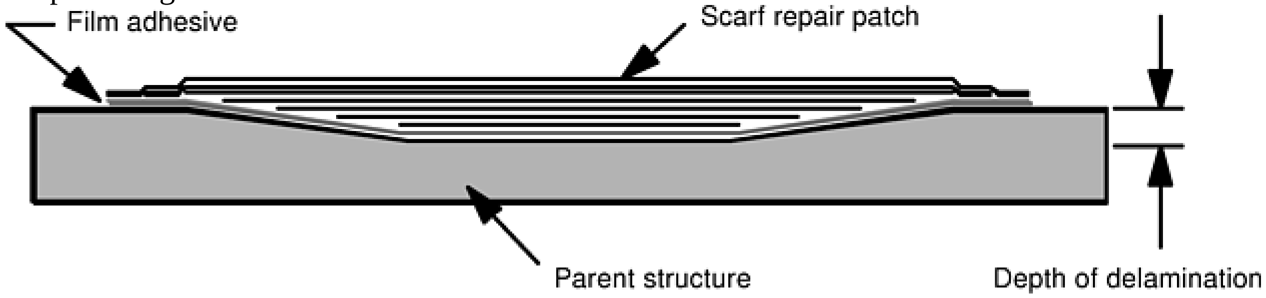

Fig. 13 Stepped-lap/scarf repair scheme

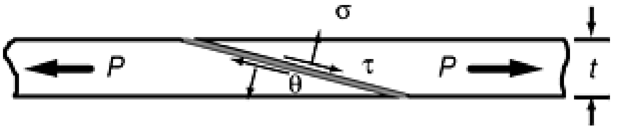

Fig. 14 Scarf joint analysis geometry

Table 3 Relationship between scarf patch size and laminate thickness for a hole size of 50 mm (2 in.)

No. of plies	**Laminate (a)**		**Scarf length**		**Patch length**		Ratio of patch length
	mm	**in.**	**mm**	**in.**	**mm**	**in.**	to hole diameter
8	1.0	0.04	19.1	0.75	88.2	3.47	**1.8**
12	1.5	0.06	28.6	1.13	107.2	4.22	**2.2**
16	2.0	0.08	38.2	1.50	126.4	4.98	**2.5**
24	3.0	0.12	57.2	2.25	164.4	6.47	**3.3**
36	4.5	0.18	85.9	3.39	221.8	8.73	**4.4**
52	**6.5**	**0.26**	**124.0**	**4.89**	**298.0**	**11.73**	**6.0**

(a) Based on a ply thickness of 0.125 mm (0.005 in.)

Additional information on adhesive bonding is provided in the articles “Bolted and Bonded Joints” and “Secondary Adhesive Bonding of Polymer-Matrix Composites” in this Volume and in Ref 14 and 15.

Mechanically Fastened Joints. As the skin thickness increases, scarf repairs become impractical in terms of repair design. At this stage, a bolted repair is more practical. The analysis of a bolted repair follows the methodology of a mechanically fastened joint using the allowable load per unit width of:

$$P_{all} = E\varepsilon_{all}t$$

The following design points are recommended for a bolted repair design:

- Attempt to use a low-modulus plug that restricts the load into the filled hole. A loaded hole (inclusion) can have a greater strength reduction than an open hole.
- Where a patch is relatively thick, taper the patch edges or use a stepped-lap configuration; this will reduce the load on the first row of fasteners, which are typically critically loaded.
- Seal the patch to the parent laminate and install the fasteners with sealant in the wet condition.

- Bearing/bypass loads require specific design attention, noting that the bearing strength of composite structures is often low and significantly affected by environmental conditions.

Additional information on mechanical fastening of composites is provided in the articles “Bolted and Bonded Joints” and “Mechanical Fastener Selection” in this Volume.

Pitfalls and Problems

Repair design for composite structures assumes several factors. The first assumption is that the repair patch materials properties are the same as those of the parent structure. This assumption is acceptable if the repair patch is autoclave precured. However, most adhesively bonded composite repair patches are co-bonding to the parent structures. This raises a number of problems:

- Repair patch material properties will not be the same as those of the parent structure. Several factors influence this property variation, particularly when using the vacuum bag and heater-blanket curing process. The inability to achieve high consolidation pressure will result in a lower fiber-volume ratio. Due to thermal variations across the heater blanket and heat sinks from local substructure changes, the cure rheology will be different.
- When doing heat-cured repairs, the level of absorbed moisture in the parent laminate can result in poor repair and bondline properties, due to the formation of voids. Only through drying out the parent laminate prior to repair can this be overcome. Significant levels of absorbed moisture can result in extensive damage to the structure, such as blown skins.
- The choice of either doing the repair in the field or removing the structural component to be repaired and doing the work in a workshop also results in structural property variability. Repairing the composite structure in a workshop where the environment is controlled will provide a better repair. This is particularly true for moisture removal and surface preparation when doing adhesively bonded repairs.

A second potential pitfall is the adequacy of the repair analysis. In the repair design analysis for both adhesively bonded and mechanically fastened repairs, the material properties are typically assumed from vendor data, with

ample margins of safety applied to cover environmental conditions. This is particularly true for bearing strength of composite materials. However, the complex interaction of stress transfer is usually not applied, even if understood. The removed damage does not result in geometrically perfect interfaces; however, the analysis assumes this to be so. The skill of the technician thus plays a critical role in the development of uniform load transfer into the repair patch. The preparation of the surface for adhesively bonded repair schemes is also critical and depends on the skill and thoroughness of the technician. Surface preparation to composite structures is not as critical as in metallic structures, but the effect of poor surface preparation is the same: the repair patch will eventually fail at the bondline interface (adhesive failure mode) due to bondline degradation.

Corrosion is always a problem in repair design application and durability. The selection of repair materials must be consistent with the parent structure. The situation is more critical in mechanically fastened repair schemes, where the composite repair scheme can be bolted to a metallic substructure. Adhesively bonded repair schemes have several concerns. The bondline, if broken, can allow moisture to enter, resulting in substructure corrosion. This is a real concern with metallic honeycomb core structures.

Finally, the stress state in the structure and the repair scheme is typically considered uniform. However, the stress state is often complex and includes some degree of out-of-plane loading. Careful design of the repair scheme is required in order to either eliminate the severity of the complex three-dimensional stress state or to allow the repair scheme to accommodate such a stress state. The first option is typically preferred but not always easy to do.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Introduction

REPAIR OF DAMAGED ADVANCED COMPOSITE COMPONENTS often is more economical than replacing them. Many thousands of composite structural repairs have been made over the years, so they obviously can be done well. For lightly loaded nonstructural parts, such repairs may sometimes be only cosmetic. For loaded structures, however, repairs must be more than cosmetic and are generally intended to restore the ability of the component to carry design loads. These types of repairs are discussed in this article, together with other issues surrounding advanced composite repair technology.

Composite repairs can be complex, with many possible variations and differences of opinion as to how they are best performed. They are not necessarily more difficult than metallic structural repairs, but they are different. The major difference is that in repairing a composite, one is not only accomplishing the repair, but also "creating" the strength of the materials as the repair plies are laid up and the resin is cured. This additional level of complexity, and the difficulty of inspecting composites after cure, leads to many of the quality- and process-

control considerations that are so important to achieving reliable repairs. New skills are required of not only repair technicians, but also of the engineers who are designing repairs for composite structures.

As structural design engineers become more comfortable with using composites in heavily loaded structures, the design allowables are creeping ever upward, and the materials are being used at higher microstrain levels, closer to their true limits. While this is necessary to achieve efficient structures, it makes the job of the repair design engineer and repair technicians more difficult. With overdesigned composite structures, there is some leeway for understrength repairs to work successfully. This may not be so in more efficiently designed structures. So repair personnel have to be careful in assuming that what they “got away with” in the past will work in the future. As always, a true understanding of the detailed complexities of these structures is what is needed to repair them safely and economically.

In a theoretically ideal repair, one is trying to match, not exceed, the strength, stiffness, and weight of the original structure. A “perfect” repair would be to replace the damaged component with a new one. Then those three parameters would be matched exactly. In an actual repair, it is not possible to match all three simultaneously. To achieve the original strength, the repaired part will be stiffer and heavier than the original. To match the original stiffness, the repaired part would be weaker and slightly heavier than the original, and so on.

Therefore, repair design involves evaluating trade-offs among these parameters, especially with stiffness-critical structures, such as helicopter rotor blades. Other considerations also come into play, such as the physical practicality of performing the repair successfully, the time involved, inspection and substantiation of the quality of the repair, cosmetic appearance, cost, and so on.

In type-certified civilian aircraft, one is obligated to follow the repair procedures outlined in the aircraft structural repair manual (SRM). If the damage is outside the allowable limits defined in the SRM, then the repair will require specific engineering support from an authorized source, and a specific repair designed for that particular damage case will be required. If the engineering support is not available, then the part must be replaced. Military organizations have their own similar procedures.

Durability and inspectability of repairs are also a concern. Since a large percentage of composite repairs are bonded rather than bolted, the long-term durability of the adhesive bond is important. Small details in the repair process, especially regarding surface preparation, are vital in determining the quality of the repair. Control of the repair materials and processes is therefore crucial.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Types of Damage

Various types of damage can occur in a fiber reinforced polymer-matrix composite as a result of impact severity, as shown in Fig. 1. Damage includes holes and punctures, delaminations, disbonds, core and resin damage, and water intrusion.

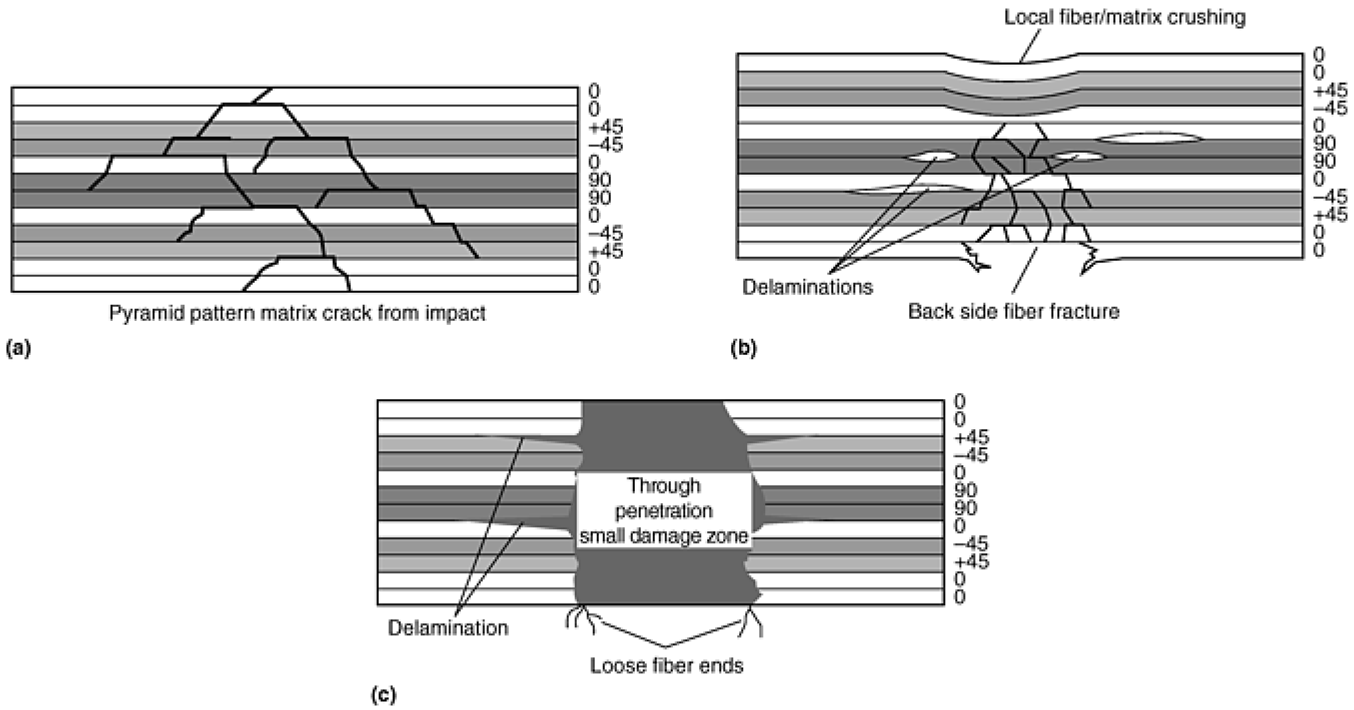

Fig. 1 Damage to fiber reinforced polymer-matrix composites resulting from different impact severity. (a) Low-energy impact. (b) Medium-energy impact. (c) High-energy impact

Holes and punctures usually are caused by high- or medium-level impact. Damage can be severe, but usually is easily detected and generally is localized near the point of impact.

Delaminations, perhaps the most common of all types of damage, often are caused by low- energy impacts, such as a tool drop or a glancing bird strike on an aircraft. They sometimes are visible if near the surface, but the full extent of damage is often not readily detectable.

Disbonds indicate an adhesive bond failure between joined structures. They usually are observed with a face sheet disbonding from an underlying sandwich core material.

Core damage can occur with any type of core. Causes of core damage include handling damage in manufacturing, impact, improper vacuum bagging, and fluid ingress.

Resin damage can be caused by many factors including fire or excessive heat, ultraviolet (UV) rays, paint stripper, and impacts. It may be hard to detect, and it is especially difficult to quantify the effects of such damage on the structural integrity of the part. As a general rule, resin damage leads to a greater loss in compressive strength than in tensile strength.

Water intrusion is especially a problem with honeycomb cores, resulting in weight gain, corrosion in aluminum honeycomb, and core cell ruptures and disbonds if water freezes and expands. A very common problem in high-temperature repairs is that the heat of curing the repair causes the trapped water to turn to steam, disbonding face sheets around the repair; this is an excellent way to inadvertently convert a small area of damage into a large one. Water intrusion also softens the cured matrix, reducing compressive properties, particularly bearing strength.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Damage Detection in Field Conditions

Visual inspection can be a quite effective and often underrated technique for detecting damaged composite structures. Even low-energy impacts may leave a slight marring, paint scrape, or faint surface blemish on a part.

A slight wave or ripple on the surface may indicate an underlying delamination or disbond. A light spot or "whitish" area on a fiberglass part may indicate trapped air, a resin-lean area, or a delamination.

However, one of the common problems with composites is "hidden damage." Often, low-energy impacts will leave no visible marks on the surface, but underlying delaminations can be extensive, spreading out in a cone-shape from the impact point. Often plies on the back side will be visibly delaminated, but this is not visible from the front. Some, but not all, hidden damage can be detected using the methods discussed in this section.

Tap testing probably is the most common inspection technique used other than visual examination. By tapping gently on the surface of a composite part, often it is possible to hear a change in sound from a clear sharp tone to a dull thud. By tapping back and forth over the area in question, and making a small mark at the point where the tone just begins to change, it is possible to outline large, irregularly shaped areas of delaminations or disbonds.

However, there are many limitations to tap testing. For example, it does not work well through a core material; that is, it is difficult to detect damage on the back side of a sandwich structure without access to both sides. It does not work well on deep damage in thick laminates— a reasonable limit typically is about 4 to 6 plies deep, depending on the type of composite material being inspected.

In addition, when performed correctly, one is listening for very small changes in tone. This means tap testing has to be done in a quiet area by a person who has good hearing. As with all nondestructive inspection techniques, the inspector has to have a good knowledge of the underlying structure. Internal doublers, bonded stiffeners, core potting compound, and the like will change the tone and could lead to false interpretations.

A digital tap tester can help overcome some of these limitations. It reads the bounce time of a small plastic tap hammer in microseconds and can give better resolution and read deeper damage than can manual tapping. It also is unaffected by external noise and so is especially good for tap testing on an aircraft ramp with jet engines running nearby.

Ultrasonic inspection consists of two main methods: pulse-echo and through-transmission. Both methods can detect many types of hidden defects, but not all defects.

Pulse-echo requires rather expensive portable equipment and a very well-trained inspector, and it can be performed with access from one side only—on a part still mounted on an aircraft, for example. It is more suitable for small-area inspections because it is difficult to cover large areas using typical portable equipment in a reasonable time. Delaminations and disbonds can be detected deeper down inside the structure than those detectable using tap testing. The method provides information about the depth of the defect, down to the particular ply level in many cases. Pulse-echo primarily is used at repair facilities or at manufacturing facilities to give more detailed information about a defect uncovered by another method. It does not work well through a core material to detect problems on the back-side skin.

Through-transmission requires access to both sides of a part and often is performed using rather expensive fixed equipment. It can be automated and can cover large areas fairly quickly and may or may not give depth information. It is most commonly used in manufacturing and large repair stations.

X-radiography requires expensive equipment and well-trained inspectors. It is an excellent method for detecting metallic inclusions and for inspecting aluminum honeycomb—it is relatively good at finding water trapped in honeycomb—but is not good for detecting delaminations parallel to the plane of the x-ray image.

Thermography uses an infrared camera to videotape parts as they are heated or cooled and uses the visible thermal differences to extract information about the part. It is useful in bondline inspection, detection of inclusions, and in some cases detecting water trapped in honeycomb.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Component Identification

Ideally, fiber reinforced composite components should be fully identified before a repair is performed. Such details as material specifications, ply numbers and ply orientations, core ribbon direction, ply buildups and drop-offs, and numerous other details need to be understood before a repair commences.
For aircraft, this type of information usually is available in the SRM, design drawings, or equivalent documents. In repairs of nonaerospace components, an SRM or equivalent often is not available. However, the types of information described previously are still needed for proper repairs and should be obtained by the repair technician. Determination of these details can often be made by careful taper sanding through a scrap of material and reading the information directly from the composite itself. A thorough understanding of composite materials, weave patterns, ply orientation concepts such as balance, symmetry, nesting, and so forth, is mandatory for this type of analysis to be meaningful.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Paint Removal

Chemical Stripping. Most paint strippers (solvents) are methylene-chloride based, which will attack cured epoxy resin, and, therefore, are not recommended for use on composite structures. Alternatives include hand sanding and various particulate-blasting methods.
Hand sanding is widely used as a paint-removal method for composites. No expensive equipment is needed, and the sanding pressure can easily be controlled to avoid laminate damage. Hand sanding is recommended for paint removal in a small area (in an area to be repaired, for example). One must be careful not to damage fibers in the surface ply, unless a specific “sanding ply” has been included on the surface of the component. The obvious disadvantage is the high labor cost, especially on large parts. However, this is by far the most common paint-removal method in preparation for repair.
Blasting involves the use of various types of blasting media including sand, aluminum oxide, plastic particles, wheat starch, and others.
Sandblasting is possible, but must be done very carefully, as it is extremely likely that fibers on the top ply would be damaged.
Aluminum oxide blasting is similar to sandblasting, and the same precautions apply.
Plastic media blasting is less aggressive than sand or aluminum oxide blasting and is used quite a bit on composites. While effective, this technique has shown some difficulties in the field. The plastic media most often are cleaned and reused in such systems, which can lead to the following problems:

- The cleaning process is largely designed to remove paint chips and solid matter. If the plastic media become contaminated with oil, grease, fuel, and so forth, these contaminates can be driven back into the composite surface, causing paint adhesion problems.
- The plastic particles become dull with reuse, and a poorly trained operator may turn up the air pressure to compensate. This can lead to damage of the composite surface or even blowing a hole through these rather brittle materials.

Wheat starch blasting is a fairly new method used to blast paint off parts. Boeing has approved this method for paint removal from composites. Corn-hybrid polymer blasting is an even newer but similar method. There is no chemical attack to worry about; wheat starch and corn-hybrid polymers are environmentally benign, biodegradable material that can easily be disposed of.
Other Methods. There are many other methods, such as dry ice blasting, Xenon flash lamps, baking-soda blasting, and so forth. Work in this field is continuing, and better methods are being sought by many organizations.

Michael J. Hoke, Abaris Training Resources Inc.

Repair Design

Designing for repair involves various considerations including structure types and repair types.
Structure types include:

Type	**Criteria**	Example
Primary	Heavily loaded or safety-of-flight structures	**Helicopter blade**
Secondary	Intermediate loading and safety structures	**Aerodynamic fairing**
Tertiary	**Lightly loaded or noncritical structures**	**Interior sidewall panel**

Note that in some cases, a structure is designated as secondary or tertiary from a design load point of view, but it may be treated as primary structure regarding the critical nature and location of the component. An example would be a lightly loaded fairing located in front of the intake of a jet engine. Failure of the fairing itself would not be structurally critical. However, if it gets sucked into the engine, the resulting engine failure could cause more interesting problems.

Repair types include cosmetic, semistructural, structural, and temporary.

A cosmetic repair is a superficial nonstructural filler as shown in Fig. 2. This type of repair will not regain any strength and must be used only where strength is unimportant. However, it can serve to keep water out of a hole until a more permanent repair is made. Due to high shrinkage with some fillers, these types of cosmetic repairs often will start to crack after a relatively short time in service.

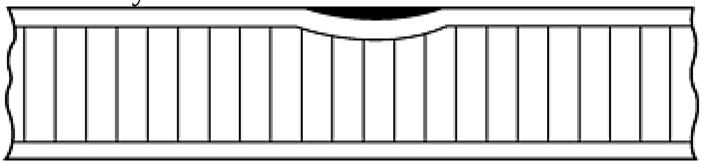

Fig. 2 Cosmetic repair using superficial nonstructural filler

Semistructural repairs include a plug-and- patch repair (Fig. 3) and resin-injection repair (Fig. 4). These types of repairs can regain some strength. The mechanically fastened plug-and- patch repair can be especially effective where thick solid laminates are used because they withstand bolt loads well. Resin injection can be effective in limited instances, where the delamination is restricted to one ply. However, not much strength is regained, and the primary benefit of this type of repair is that it is quick and inexpensive. At best, one can hope to slow the spread of a delamination with this type of repair, and it is generally considered a temporary measure.

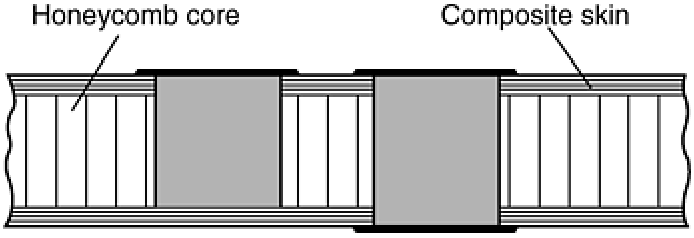

Fig. 3 Semistructural plug-and-patch repair

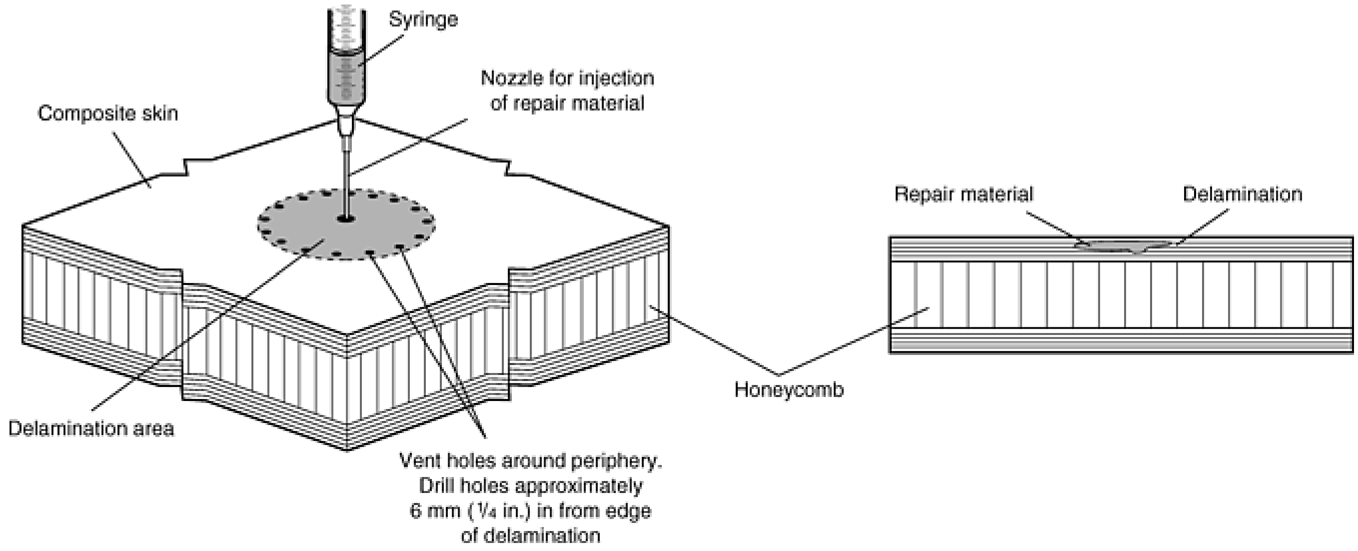

Fig. 4 Semistructural resin-injection repair

Structural repairs include mechanically fastened doublers (metallic or precured composite), bonded external doublers, and flush (aerodynamic) patches.

Full structural repairs using bolted doublers (Fig. 5) can be used in heavily loaded solid laminates and are often the only practical means of repairing such structures. However, such repairs are not aerodynamically smooth and may cause “signature” problems in structures where low observability is a design criteria.

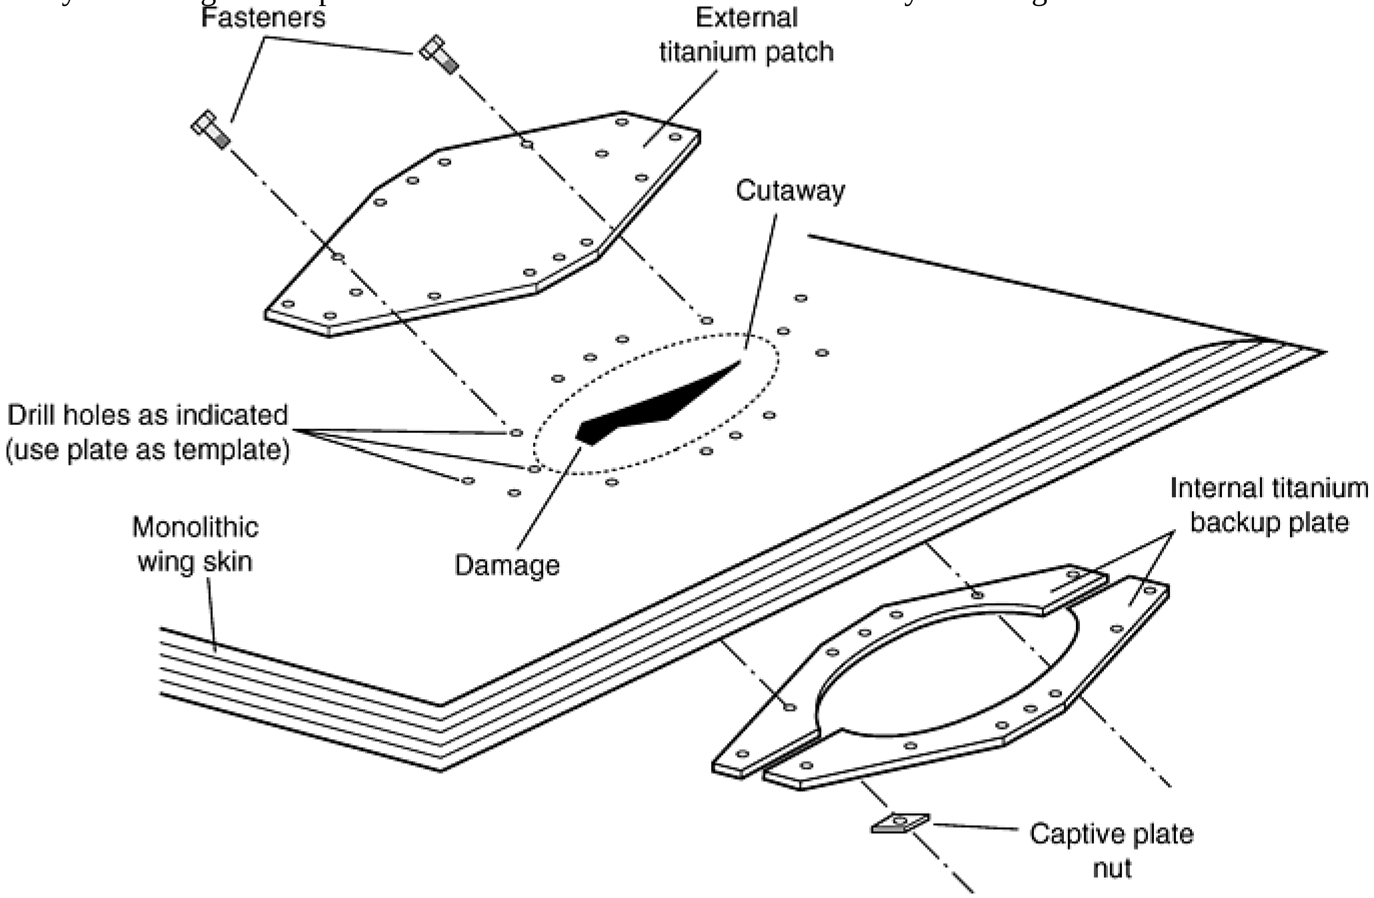

Fig. 5 Mechanically fastened doubler (bolted patch repair) on thick skin composite

Bolted repairs are used in repairing structures such as F-18 wing skins, Boeing 777 horizontal and vertical stabilizers, AV-8B Harrier wing skins, and other similar items. It is important to note that the original design must allow for the use of bolted repairs, otherwise a significant reduction in design load allowables will result.

Bonded (as opposed to bolted) doublers often are used, especially with wet lay-up materials, to perform repairs to lightly loaded, thin laminate structures. They may be either room- or high- temperature cured, depending on

the repair matrix system. They can regain a significant portion of the original strength of the structure, or even full strength, although with a significant stiffness and weight penalty in many cases. They are generally easy and relatively quick and do not require the highly developed skills of the flush repairs described below.

Flush (aerodynamic) patches, called “taper sanded” or “scarfed” repairs, are most commonly applied to thin solid laminates or sandwich structures. They require careful (smooth, flat) removal of material at a precise angle, all around the cleaned-up damaged area (Fig. 6). This is usually accomplished by hand using a compressed-air-powered high-speed grinder. Significant skill and practice on the part of the repair technician are mandatory.

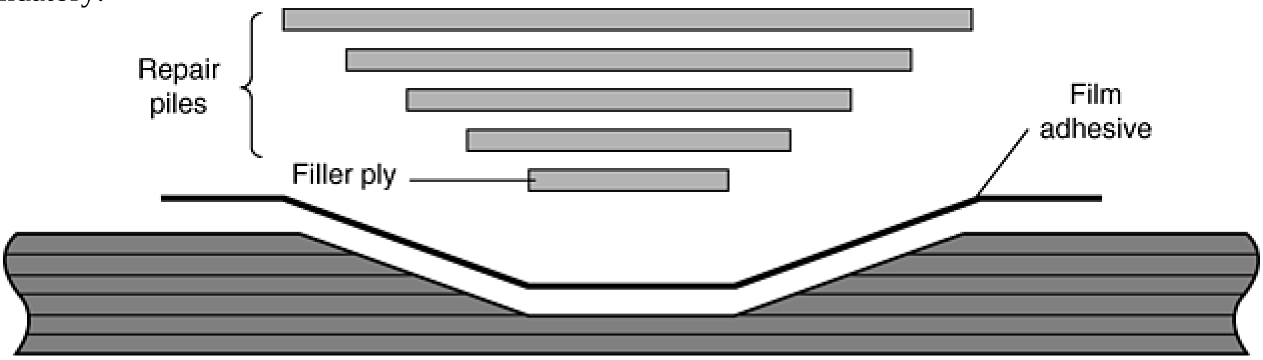

Fig. 6 Scarf removal for flush (aerodynamic) repair

These repairs currently are considered the best in terms of the strength, stiffness, and weight trade-offs discussed previously and are very commonly called out in aircraft SRMs. They can be almost perfectly flush with the surface if performed very carefully. Typical scarf distances are from 20 to 120 times the thickness of the laminate being scarfed.

Stepped repairs are similar in geometry to scarfed repairs, but the plies are cut back one by one in a terraced pattern (Fig. 7). The resulting plateaus are then filled in with new plies. Many of the same advantages as scarfed repairs are obtained. However, it can be very difficult in many laminates to cut cleanly through a ply without damaging any fibers in the ply below. The sharp edges of the steps also can lead to abrupt stress concentrations in the repaired laminate. While theoretically all of the repair plies in a stepped repair can lay perfectly flat, which is not possible at the very edges of a scarfed repair, the practical difficulties of performing a stepped repair without damaging underlying plies have led to a reduction in use in recent years.

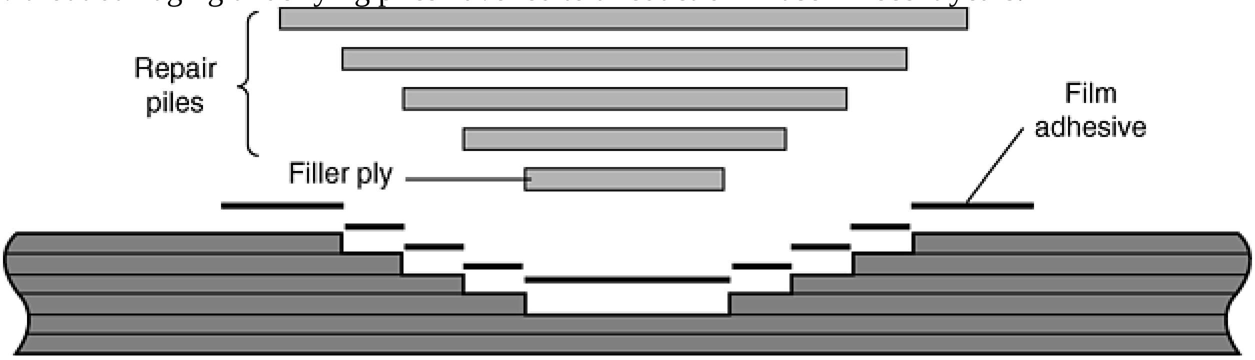

Fig. 7 Step removal for flush (aerodynamic) repair

Temporary repairs commonly are used in cases of battle damage and limited service (ferry flight, etc.). Temporary repairs often are performed to return an aircraft to a location where a permanent repair can be performed. Structural repair manuals spell out the limits of such repairs. They often are performed using materials such as speed tape, potting compound, or other such materials. The primary purpose is to limit the further spread of damage—and to keep water, airflow, and so forth out of the damaged area—until a permanent repair can be made. If a temporary repair is desired that falls outside the allowable SRM limits for such repairs, then engineering approval is needed, and for U.S.-certified civilian aircraft a “ferry permit” might be required to allow a one-time flight to a station that can perform a permanent repair.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Repair Design Considerations

Stiffness Discontinuities. Repairs should not have high stiffness near edges. This leads to peel mode failures in adhesive bonded repairs. In addition, an abrupt change in stiffness at the edge of a repair can lead to failure of the underlying part during structural loading at the edge of the repair. This failure can occur at a lower load than that at which the unrepaired part would have failed, due to the high concentration of load at the edges of the stiff repair. This is why gently tapered repairs are often performed. Softening of the edge of the repair is often performed by ply drop-offs and/or “pinking” the edges of the outermost repair plies.

Available Equipment. Often the equipment and materials available determine to a large extent the repair scheme. For example, SRMs frequently offer several different repair schemes, such as wet lay-up room-temperature cure, generally with a higher-temperature postcure; prepreg 121 °C (250 °F) cure; or prepreg 177 °C (350 °F) cure. As a general rule, the higher the temperature, the larger the allowable repair. However, in some cases, such as a honeycomb core structure having possible water contamination, a lower-temperature repair often is preferable to avoid further damage. As a general guideline, if multiple repair methods are authorized for a given area of damage, choose the lowest-temperature approved method. The lower the temperature, the fewer the problems, and the lower the chances of moisture turning to steam and disbonding a sandwich skin or creating excessive porosity in a bondline.

An additional important equipment consideration concerns availability of vacuum bagging and curing equipment. These items are discussed in the following paragraphs.

Lightning-Strike Considerations. Occasionally, the surface of an external composite component will be a ply or layer of conductive material. In addition to a normal structural repair, one must also recreate the electrical conductivity designed into such a part. These conductive materials are of many different types, ranging from nickel-coated graphite cloth to metal meshes to aluminized fiberglass to conductive paints. These types of repairs generally require a conductivity test be performed with an ohmmeter to verify minimum electrical resistance across the structure. It is extremely important in repairing these types of structures to use only the approved materials from the specific vendors authorized, including such items as potting compounds, sealants, adhesives, and so forth.

Available Quality-Assurance Methods. It is important to consider whether the quality of the repair is inspectable. How does one know, for example, that a bonded repair will not fall off in the short term (the next day or week) or the long term (the next year)? This is a difficult problem. As of 2000, there is no known commercially available method to nondestructively measure the strength of an adhesive bond. One can destructively test them, carefully control the process of making the actual bonded joints, and get a good, but not perfect, degree of confidence in the strength of a bond.

However, some things can be inspected. If there are delaminations in a repair, this can usually be detected by tap testing or ultrasonic inspection. Obvious resin starvation, ply wrinkles, and so forth also can be observed. If a faulty repair is suspected, then the usual course of action is to remove and replace it.

Training of Repair Personnel. As composite structural repairs become more common on heavily loaded primary structures, the quality of the repairs becomes more critical. In years past, composite components often were so overdesigned that they could tolerate poor repairs and still perform adequately at their design loads.

As engineers become more confident at designing structures to be operated at higher loads, more near the true limits of the materials, understrength repairs are becoming more of a problem. Repair techniques that are acceptable on a lightly loaded structure may be truly dangerous on a heavily loaded structure. The job of the repair specialist is becoming more difficult as composites become more commonplace.

Therefore, training is becoming more important. Development of more standardized materials, processes, and training for repairs is proceeding slowly but steadily. Because a fundamental issue with composite repairs is their limited inspectability, the quality of the repair is very much dependent on the training and integrity of the repair specialist.

Michael J. Hoke, Abaris Training Resources Inc.

Repair Instructions

Manufacturer's Repair Instructions. In military or type-certified-civilian aircraft, repairs must be performed in accordance with approved repair instructions issued by the aircraft manufacturer or military organization responsible. In the airline world, these instructions are located in SRMs. For military aircraft, these are in Technical Orders, Technical Manuals, or the equivalent.

Classification Criteria. Typically, these repair instructions have limits on the size and location of repairable damage. These limits vary considerably from part to part, depending on such things as location of the damage, size and severity of the damage, adjacent damage, part construction details, criticality of the structure, ease of subsequent inspection, temperature requirements, and so forth.

Engineered Repairs and Instructions. If the damage falls outside the allowable repair criteria, then either the part must be replaced, or a specific repair must be designed for that particular component and damage level by an engineer specifically trained and qualified to design composite repairs. This type of engineered repair design is very often done with the close cooperation of the aircraft manufacturer or may be done by engineers from the manufacturer.

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Repair Materials

When performing a permanent repair, the most common repair techniques involve using the same materials used to manufacture the original structure to try to recreate the original structural properties as closely as possible. However, this is not feasible in some cases, especially when the original structure was manufactured with a fiber/resin system that required an autoclave cure, and the repair is being performed without using an autoclave. Therefore, material substitutions may be allowed or even required by the SRM. In battle damage or temporary repairs, often more flexibility in material substitution is allowed than would be normal for permanent repairs.

In any composite repair, the repair materials must be considered and evaluated before the repair is begun to ensure that the repair is structurally sound. Types of repair materials are shown in Table 1.

Table 1 Types of repair materials for making fiber reinforced polymer-matrix composites repairs

Matrix resin systems [(a)]
Wet lay-up
Prepreg
Low temperature
High temperature
Reinforcement fibers and fabrics
Fiberglass
Aramid
Carbon
Boron

Others
Reinforcement form
Unidirectional tape
Woven cloth
Weave style
Core materials
Honeycomb
Foam
Balsa wood
Potting compounds
Others
Lightning-strike materials
Aluminum mesh
Copper mesh
Conductive fibers
Nickel coating
Conductive paints
Flame spray coatings

(a) Also must consider cure cycle requirements and available equipment

Repair Applications, Quality Control, and Inspection

Michael J. Hoke, Abaris Training Resources Inc.

Curing Methods

Portable repair systems are suitcase-sized or smaller units designed to allow for the accurate application of controlled heat and vacuum to a composite repair. They are especially useful for field repairs, in situations where it is not possible to remove the damaged part for repair. Portable systems offer programmable cure cycles, with hard-copy documentation of the actual temperatures and vacuum achieved during the repair. They are most commonly used to control heat blankets, but can also be used to control heat lamps, hot air guns, and even ovens. An electrical power source and a clean compressed air source are required, and the system relies on accurate thermocouple readings. Thermocouple features for “J”-type wire and plugs, accurate to 370 °C (700 °F), are:

Grade	**Accuracy**	Cost
Standard grade	±0.75% or ±2 °C (4 °F); two can vary 4.5 °C (8 °F)	**$1–2/m ($0.30–0.60/ft)**
Special grade	**±0.40% or ±1 °C (2 °F); two can vary 2 °C (4 °F)**	**$12–20/m ($3.60–6.00/ft)**

Wires (24 or 28 gage) are insulated with Kapton coating. Calibration is not a function of length. 0.5 °C (1 °F) temperature change per 38 m (125 ft)

Vacuum bags always are used with prepreg materials and often are used with wet lay-up materials.

Ovens and autoclaves offer the capability to use original molds (if available) and require that panels be removed from the structure. The size of the repaired panel is limited by the size of the available equipment.

Repair Applications, Quality Control, and Inspection

Ship Structure Repairs

A.P. Mouritz, RMIT University, Australia; R.S. Trask, DERA Farnborough, United Kingdom; A.J. Russell, Dockyard Laboratory Pacific, DRDC, Canada

Introduction

A WIDE VARIETY of marine craft, boats, and ships can be made of fiber-reinforced polymer composites, including yachts, fishing trawlers, naval patrol boats, minehunting ships, and corvettes. Composites are also being used increasingly in the superstructures of ferries and naval frigates, funnels of cruise liners, and antenna masts of large warships. Future applications for composites include rudders, propellers, and propeller shafts for naval ships and propulsors and control surfaces for submarines. Most composite ship structures are made of thick-section glass-reinforced polyester (GRP) laminate or a sandwich material consisting of GRP face skins covering a balsa or polymer foam core (Ref 1).

There are many ways that a composite component can be damaged in service, but in general it is due to mechanical loading or environmental conditions that are either unexpected or of low probability, and hence were not allowed for in the original design. A description of the various damage mechanisms to GRP marine composites is given in Table 1. The most common types of damage to GRP vessels are gouges and delamination cracks at the outer hull surface caused by impact with debris in the water and repeated sliding against a wharf in heavy seas. Mechanical damage can include surface scratches, matrix cracking, delamination cracking, fiber failure, and, in severe cases, rupture and penetration of the composite hull. The significance of these damage types will depend upon the particular ship structure. Table 2 gives descriptions and illustrations of the different types of damage. Other types of damage commonly experienced by sandwich composites is disbonding of skins from the core, which is normally caused by poor design or fabrication, and core crushing caused by impact or excessive overloading.

Table 1 Common damage mechanisms of marine composite structures

Damage mechanism	Description
Impact damage	**This is the main cause of damage in composite structures. It occurs most often from low-velocity impacts, either locally, such as a tool being dropped onto a surface, or from a more general collision between moving objects. Abrasion of the surface can occur by the vessel rubbing against the wharf.**
Overload	**The design loads may be exceeded by unexpected loading conditions. (This could be due to inferior design or poor-quality fabrication.)**
Fatigue	**Composite materials are usually highly fatigue resistant to fatigue loading, but damage may still occur at high strains, usually initiating at notches and fastener holes.**
Environment	**If the maximum operating temperature of the material is exceeded, or if it is exposed to fire or chemicals (for example, fuel or paint stripping fluid), then damage such as decomposition of the resin matrix may occur. The properties of the matrix material and fiber-matrix interface can also degrade due to weathering (e.g., moisture, ultraviolet radiation).**
Wartime environment	**Small-arms fire, missile strikes, air blasts, and underwater explosions can also damage naval ships.**

Table 2 Types of damage to marine composites

Defect type	**Defect description**	Illustration of defect
Surface impact damage or gouge	Extended surface indentation, often approximately linear in form, on the laminate surface. Often associated with witness marks from the impactor and delamination damage. Direction of impact event can be inferred from the gouge orientation.	Abrasion damage	The wearing away of a portion of the GRP laminate by either natural (rain, wind, etc.) or man-made (overblasting, collision) events. Confined to the laminate surface	Delamination damage	Single plane or multiplane separation of adjacent layers within a multilayer component. In GRP laminates, it can be associated with a lightening of the damaged region. Often has a curved boundary	Fracture	**Through-thickness discontinuity or separation of the GRP laminate. Defined both as surface rupture (partial separation) of the laminate and as complete separation due to external or internal forces**	
The repair of minor surface damage, such as to gel coats, is not necessary unless the appearance of the ship is important or the long-term properties of the composite will be degraded. The repair of damage consisting of

delaminations, broken fibers, and joint failures is essential when the structural integrity or watertightness of the vessel is compromised. Currently, there are no clear guidelines for determining whether damage has weakened a vessel. However, the hulls of most composite ships have good damage tolerance because of the high safety factors used in design. For example, the design safety factors for minehunting ships are typically between 3 and 6, and this allows the hull to contain a delamination at least 0.3 m (1 ft) long without the stiffness, strength, or fatigue performance being notably affected (Ref 2). Fracture mechanics techniques and finite element analysis tools are being developed to estimate the loss in mechanical performance of composite ship structures due to damage (e.g., Ref 2), although the models are usually simplistic in that only single cracks and simple load conditions are considered. Despite these developments, the amount of damage needed to degrade the structural integrity of a composite ship structure is extremely difficult to specify accurately using modeling techniques. As a result, it is recommended that repairs be made whenever damage consists of delamination cracks or broken fibers.

The aircraft industry has undertaken most of the research, development, and certification of repair techniques for composite structures (e.g., Ref 3, 4, and 5). Some repair methods that were originally developed for aircraft composite structures, such as adhesive patching and scarf repairs, were adapted later for composite ship structures (e.g., Ref 6, 7, and 8). With some repair methods, such adaptation has been fraught with danger, because the composite structures for aircraft are different from composite ship structures. Furthermore, some boat builders are using in-house repair methods that have not been scientifically evaluated for structural efficiency or durability. Navies and coast guards are alleviating the problem to some extent by the introduction of repair standards that have been certified for composite vessels (Ref 9, 10, and 11). The methods outlined in this article, which covers gel coat repairs, patching, scarfing, and step repairs, have undergone extensive development and rigorous testing for use on composite ship structures. Resin infusion repair, which is a relatively new method for repairing marine composites, is also briefly described, even though it has not been completely assessed for ship structures.

Ship Structure Repairs

A.P. Mouritz, RMIT University, Australia; R.S. Trask, DERA Farnborough, United Kingdom; A.J. Russell, Dockyard Laboratory Pacific, DRDC, Canada

Repair Classification, Characterization, and Cycle

The objective of any repair is to return the ship structure as far as practical to its undamaged condition, such that it can support all design loads for the intended service life. Clearly, the objective of the repair will vary on the specific circumstances, but it is likely to include:

- Restoration of static strength, stiffness, and/ or elastic stability of the structure
- Restoration of fatigue performance and long- term durability of the structure
- Restoration of surface profile (e.g., clearances or appearance unaffected)

In addition to achieving the structural requirements, the repair will also be designed to meet additional factors:

- Minimum weight increase (if applicable)
- Simple procedures for implementation
- Accessibility to the damage
- Minimum downtime of equipment and minimum total cost

Emphasis on each of the previous factors will depend on the type of structure, the repair environment, and whether the repair is nonstructural or structural. For example, a structural repair to a composite hull will be more lengthy, compared with the repair of an internal bulkhead. For repairs carried out in-service and away from the dedicated repair yards, the need to use simple procedures takes a higher priority than it might for repairs carried out at a specialized maintenance facility.
When considering bonded composite repairs, it is important to correctly characterize the severity of the damage and the implications on the operational capability of the structure. For the purpose of simplicity, the different repair types can be classified as nonstructural or structural methods. A description of these repair types is provided in Table 3. Nonstructural damage can be defined as any form of damage contained within the surface layers of the composite, or areas of damage penetrating the composite that are of little structural significance. Typical approaches for this type of damage include:

- Mark and monitor over time
- Cosmetic repair
- Temporary repair

Table 3 Description of damage types

Damage type	**Repair classification**	Description
Nonstructural	Mark and monitor	**This approach is undertaken when the nature of the damage does not warrant any form of repair. With this technique, it is necessary to record all information about the nature of the damage in order to be able to compare any worsening of the defect while the structure is subjected to operational loading.**
	Cosmetic	**Cosmetic repairs are designed to repair localized surface defects to the original profile and to prevent moisture ingress.**
	Temporary	**Temporary repairs are only to be conducted when there are operational reasons that prevent the recommended repair approach. These types of repairs must be made permanent at the next designated maintenance period.**
Structural	Minor	**Restoration of the structure to full serviceability, but requiring increased inspection frequencies to ensure that the repair remains effective**
	Major	**Restoration of the composite structure to its original integrity**

Structural damage can be defined as any form of damage that affects the stiffness or strength of the vessel, that is, damage occurring in areas of the vessel that have structural significance. Typical repair methods for this type of damage include:

- Minor repair (restoration to full serviceability)
- Major repair (restoration to original integrity)

A typical repair cycle for a composite structure is summarized in Fig. 1. The repair cycle itself contains a number of distinct levels: the survey of the damage and defect identification; making the repair decision; fabricating the repair; and then monitoring its performance throughout the life of the structure. Although all stages are important, a critical stage of the cycle concerns the defect identification phase, when it is essential to gather as much information as possible to help make an informed decision. Furthermore, a diligent approach at this stage will help eliminate the necessity of requesting any additional structural surveying, which only serves to delay the repair process. The second area that requires close control concerns the fabrication of the repair. In some cases, a repair might involve simple filling of cosmetic damage. However, at the other extreme, a badly damaged hull laminate may well necessitate major reconstruction.

Repair to Gel Coats

Gel coats on marine composites can experience hairline cracking, blistering, and abrasion that can be unsightly and may, over a long period, affect the mechanical performance of the underlying laminate (Ref 12, 13). Gel

coat cracks are caused by many factors, including inadequate design, poor application of the gel coat, impact loading, stress concentrations around drilled holes, thermal expansion, and thermal fatigue effects. Blisters usually occur because of poor adhesion between the gel coat and the composite, or by hydrolysis of the gel coat and subsequent ingress of moisture by osmosis. Most blisters are 2 to 50 mm (0.08 to 2.0 in.) in diameter and raised about 1 to 3 mm (0.04 to 0.12 in.) above the surrounding laminate. Blisters usually occur within the gel coat or at the bond line with the laminate, but occasionally blistering occurs beneath the first or several ply layers in the composite (Fig. 2). Gouges in gel coats occur mostly by the repeated action of the hull sliding against the dock, and severe abrasion marks can be several meters long. Removal of antifouling coatings by scraping can also cause mechanical damage, while the use of chemical paint strippers may degrade the gel coat properties. Some solvent-based paint strippers may impair the abrasion resistance by causing a permanent loss in hardness, while alkaline formulations may increase the likelihood of cracking.

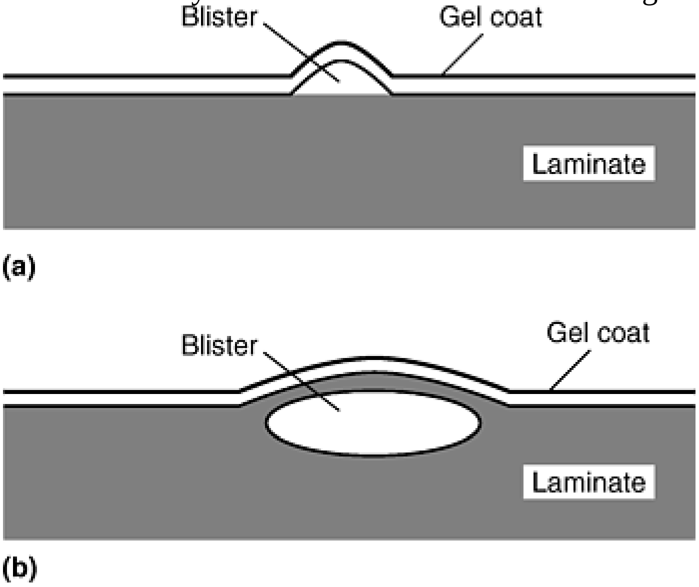

Fig. 2 Blistering. (a) Blistering of a gel coat. (b) Blistering beneath a gel coat

The cracks, blisters, and abrasions to gel coats are usually cosmetic when they first develop and do not affect the structural integrity of the vessel. Blisters less than 5 mm (0.2 in.) in diameter, small cracks, and abrasion marks need not be repaired, although it is recommended they be regularly monitored, because over time the damage may spread. Larger damaged areas may be repaired using the following process:

1. Cracks, blisters, or gouges should be removed by light sanding. The gel coat can be removed until the laminate surface is exposed. Sanding of the laminate must be avoided, unless dry fibers are exposed or the damage occurs immediately beneath the laminate surface.
2. The sanded area should be thoroughly cleaned and dried.
3. The affected area should be filled with an epoxy, vinyl ester, or polyester resin. Care must be taken to ensure that the filler resin is compatible with follow-on gel-coating materials to ensure long-term adhesion and durability. For example, most common marine gel coats are compatible with polyester and vinyl ester commonly used as the matrix resin in many marine composites, but the gel coats may not adhere strongly to epoxy resin.
4. In repairs that require the removal of a small amount of laminate, the cavity should be filled with chopped strand mat wetted with resin or a filler compound consisting of resin and milled glass fibers. The resin used should be the same matrix resin of the composite, or a toughened resin that is compatible with the composite.
5. After curing, the repaired area can be painted, if necessary.

Composite Patch Repairs

Composite patching is one of the most common techniques for repairing minor structural damage to small marine craft with hulls thinner than about 8 to 10 mm (0.31 to 0.40 in.), such as canoes, powerboats, and small yachts. Patching can also be used to repair secondary structures to large composite ships, such as decks and superstructure, when a scarf repair is not possible or necessary. Composite patches can be easily and quickly applied while the boat is dockside.

A schematic diagram of a bonded composite patch is shown in Fig. 3. With a patch repair, the sound material surrounding the damaged area is first sanded and cleaned of dust. Because relatively little material is removed by sanding, it is important to then clean the prepared surface with a nonreactive solvent to remove any contamination. Several layers of glass-reinforced polyester are applied over the damaged area and then cured. A distinct feature of the repair is the offsetting of the ply drop-offs around the edges of the patch. This is done to minimize the localization of edge peel strains that can occur with this type of repair. The consolidation of the repair is improved if the patch is compacted during curing by a vacuum bagging process, although this may not always be practical, particularly when performed as a field repair. Patches rarely recover more than 70% of the original strength, due to the uneven shear stress distribution along the adhesive layer. Bolting can be used to more firmly secure an adhesively bonded patch to the composite substrate and support out-of-plane loads, although drilling the bolt holes can introduce further damage and create stress concentrations.

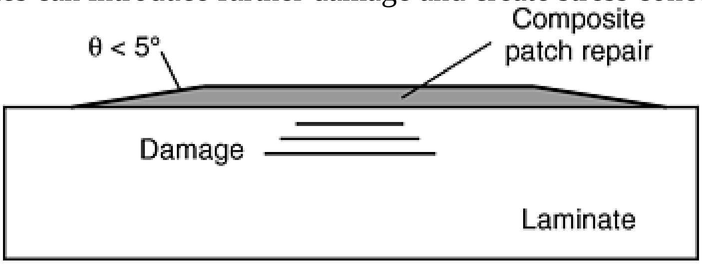

Fig. 3 Configuration of a composite patch repair

Ship Structure Repairs

Scarf Repairs

The most common technique for repairing damaged composite ship structures is the scarf repair. Scarf repairs are popular with many boat builders because they can be applied to almost all types of craft, are durable and watertight, and usually restore an acceptable degree of structural integrity. The repairs restore between 50 and 90% of the original stiffness and strength of the composite structure, depending upon the quality of the repair

and whether it is loaded in bending, compression, or tension. Disadvantages of scarf repairs are: they must be performed at a dockyard by skilled workers; they are time-consuming; and they may require the removal of a large amount of undamaged material to form the required taper angle. Scarf repairs can be made on both single-skin laminates and sandwich composites.

Laminates. Three types of scarf repairs that can be used to repair single-skin laminates are commonly known as single-scarf, double-scarf, and partial-thickness scarf (Fig. 4). Single-scarf repair is generally used when access to both sides of the damaged structure is not possible, or on composite structures thinner than several millimeters. Double-scarf repair should be used whenever practical, and is strongly recommended for the repair of damage that severely degrades the mechanical properties of the composite structure, such as a hole through the hull near or below the waterline. Partial-thickness repair is applied to thick composite structures that have damage confined to a region close to the surface, such as near-surface delaminations or gouges that penetrate only partway through the laminate.

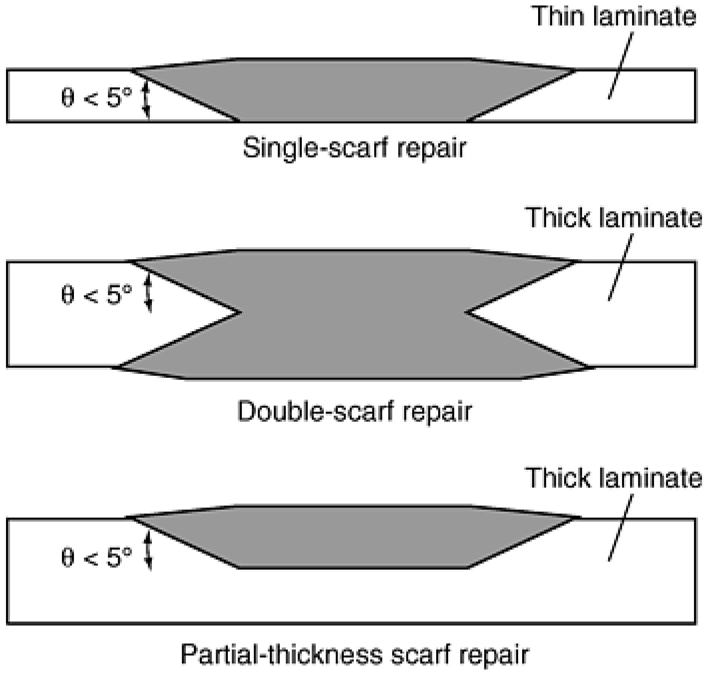

Fig. 4 Illustrations of different types of scarf repairs for single-skin composites

Scarf Repair Steps. Scarf repairs are performed in the sequence of steps described below.

Step 1: Inspection and Mapping of Damage. The size and depth of damage to be repaired must be accurately surveyed using appropriate nondestructive evaluation (NDE) techniques. A variety of NDE techniques can be used to inspect for damage in composite ship structures, and these are reviewed by Bar-Cohen (Ref 14). The simplest technique is visual inspection, where “whitening” due to delamination and/or resin cracking can be used to indicate the damage area in semitransparent composites such as glass/ polyester and glass/vinyl ester laminates. Visual inspection is not an accurate technique because not all damage is detectable to the eye, particularly damage hidden by paint, damage located deep below the surface, and damage in nontransparent composites such as carbon and aramid laminates. A popular technique is tap testing, where a lightweight object such as a coin or hammer is used to softly tap the composite surface. A change in the frequency of the tapping sound is used to indicate the presence of damage. The main benefits of tap testing are that it is simple and can be used to rapidly inspect large areas. Tap testing can usually be used to detect delamination damage close to the surface, but becomes increasingly less reliable the deeper the delamination is located below the surface. Tap testing is not useful for detecting other types of damage, such as resin cracks and broken fibers. More advanced NDE techniques for inspecting composite ships are impedance testing, x-ray radiography, thermography, and ultrasonics (see the article “Nondestructive Testing”in this Volume). Of these techniques, ultrasonics are arguably the most accurate and practical, and are often used for surveying damage. Ultrasonics can be used to detect small delaminations located deep below the surface, unlike visual inspection and tap testing.

Step 2: Removal of Damaged Material. The damaged laminate must be removed and the edges of the sound laminate tapered back to a shallow angle. The taper slope ratio, also known as the scarf angle, should be less than 12 to 1 ($\theta < 5°$) to minimize the shear strains along the bond line after the repair patch is applied. The

shallow angle also compensates for some errors in workmanship and other shop variables that might diminish patch adhesion.

Step 3: Surface Preparation. The laminate close to the scarf zone should be lightly abraded with sandpaper, followed by the removal of dust and contaminates. It is recommended that if the scarf zone has been exposed to the environment for any considerable period of time, it should be cleaned with a solvent to remove contamination.

Step 4: Molding. A rigid backing plate having the original profile of the composite ship structure is needed to ensure the repair has the same geometry as the surrounding structure.

Step 5: Laminating. Laminated repairs are usually done using the smallest-ply-first taper sequence that is illustrated in Fig. 5(a). While this repair is acceptable, it produces relatively weak, resin-rich areas at each ply edge at the repair interface. A better alternative is the largest-ply- first laminate sequence, where the first layer of reinforcing fabric completely covers the work area, followed by successively smaller layers, and then finished with an extra outer layer or two extending over the patch and onto the sound laminate for some distance, as shown in Fig. 5(b).

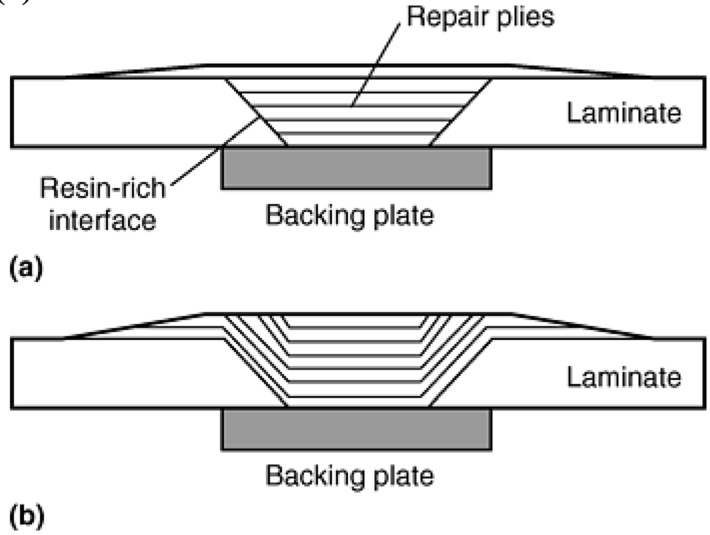

Fig. 5 Illustrations of (a) conventional and (b) improved scarf repair techniques

Selection of the reinforcing material is critical to ensuring the repair has acceptable mechanical performance. The reinforcing fabric or mat should be identical to the reinforcement material used in the original composite. Also, the fiber orientations to the reinforcing layers within the repair laminate should match those of the original hull laminate, so that the mechanical properties of the repair will be as close to original as possible. Resin selection is another important factor in repair. Isophthalic laminating-grade polyester resins are generally acceptable in most marine repairs, although vinyl esters are recommended for hull repairs below the waterline to achieve superior adhesion, better durability, and higher mechanical properties.

The laminating process used in the repair should be similar to that used for original construction of the ship laminate to ensure the repair material has the same fiber-to-resin ratio as the original structure. In other words, a ship laminate originally made using vacuum bagging or resin infusion should not be repaired with an open hand lay-up process, because this will result in a repair with a much lower fiber-to-resin ratio than the base material.

Step 6: Finishing. After the patch has cured, a gel coat and/or paint should be applied.

Properties and Durability of Scarf Repairs to Laminates. Scarf repairs to marine craft should ideally have similar mechanical properties and durability to that of the original composite. Unfortunately, this is not always the case, with the efficiency of a scarf repair being affected by factors such as matching plies, quality of adhesive, scarf angle, and the general quality of workmanship. Most scarf repairs restore up to 80 to 90% of the original stiffness, strength, and fatigue life, and this is considered adequate for a permanent repair. However, the restoration of properties may be much lower than this in some cases. In other cases the stiffness and strength of the repair may be greater than the original mechanical properties of the laminate. This situation is to be avoided because it creates a “hard” spot that may affect the long-term fatigue performance of the structure. Scarf repairs have good long-term durability in the marine environment, and are affected no more than the original structure by contaminates such as oil and fuel.

Sandwich Composites. Sandwich composites used in marine craft can experience three classes of damage, known as type A, B, or C, as illustrated in Fig. 6, 7, and 8. Type A damage is confined to one skin, and is

usually produced by gouging or a low-speed impact that creates matrix cracks, fiber breaks, and delaminations in one of the skins. Type A damage can also include disbonding of one skin from the core. Type B involves damage to one skin and the core, where the core may be crushed or cracked. Type C is damage to both skins and the core, and can be complete rupture of the sandwich structure.

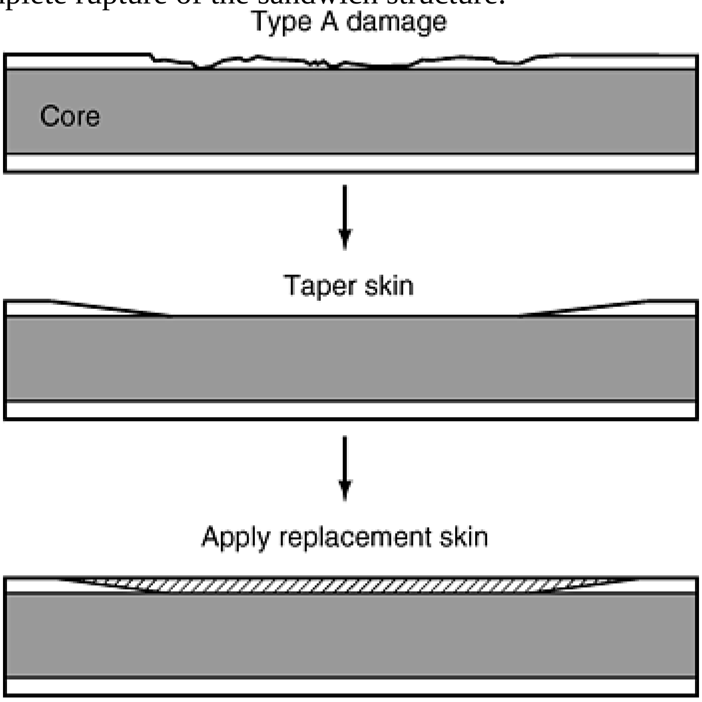

Fig. 6 Schematic of basic steps in the scarf repair to a sandwich composite with type A damage. (Adapted from Ref 15)

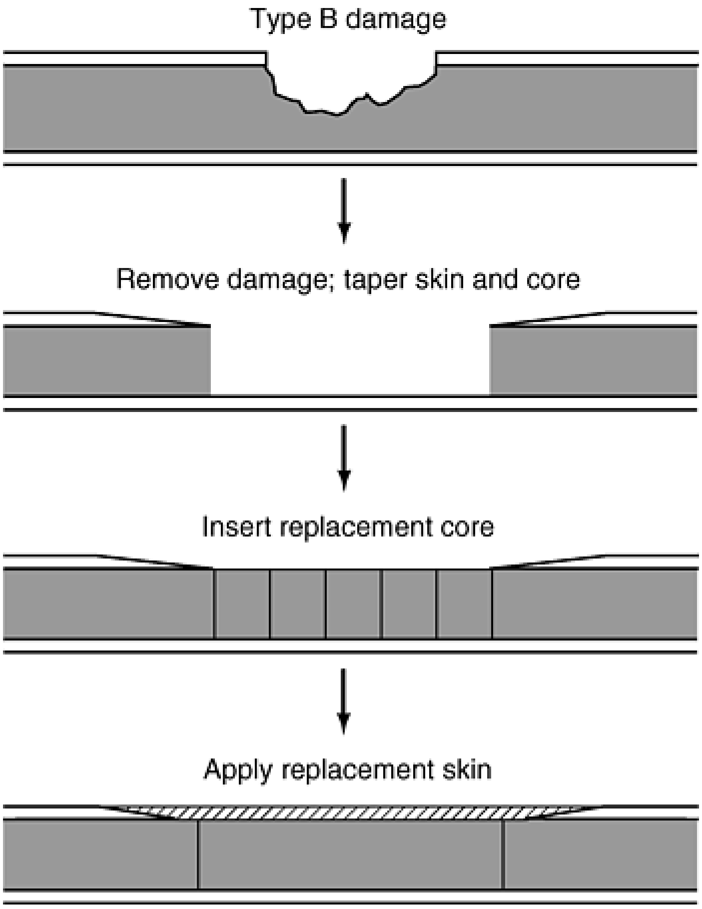

Fig. 7 Schematic of steps in the repair to a sandwich composite with type B damage. (Adapted from Ref 16)

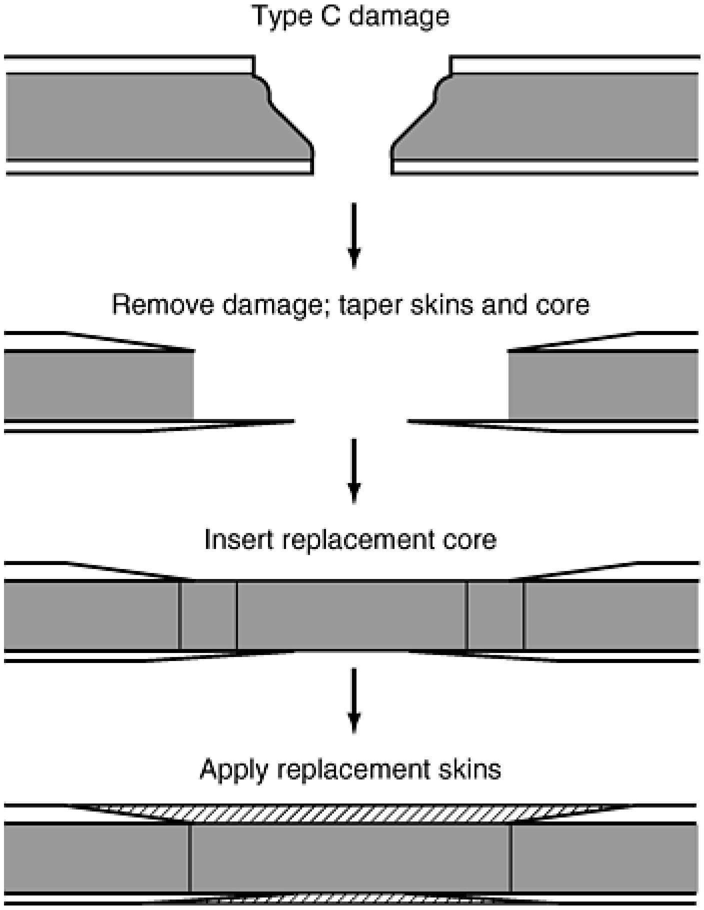

Fig. 8 Schematic of steps in the repair to a sandwich composite with type C damage. (Adapted from Ref 16)

The first step in the scarf repair of a sandwich composite is to inspect and map the damage. The detection of core failures for types B and C damage is difficult using most conventional nondestructive inspection techniques, such as tap testing and ultrasonics. Nondestructive evaluation techniques that may be used to detect damage are impedance testing, thermography, and, possibly, microwave. The repair of type A damage is similar to a single-scarf repair of a single-skin laminate (Fig. 6). The damaged skin is removed, the surrounding sound material is tapered to a scarf angle of about 5°, and then the skin is replaced, often with an extra lay of GRP to ensure high stiffness and strength. Afterwards, the repaired area can be gel coated and painted. The reinforcement and resin should be the same as those of the original skin. It is also suitable in some cases to use resins with higher elongation properties than the original resin, provided both resins are compatible. In addition, the plies must be laminated in the same stacking sequence as the reinforcement in the original skin to achieve optimal structural efficiency. A major problem with scarf repairs of sandwich composites is the entrapment of air at the bond line between the new skin and core, which can result in lower mechanical properties. This problem can be overcome by good workmanship to establish an acceptable bond between the lowest repair ply and the core. The removal of air from along the bond line can also be achieved by vacuum bagging of the wet lay-up repair or by using prepreg repairs.

Different techniques are available for repairing type B damage, with one such technique shown schematically in Fig. 7 (Ref 11, 16, and 17). The main differences between type B repair techniques are the geometry of the replacement core and the taper angle to the core. When the core has been slightly damaged, it is possible to apply a foaming adhesive or a laminate as a replacement. When the core has been extensively damaged, it must be cut out and replaced with the original core material. Some methods recommend replacing the damaged core with square or rectangular blocks with a scarf angle of 90° (Fig. 7). Other methods recommend using triangular wedges with a scarf taper of 45°. Accurately machining a 45° taper through the core of a damaged boat can be

difficult, and therefore most boat builders prefer a scarf angle of 90°, however the repairs are more prone to shear core failure along the bond line.

The replacement core is bonded into place using a polyester resin, syntactic foam putty, or rubber-toughened vinyl-ester-based putty and, if necessary, fastened with small screws or pins (Ref 16). Extreme care is needed when inserting the replacement core sections so that air does not become trapped along the bond line with the undamaged skin. Entrapped air usually occurs during hand lay-up repairs, and the problem can be prevented using vacuum-bagging methods to consolidate the repair. After the replacement core has been inserted, the skin is replaced using the same method as for the type A repair. Type B repairs usually recover about 80% of the structural properties, although repairs having strength and fatigue properties as low as 50% of the original material have been reported (Ref 17, 18).

Various techniques are available for repairing type C damage. A type C repair method is illustrated in Fig. 8, which is an extension of the type B repair shown in Fig. 7. The steps involved in a type C repair are similar to those for a type B repair, with the only obvious difference being the need to replace the second damaged skin. Supplemental “doubler” laminates, larger in area than the repair itself, are commonly applied to the interior laminates in this type of repair, where facing or cosmetic considerations make oversized repair plies impractical for the outer skin. The mechanical properties of sandwich composites repaired by a type C technique are generally similar to those of the original material (Ref 17).

---

Step Repairs

Typical sea-loading conditions on a GRP ship induce cyclic horizontal bending of the hull and shear and torsion of the hull girder, together with static and wave-induced pressures on the hull surface (Ref 1). Due to the bending nature of these loading situations, a step repair profile should be selected in preference to the scarf profile. A schematic illustration showing the basic stages of the step repair technique is given in Fig. 9. As with the other repair techniques, the first stage involves accurately surveying the extent of damage using NDE techniques. After this, the area immediately surrounding a damaged section of hull is removed using a cut and peel-back method, as shown in Fig. 10. A rectangular stepped surface is created by cutting into the hull to a set depth and peeling out material within this area along the level of the laminate. This process is repeated within the peeled out area down to the depth of the damage/delamination, as shown in Fig. 9. The step lengths and step depths are determined depending on the structural criticality of the damaged site.

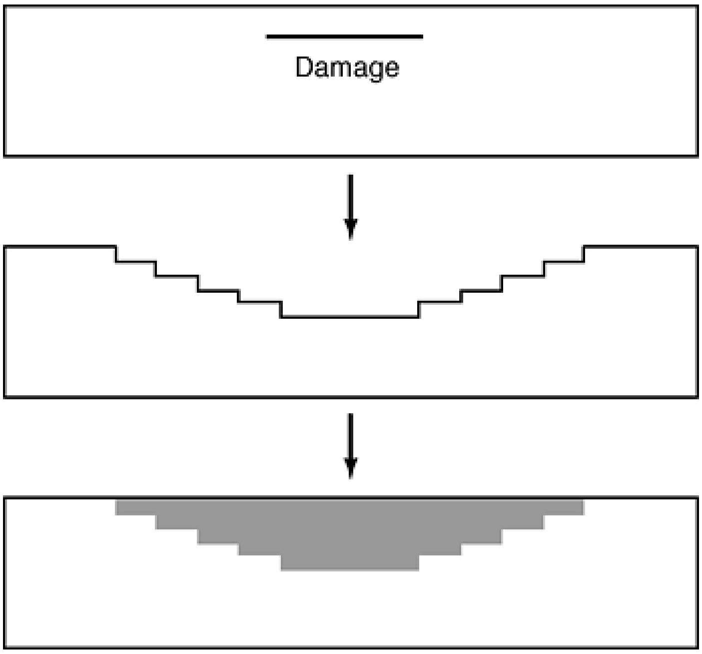

Fig. 9 Schematic of the stages in the step repair of a single-skin composite

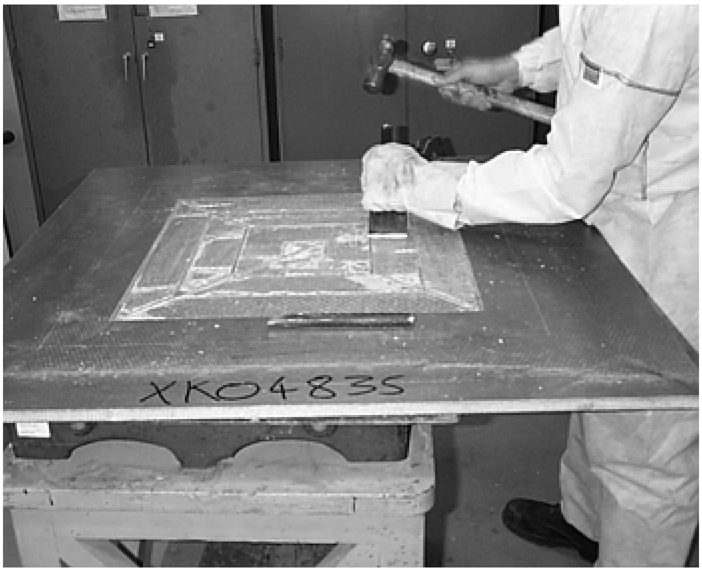

Fig. 10 Mechanical extraction of damage to form a step profile

Producing a stepped profile can be difficult, particularly when performed at sea or in bilges, and it is common to experience problems with the repair. Figure 11 highlights the most common problem with the repair step, namely, the problem of excessive undercutting. When the step into the parent material is made, it is necessary to cut slightly deeper (1–2 mm, or 0.04–0.08 in.) than the nominal step depth. This is so the repair area can be peeled out of the bulk material without delamination extending into the remaining material. Due to the waviness in the ply layers of a composite made by the hand lay-up process, the temptation (on the part of the person cutting out the damage) is to always cut slightly deeper than necessary to prevent this peel-back into the parent laminate. Although it may be expected that the undercut would pose a structural weakness in the repair site, this generally does not appear to be the case. For example, in the Royal Navy composite minehunting vessels, where this technique is used for the repair of all structural damage, there has been no indicated in-service failure of this type of repair.

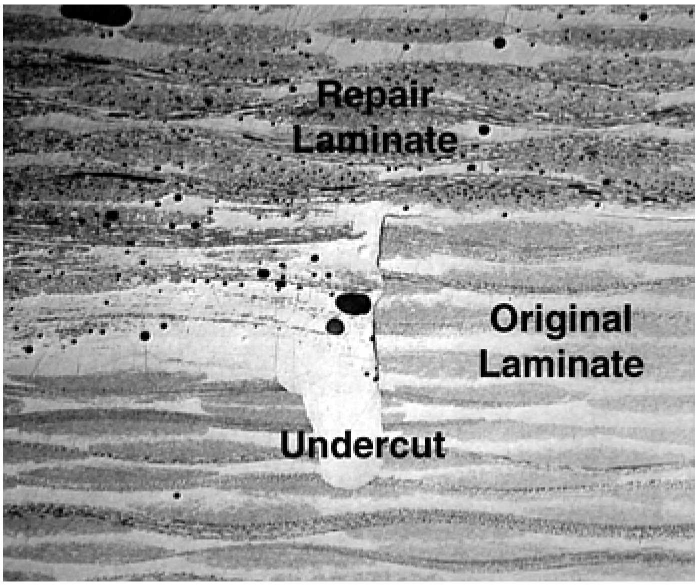

Fig. 11 Micrograph showing a typical undercut in a GRP step repair

After the damaged material is removed and the step profile is complete, the hollowed-out area is given a standard surface preparation, and the repair material is laid up into it with only manual consolidation and cured in situ at ambient temperature.

Resin-Infusion Repairs

Resin-infusion repair methods are relatively new techniques being developed to restore minor structural damage to single-skin laminates and to repair disbonds between the skin and core of sandwich composites (Ref 19). As with any repair technique, the first step in a resin-infusion repair is to survey and map the extent of damage. Narrow holes are then drilled through the damaged material at several locations, with the holes usually spaced 5 to 30 cm (2 to 12 in.) apart. Plastic hoses are connected from the holes to a vacuum pump, which extracts any moisture that may have seeped into the crack. Following this, some of the hoses are connected to a resin source. Resin is then drawn under vacuum into the crack, until filled. The hoses are disconnected, the resin cured within the defect, and the repair is complete. A resin-infusion repair to a composite ship is shown in Fig. 12.

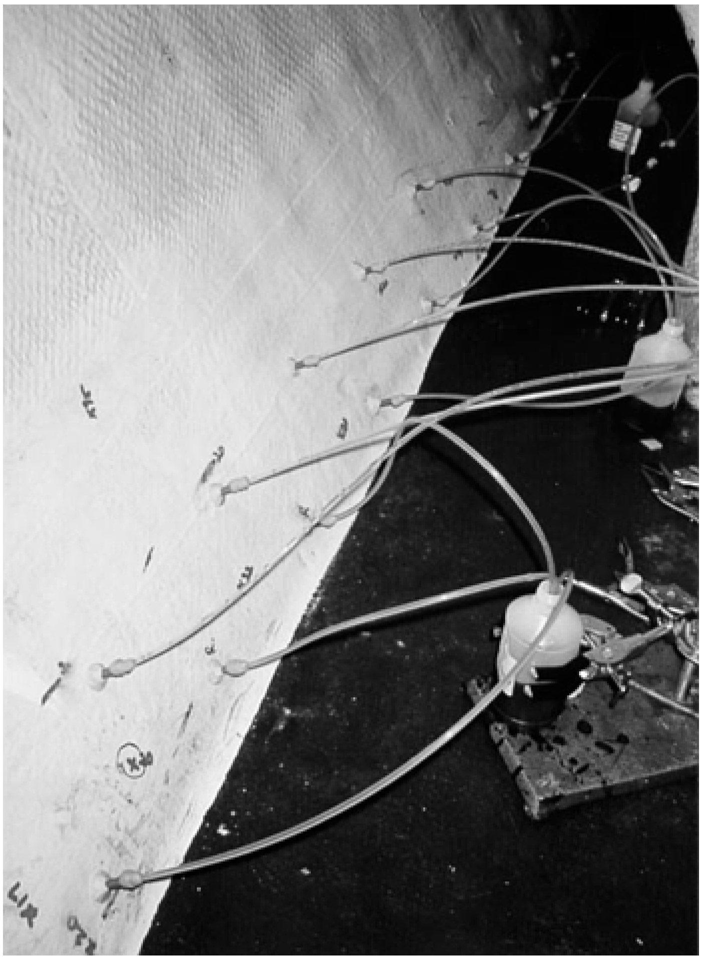

Fig. 12 Resin-infusion repair of a composite ship structure

The resin-infusion method has not been thoroughly tested on a wide range of marine craft, although in the future the method may be used increasingly instead of scarf or step repairs because it is cheaper, simpler, and does not require removing a large amount of undamaged material. However, there are several factors that are likely to limit the severity of damage that can be repaired in this way. These include the difficulty of removing contaminants, such as salts and oily residues, from the fracture surfaces prior to rebonding, the inability to mend broken fibers, and problems establishing the effectiveness of a given repair.

An alternate to resin infusion is a resin-injection repair, where resin is forced into the cracks and disbonds under an externally applied pressure. The advantage over resin infusion is that it has a greater potential for infiltrating most of the damage, and can be implemented with some flow-through of the resin in order to flush contaminants from the disbonded surfaces. However, it is difficult to fill the crack front with resin because of entrapped air, and the externally applied pressure may cause further growth of the cracks. Resin-injection repairs have been developed for use on aircraft composite structures, but have not yet been widely adapted for composite ship repairs. While both resin-infusion and resin- injection repairs can be remarkably successful in restoring stiffness and strength, validating the structural efficiency of a specific repair is likely to remain a problem.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Introduction

FIBER-REINFORCED POLYMER (FRP) COMPOSITE MATERIALS provide an outstanding means for rehabilitating and strengthening existing reinforced and prestressed concrete bridges, buildings and other structures. Whether a structure has been damaged due to overload, earthquake or materials deterioration, or whether the structure requires strengthening to resist increased future live loads, wind, or seismic forces, FRPs provide an efficient, cost- effective, and easy-to-construct means or reinforcing concrete members. These advanced composites may be designed to act as flexural, shear, and confinement reinforcement. Use of these composites requires less disturbance to building occupancy, bridge traffic, and other functions than rehabilitation that uses additional steel reinforcement.

The concept of strengthening with FRP was pioneered by Professor U. Meier at the Swiss Federal Laboratories for Materials Testing and Research Institute in the early 1980s. His extensive research activities led to the first-time field implementation of FRP rehabilitation for both bridge and building applications. Both the Ibach bridge near Lucerne, Switzerland and the City Hall of Gossau, St. Gall in northeastern Switzerland were strengthened in 1991 by bonding pultruded carbon-fiber polymer plates to the exterior surfaces of the concrete structures. Details on some of these and other early applications are described in Ref 1. Since then, there has been keen worldwide interest not only to use polymeric materials in strengthening structures, but also to examine their structural behavior under a variety of loading and environmental conditions. Reference 2 is a review highlighting some fundamental concepts pertaining to the use of FRP materials in structural rehabilitation; comprehensive expositions of past research activities, test results, and case studies on the same subject are given in a monograph (Ref 3).

To effectively design and execute a rehabilitation scheme using FRPs, the engineer must fully understand the condition of the existing structure, the properties and characteristics of the composite materials, the interaction between the FRP and concrete, and construction methodology.

The terms rehabilitation, repair, and strengthening are defined as follows:

- Rehabilitation: the process of repairing or modifying a structure to a desired useful condition
- Repair: the process of replacing or correcting deteriorated, damaged, or faulty materials, components, or elements of a structure
- Strengthening: the process of increasing the load-carrying capacity of a structure or portion thereof

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Structural Assessment

The structure must be evaluated prior to application of FRPs, so that the actual load-carrying capacity may be determined and the causes for prior deterioration or damage may be identified and eliminated. Cracked, chipped, and deteriorated concrete must be repaired; corroded steel reinforcement must be cleaned and evaluated prior to further rehabilitation.

The first step of the structural assessment should be a review of the plans, specifications, and construction records of the structure. These documents provide the minimum strength of the concrete and reinforcement, the size of the members, and the size and location of all reinforcement. An analysis based upon these plans gives an estimate of the anticipated strength of the structure, provided no deterioration has occurred.

The second step, site observation, includes measurement of the geometry of the structure and determination of cracks and other deterioration or damage. The geometry is compared with the plans to assure the correctness of the documentation. The presence of cracks and damage provides a basis for the design of repairs needed prior to rehabilitation.

Provided that cracking and deterioration are not extensive, nondestructive testing of the structure is used to verify the strength of the concrete and the location of the reinforcement. The quality of the concrete can be investigated using acoustic impact (e.g., chain dragging), rebound hammers (Schmidt Hammer shown in Fig. 1), and penetration resistance (Windsor Probe). Magnetic detection devices (pachometers) may be used to measure the extent and location of reinforcement. If the quality of the concrete appears poor, destructive tests are necessary. Cores are taken; cutting of reinforcement is avoided. Compression testing of the cores provides an acceptable determination of compressive strength (f'_c). Petrographic analysis is required if the suspected cause of deterioration is alkali-silica reaction.

Fig. 1 Schmidt Hammer for evaluating concrete quality. Courtesy of PROCEQ SA

Cracking and/or pop-outs in the vicinity of reinforcement indicate potential corrosion of the reinforcement. In those locations, the concrete should be removed and the reinforcement inspected. If the reinforcement is rusted such that loose rust is noted, the concrete must be removed from around the corroded reinforcing bars, and the bars must be cleaned of rust. The actual cross-sectional area of the bars should be determined and used in subsequent analysis. Further, the chloride content of the concrete should be determined, along with its electrical potential, so that the probability of continued active corrosion is determined. Permitting active corrosion of the reinforcement to continue after FRP rehabilitation will limit the life of the rehabilitation system.

With the previously mentioned assessment complete, areas of damaged and deteriorated concrete should be repaired prior to placement of FRP materials. Areas where concrete has been removed and corroded reinforcement cleaned should be patched with compatible materials. In general, Portland cement mortar patches provide good bond and compatibility with the existing concrete substrate. Polymer concretes are preferred for small patches (less than 20 mm, or 0.79 in. thick).

Where damage has occurred due to overload, differential settlement, or restraint of shrinkage and creep of the concrete, cracks may be large. An assessment of those cracks may indicate that the concrete cannot transmit shear or compressive forces. In such cases, cracks with widths between 0.3 and 3.0 mm (0.012 and 0.12 in.) should be filled by injection with a low viscosity epoxy; cracks wider than 3.0 mm (0.12 in.) should be injected with either a polymer or cement grout. Wherever cracks are injected and patches are placed, the surface of the resulting structure should be smooth and even for optimal application of the FRP.

Finally, the strength of the existing structure should be assessed, based on the actual condition of the structure.

A. Zureick and L. Kahn, Georgia Institute of Technology

Composite Materials Reinforcing Systems for Concrete Strengthening

Fiber-reinforced polymer composites used for strengthening reinforced concrete structures are made of aramid, carbon, or glass fibers with an epoxy thermoset-resin matrix to bind them together. They can be classified into two systems: shop-manufactured and field-manufactured.

Shop-manufactured composites are premanufactured in the form of plates, shells, or other shapes and are bonded in the field to the surface of the concrete member using structural adhesives. These composites are manufactured by a variety of techniques, such as pultrusion, filament winding, and resin transfer molding. Some of the common commercially available shop-manufactured composite systems are briefly described below:

- CarboDur (Sika Corporation, Lyndhurst, NJ) composites are 1.2 mm (0.05 in.) thick carbon-epoxy pultruded unidirectional plates that can be bonded to the concrete surface with an epoxy-based adhesive. The fiber volume in this system is approximately 68% (Fig. 2).
- SNAP-Tite (ISCO Industries LLC, Louisville, KY) a 3 mm (1/8 in.) thick prefabricated E-glass/isophthalic polyester shell that can be bonded to a round concrete column using polyurethene adhesive. Additional shells can be bonded over the first bonded shell to achieve the desired thickness.
- Hardshell structures are prefabricated E- glass/vinyl ester shells manufactured by the vacuum-assisted resin transfer molding process with a fiber volume of about 60%. The shells can be bonded to round concrete columns using an adhesive system.

Fig. 2 Application of shop-manufactured carbon composite plates to the underside of a bridge deck

Field-manufactured composites are fibers in the form of tows or fabrics and are impregnated in the field before being placed on the surface of the structure requiring strengthening. Impregnation can be accomplished manually (hand lay-up), by a portable impregnator machine, or by infusion under vacuum. The composite is bonded to the concrete and left to cure under ambient or elevated temperature.
Commercially available field-manufactured composite systems include, but are not limited to, the following:

- MBrace (Master Builders, Inc., Cleveland, OH) and Replark (Mitsubishi Chemical Corp., Tokyo) are similar systems that include a primer, putty, epoxy-resin matrix, and dry unidirectional carbon-fiber sheets weighing approximately 300 g/m^2 (8.8 oz/yd^2). The composite reinforcing system is manufactured by the hand lay-up technique.
- SikaWrap Hex (Sika Corporation, Lyndhurst, NJ) and Tyfo Fiberwrap Systems (Fyfe Co. LLC, San Diego, CA) are unidirectional fabrics weighing approximately 612 g/m^2 (18 oz/ yd^2). The fabrics are impregnated with epoxy resin using a portable impregnator machine, as illustrated in Fig. 3.

- XXsys Technologies, Inc. system is one in which columns are wound with prepreg carbon tows using a Robo-Wrapper (XXsys Technologies, Inc., San Diego) winding machine as shown in Fig. 4. The resin is cured at elevated temperature, using a portable oven known as Robo-Curing System shown in Fig. 5.

Fig. 3 Portable impregnator machine for field manufacture of fiber-reinforced composites

Fig. 4 Robo-Wrapper machine for winding columns with prepreg carbon tows. Courtesy of XXsys Technologies, Inc.

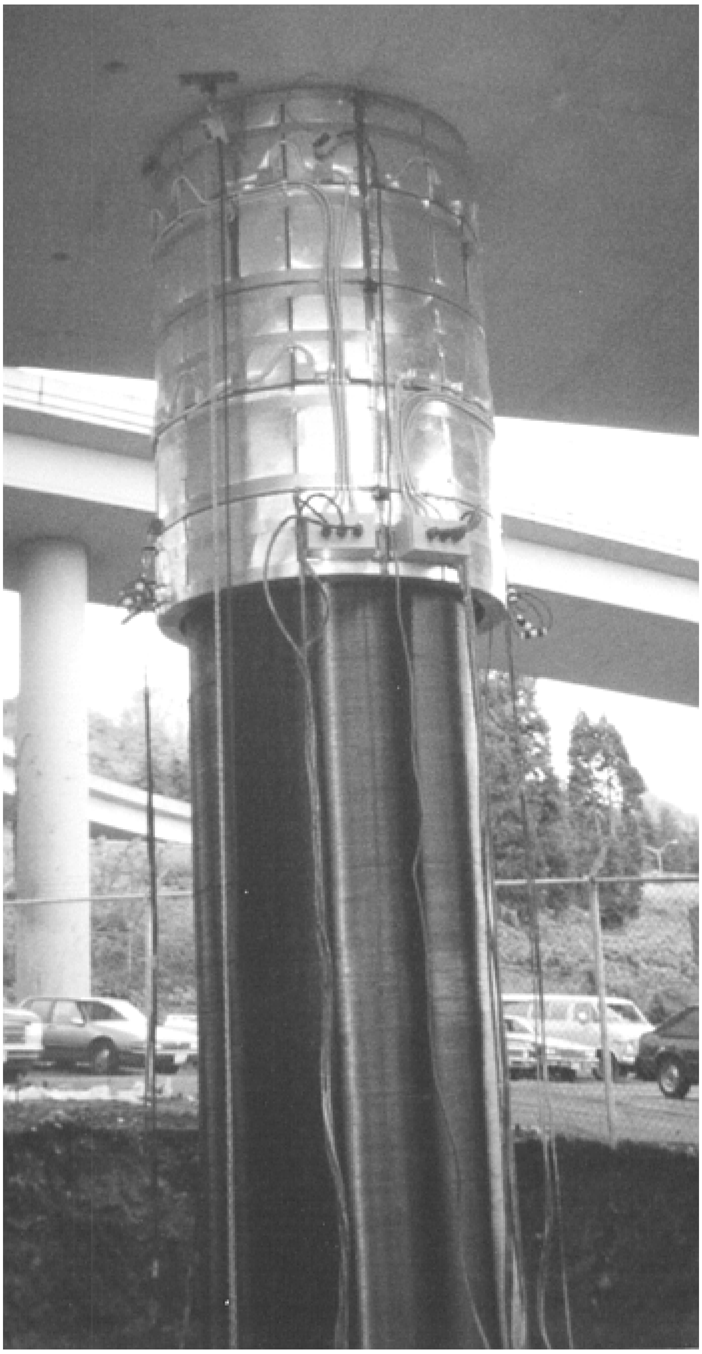

Fig. 5 Portable oven (Robo-Curing System) for curing columns wound from prepreg carbon tows. Courtesy of XXsys Technologies, Inc.

An advantage of the shop-manufactured composites over the field-manufactured composites is the ability to control the quality and uniformity in the composite reinforcing systems. An advantage of the field-manufactured composites is their ability to conform to nonuniform concrete surfaces.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Properties of Polymer Composite Reinforcing Systems

Because of the absence of national codes and standards, manufacturers report their data in a variety of ways. This variation presents both the engineer and the owner with a dilemma for properly comparing different systems and for assessing the benefit of using such materials in construction projects. Reported data should include the method of testing used to obtain such data, the number of tested specimens, the number of batches from which test specimens were drawn, the mean value, the minimum and maximum values, and the coefficient of variation. Manufacturers also may elect to provide the minimum guaranteed property values, along with the methods by which such values are obtained. As a minimum, the contractor should furnish the owner the following information pertaining to the matrix (binding resin or adhesive):

- For the matrix material and any of its components, the commercial designation, name of manufacturer, and materials safety data sheet, prepared in compliance with the Federal Occupational Safety and Health Administration (OSHA) Hazard Communication Standard 29 CFR 1910.1200
- The density of the matrix material and any of its components, determined according to ASTM D 792, “Test Methods for Specific Gravity and Density of Plastics by Displacement”
- The gel time, determined according to ASTM D 2472, “Standard Test Method for Gel Time and Peak Exothermic Temperature of Reacting Thermosetting Resins”
- The curing behavior, determined according to ASTM D 4473, “Standard Practice for Measuring the Cure Behavior of Thermosetting Resins Using Dynamic Mechanical Procedures”
- The water absorption, determined according to ASTM D 570, “Standard Test Method for Water Absorption of Plastics”
- The glass transition temperature, according to ASTM D 3418, “Standard Test Method for Temperatures of Polymers by Differential Scanning Calorimetry”
- The tensile properties, according to ASTM D 638, “Standard Test Method for Tensile Properties of Plastics”
- The compressive properties, according to ASTM D 695, “Standard Test Method for Compressive Properties of Rigid Plastics”
- The flexural properties, according to ASTM D 790, “Standard Test Method for Flexural Properties of Unreinforced and Reinforced Plastics and Electrical Insulating Materials”

The contractor should furnish the following information about the reinforcement materials:

- The commercial designation, name of manufacturer, fiber form (e.g., yarns, strands, tows, fabric, and prepreg), fiber orientation, fiber dimensions, and fiber surface treatments
- The density of the fiber, according to ASTM D 3800, “Standard Test Method for Density of High-Modulus Fibers”
- For prepregs, the matrix solid content and matrix content, determined according to ASTM D 3529, “Standard Test Method for Matrix Solids Content and Matrix Content of Composite Prepreg”
- For epoxy-carbon fiber-based prepreg, the volatiles content, reported according to ASTM D 3530, “Volatiles Content of Carbon- Fiber Prepreg”

For a composite system, cured under specified conditions approximating the conditions of the actual use, the following materials properties determined experimentally should be provided:

- The density, according to ASTM D 792, “Test Methods for Specific Gravity and Density of Plastics by Displacements”
- The tensile properties (ultimate strength, ultimate strain, and modulus) of the composite materials, according to ASTM D 3039, “Test Method for Tensile Properties of Polymer Matrix Composite Materials”
- The fiber volume, according to ASTM D 2584, “Test Method for Ignition Loss of Cured Reinforced Resins,” or D 3171, “Test Method for Fiber Content of Resin-Matrix Composites by Matrix Digestion”
- The void volume, according to ASTM D 2734, “Test Method for Void Content of Reinforced Plastics”
- Moisture diffusivity and absorption or desorption properties, according to ASTM D 5229, “Test Method for Moisture Absorption Properties and Equilibrium Conditioning of Polymer Matrix Composite Materials”

The wealth of information gained from over 30 years of composite applications for aerospace use makes the task of reporting properties straightforward in the case of shop-manufactured composites. However, difficulties arise when composites are manufactured in the field, especially with the hand lay-up technique, where both geometrical (e.g., thickness) and materials properties (e.g., mechanical) are strongly influenced, not only by the operator fabricating the composites but also by climate curing conditions, dust from occasional wind, and other environmental factors.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Materials Property Requirements for Design

When used to strengthen concrete structures, polymeric composite reinforcing systems will virtually always be subjected to not only various combinations of loads (e.g., dead loads, live loads, wind loads, and earthquake loads) but also to complicated environmental exposures (ambient temperature, solar radiation, humidity, organic growth, chemicals, etc.) that change continually. Therefore, the composite properties need to be stable or undergo insignificant changes during the lifetime of the strucuture.

Temperature is of particular importance. Defining the operating temperature range requires a proper examination of the climatological data for the location in which the structure is to be built. The data can be statistically analyzed for trends and variations (see Ref 4), so that high and low temperature values can be estimated for a given region and time interval; these values have a specified annual probability of being within the admissible range. Temperature records in the United States are readily available through the National Climatic Data Center. We define the operating temperatures as the range bounded by the overall temperature maximum and minimum recorded daily in a given location from the observed climate. Figures 6 and 7 show these extreme values for each state individually.

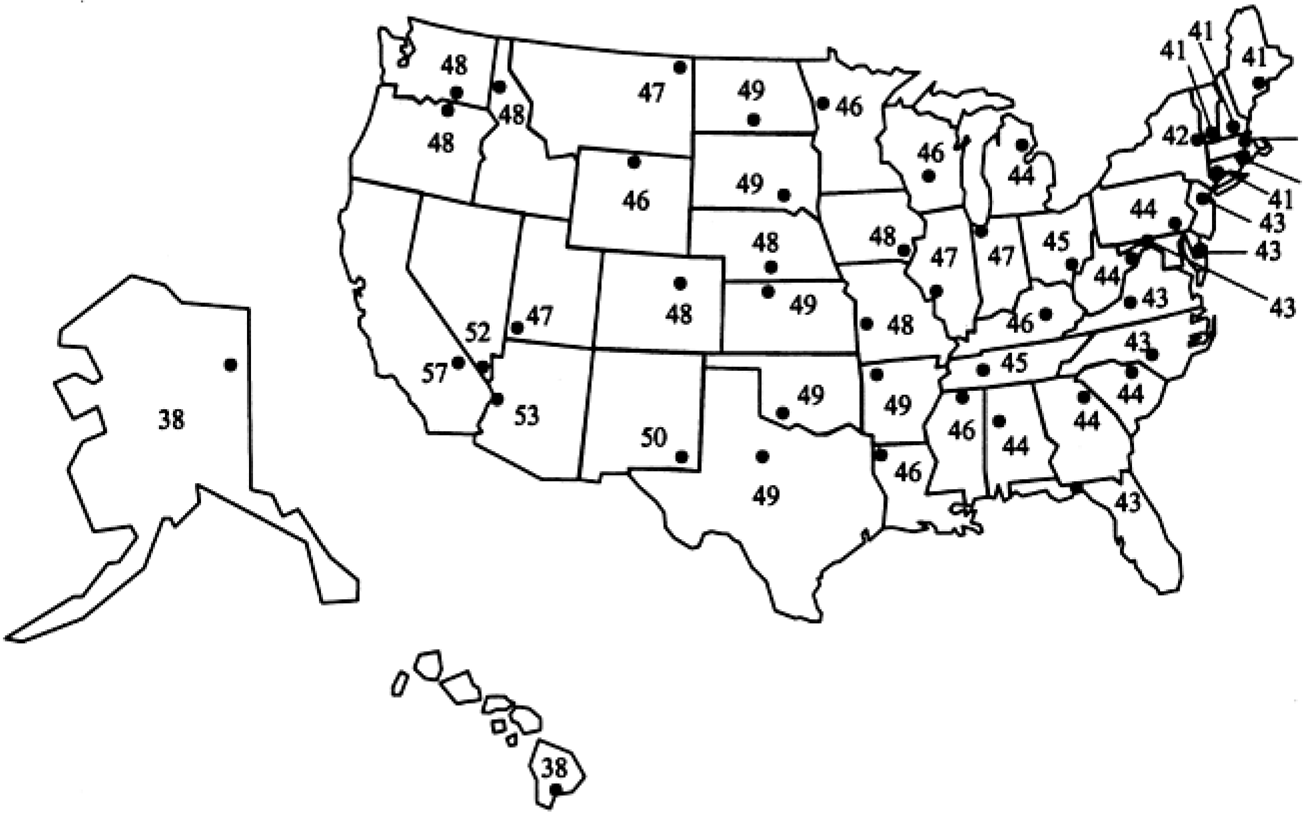

Fig. 6 Record highest temperature (°C) by states through 1998. Source: National Climatic Data Center

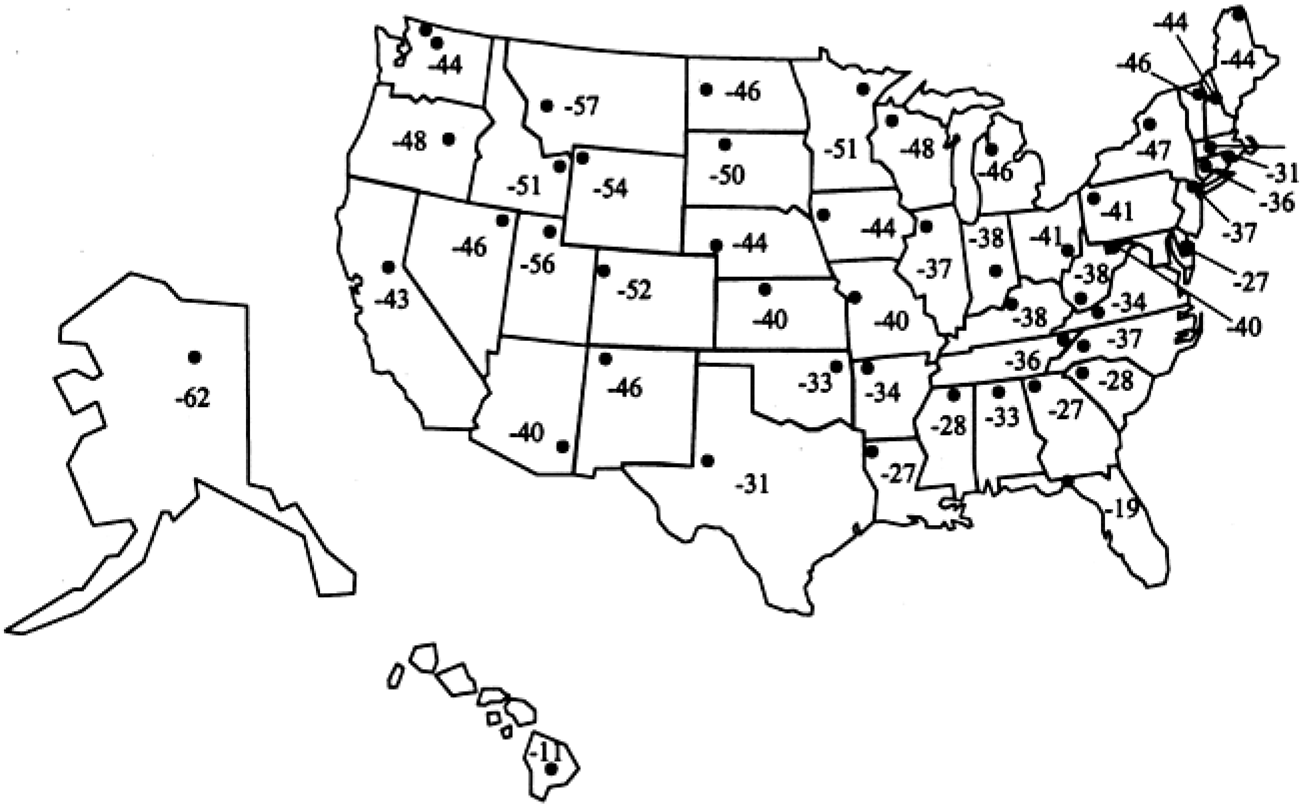

Fig. 7 Record lowest temperature (°C) by states through 1998. Source: National Climatic Data Center

To appropriately select the polymeric composite most suitable for strengthening purposes, the designer relies upon the dimensional stability, strength, and stiffness properties of the materials for which the main determinant is their glass transition temperature, (T_g). The T_g is defined as the approximate temperature value or temperature range at which the matrix changes from a glassy to a rubbery state. Above T_g, the composite softens and its mechanical properties are degraded, as illustrated in Fig. 8. In addition, it is to be noted that T_g decreases as the moisture content in the composite increases. The T_g of the resin, when cured in a manner recommended for rehabilitation, should be at least 30 °C (86 °F) above the operating temperature. Note that measurements on actual structures strengthened with carbon-fiber composites showed that the composite surface temperature was approximately 15 to 20 °C (59 to 68 °F) higher than the air temperature. Polymers with a T_g of less than 55 °C (131 °F) must be avoided when rehabilitating civil engineering structures, because their mechanical properties degrade under various service environmental conditions. Polymers demonstrate significantly greater creep above T_g than at the operating temperature. For example, the bond strength in a concrete beam reinforced externally with carbon/epoxy composites having T_g of 50 °C (122 °F) is reduced by almost 40% when the temperature rises from 20 °C (68 °F) to 60 °C (140 °F).

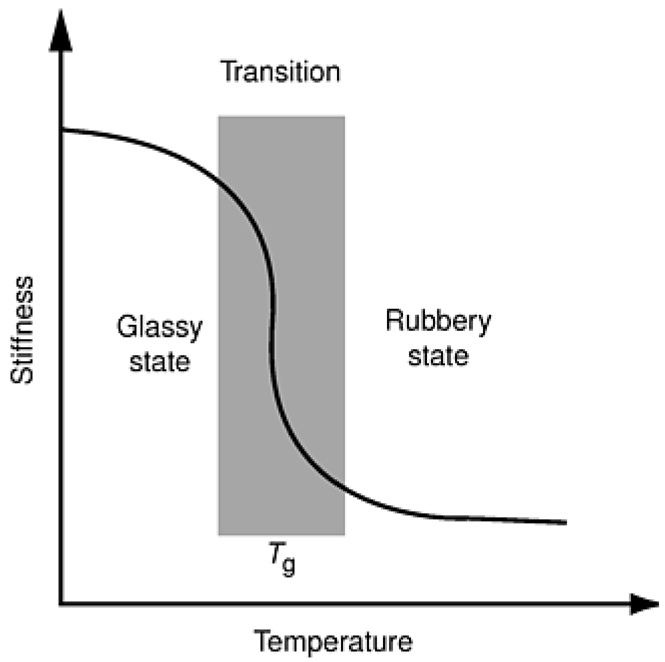

Fig. 8 Affect of temperature on the stiffness of composites. Above the glass transition temperature, T_g, the composite softens.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

FRP-Reinforced Concrete Behavior

The failure mode of a FRP-rehabilitated reinforced concrete member depends on whether the failure is flexural, shear, or axial and on the ratio of steel and FRP reinforcement. In flexure, the failure of the member may be determined by either the maximum compressive strain in the concrete (assumed as 0.003), the effective ultimate strain in the FRP, or the FRP-to-concrete bond. In shear, the failure is typically controlled by the strain in the FRP or by the FRP-to-concrete bond. Finally, when a composite is used to confine an axial load-resisting member, the ultimate failure of the member is controlled by concrete axial strain or by tensile strain in the composite. Experiments by the authors and others (see Ref 2) have shown that the ultimate flexural response of FRP-strengthened concrete beams is generally controlled by the delamination of the FRP from the tension side of the beam. This delamination is different from a bond failure, in that the delamination results from a tensile-shear failure in the concrete at a level adjacent to the FRP; a bond failure results from either an inadequate length of FRP needed to develop the strength of the FRP or from a failure of the adhesive, as evidenced by a separation of the adhesive from the FRP. The tension-shear failure in the concrete is a consequence of the tensile strength of the cement paste and local stress risers. Flexural cracks in the concrete, large pieces of aggregate near the surface, and deviations in field construction of the FRP are causes of these stress risers.

The values of FRP strain at which concrete tensile-shear delamination occurs vary widely, especially between shop- and field-manufactured composites. The strain is almost never as high as the breaking strain of the FRP; that is, the breaking stress of a composite is generally not the cause of failure.

Based on the evidence to date, the authors recommend a value of 0.004 as the effective ultimate strain (ϵ_{max}) in the FRP for flexural rehabilitation. While the strain at concrete tensile-shear delamination may be less than this, it is generally significantly greater. The 0.004 value provides for the uncertainties associated with field construction and the misalignment of fibers, and it gives reasonable stresses in the composite for flexural design.

Flexure. Figures 9 and 10 illustrate a beam in flexure, where a composite is bonded to the bottom tension surface. It is assumed that the reinforced concrete member carries the dead load of the structure and that the rehabilitated beam carries the total factored load. Under an ultimate moment, either strain condition in Fig. 9 or in Fig. 10 exists; Fig. 9 defines failure as crushing of the concrete with a compression strain ϵ_c of 0.003, while Fig. 10 defines failure as a maximum, effective ultimate strain in the composite, which is taken as 0.004, as discussed previously. Under the condition of Fig. 9, the full capacity of the concrete in compression is developed, and an equivalent rectangular stress block analysis may be used. The steel reinforcement may or may not be yielding (in the figure it is assumed to yield); the composite is elastic. Under the condition of Fig. 10, a parabolic stress distribution is assumed for the concrete, such as the Todeschini model (Ref 5); the composite has reached its maximum, effective ultimate strain. The steel reinforcement is typically yielding. In the rectangular stress block model (Fig. 9):

$$a=\beta c$$

where c is the distance between the neutral axis and the compressive face of the section, and

$$\beta = 0.85 \text{ for } f_c' \leq 28 \text{ MPa (4000 psi)}$$

$$\beta = 1.05 - 0.05\frac{f'c}{1000} \text{ for } f'c \text{ in units of psi}$$
$$\text{when } 4000 \text{ psi} < f'c < 8000 \text{ psi}$$
$$\beta = 1.05 - \frac{f'c}{6.9} \text{ for } f'c \text{ in units of MPa}$$
$$\text{when } 28 \text{ MPa} < 56 \text{ MPa}$$

and

$$\beta = 0.65 \text{ for } f_c' \geq 56 \text{ MPa (8000 psi)}$$

Further:

$$\alpha = \frac{A_s f_y + T_{FRP}}{0.85 f_c' b}$$

where b is the width of the concrete under compression, A_s the area of steel reinforcement, f_y is the yield stress of the steel, and T_{FRP} is the tensile force in the composite. The nominal moment capacity M_n is:

$$M_n = A_s f_y \left(d - \frac{a}{2}\right) + T_{FRP}\left(h - \frac{a}{2}\right) \quad \text{(Eq 1)}$$

where d is the distance from the compression face to the centroid of steel reinforcement and h is the depth of the section. In the Todeschini model, the concrete compressive stress-strain distribution is assumed parabolic according to the following equation:

$$f_c = \frac{2(0.9 f_c')(\varepsilon_c / \varepsilon_o)}{1 + (\varepsilon_c / \varepsilon_o)^2} \quad \text{(Eq 2)}$$

where f_c and ϵ_c are the maximum compressive stress and strain in the concrete, respectively. f'_c is the compressive strength of the concrete and ϵ_o is the strain, corresponding to the maximum stress, computed from the following equation:

$$\varepsilon_o = 1.71\frac{f_c'}{E_c} \quad \text{(Eq 3)}$$

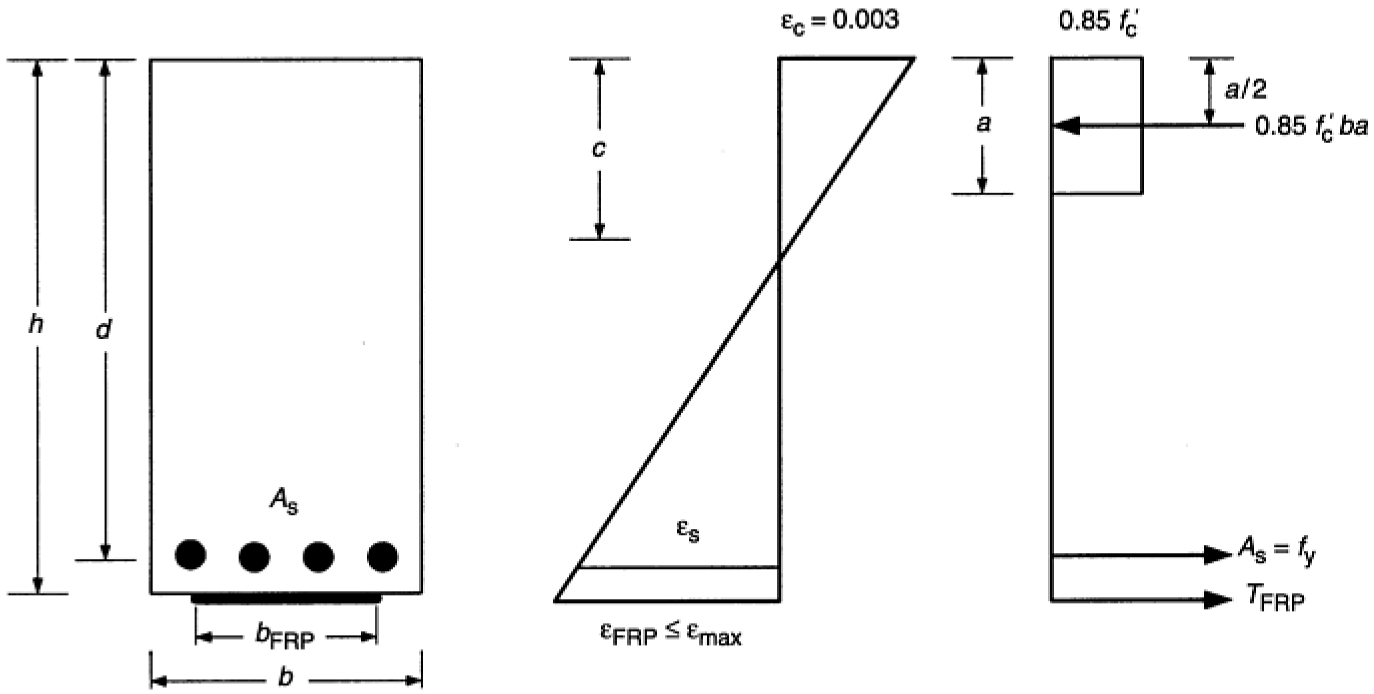

Fig. 9 Flexural condition based upon ultimate compressive strain of the concrete ϵ_C. b_{FRP} =width of composite. The other terms are defined in the text.

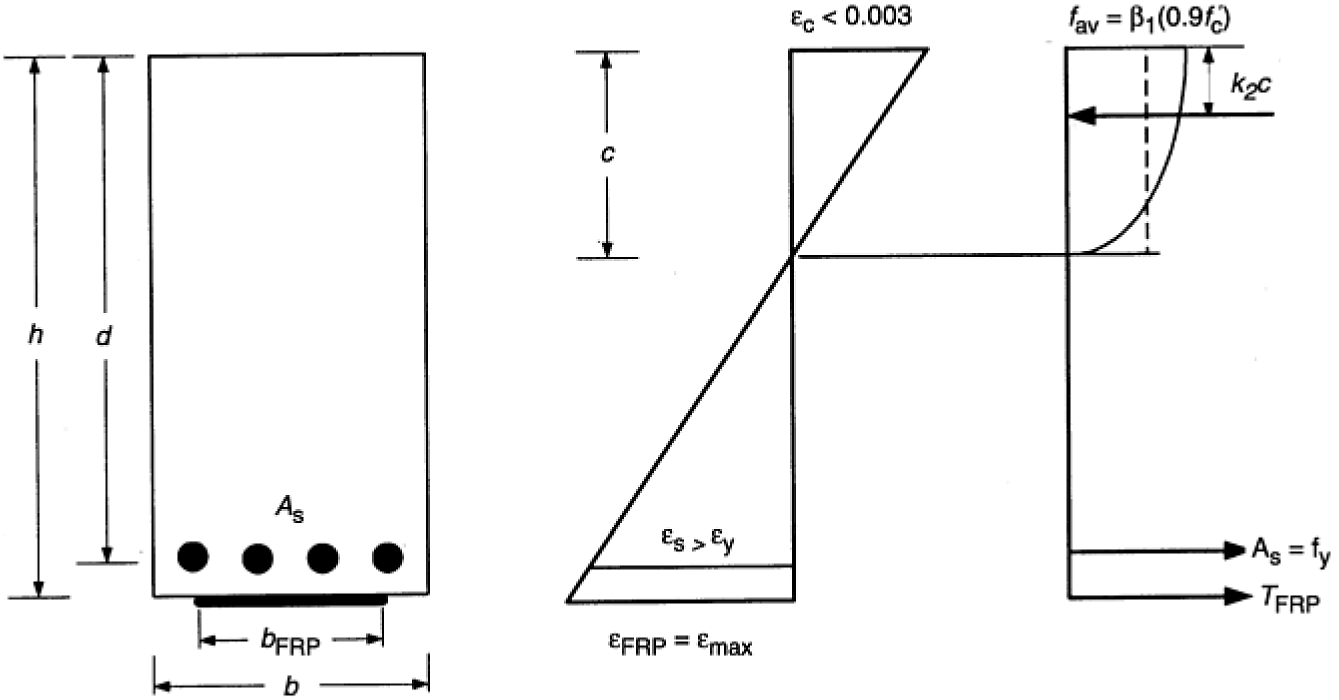

Fig. 10 Flexural condition based upon maximum, effective ultimate strain in the composite ϵ_{FRP}=ϵ_{max}. The terms are defined in the text.

The modulus of elasticity, E_c, for normal- weight concrete can be computed from:

$$E_c = 57{,}000\sqrt{f'_c} \qquad \text{(Eq 4)}$$

where the unit for f'_c is in psi and

$$E_c = 4{,}730\sqrt{f'_c} \qquad \text{(Eq 5)}$$

where the unit for f'_c is in MPa.

Based upon Eq 2, 3, 4, and 5, the compressive force in the concrete may be computed from an assumed rectangular stress block having a depth of "*c*" and an average stress $\beta_1(0.9f'_c)$ as illustrated in Fig. 10, where β_1 is a factor computed from the following equation:

$$\beta_1 = \frac{\ln\left[1+\left(\frac{\varepsilon_c}{\varepsilon_o}\right)^2\right]}{\left(\frac{\varepsilon_c}{\varepsilon_o}\right)} \qquad \text{(Eq 6)}$$

The center of gravity of the compression zone is $k_2\,c$ from the compression surface, where:

$$k_2 = 1 - \frac{2\left[\left(\frac{\varepsilon_c}{\varepsilon_o}\right) - \tan^{-1}\left(\frac{\varepsilon_c}{\varepsilon_o}\right)\right]}{\left(\frac{\varepsilon_c}{\varepsilon_o}\right)^2 \beta_1} \qquad \text{(Eq 7)}$$

Assuming yielding of the steel reinforcement, the nominal moment resistance is then given as

$$M_n = A_s f_y\,(d - k_2 c) + T_{FRP}\,(h - k_2 c) \qquad \text{(Eq 8)}$$

Figure 11 illustrates a failure of a slab in flexure where the concrete in compression crushed prior to the delamination of the composite reinforcement. Figure 12 shows a delamination type of failure.

Fig. 11 Crushing of concrete deck in flexural failure. The fiber-reinforced polymer tensile reinforcement remained elastic while the steel reinforcement yielded.

Fig. 12 Delamination of fiber-reinforced polymer composite from concrete slab in flexural failure. The concrete remaining on the composite indicates good bond.

Shear. FRPs are applied to the side faces of a beam in order to improve the shear strength of the member, as shown in Fig. 13. The effective ultimate strain for the FRP in this shear condition is 0.004. This effective ultimate strain is used for shear conditions to assure aggregate interlock shear in the concrete and to compensate for the lack of adequate bond development length in the FRP reinforcement. The diagonal shear-tension cracks formed in the concrete must be kept small, to allow for shear transfer across the crack for full development of the concrete shear strength, V_c. On the sides of beams and columns, the transverse FRP reinforcement generally has about 25 mm (1 in.) to develop its effective strength, so that it can participate in shear strengthening. This short length is insufficient to develop the same strength in the FRP as found for flexural strengthening. When the ultimate strain is limited to this 0.004 strain value, it may be assumed that the concrete, V_c, transverse steel shear reinforcement, V_s and FRP materials V_{FRP}, act together to provide shear strength, V_n, as given by:

$$V_n = V_c + V_s + V_{FRP} \quad \text{(Eq 9)}$$

Fig. 13 Fiber-reinforced polymer sheet applied to the side of a beam to increase the shear strength of the beam

At that effective ultimate strain, the steel stirrups are yielding and the concrete strength may be taken as:

$$V_c = \frac{\sqrt{f_c'}}{6} b_w d \quad \text{(Eq 10)}$$

where b_w is the width of the web and the unit of f'_c is in MPa or

$$V_c = 2\sqrt{f_c'} b_w d \quad \text{(Eq 11)}$$

where f'_c is in psi. The steel strength is:

$$V_s = \frac{A_v f_y d}{s} \quad \text{(Eq 12)}$$

where s is the stirrup spacing, A_v is the area of the stirrups crossing one diagonal crack, and the FRP strength is:

$$V_{FRP} = \frac{T_{FRP} d_{FRP}}{S_{FRP}} \quad \text{(Eq 13)}$$

where T_{FRP} is the strength at a strain of 0.4%, S_{FRP} is the center-to-center spacing of FRP strips, and d_{FRP} is the length of the FRP strips. The strips should be wrapped under the bottom of the section. While it would be most desirable to wrap the FRP over the top of the beam, it is generally impossible to do so. Most beams have a slab cast atop the beam. Slots could be drilled through the slab for wrapping the FRP around the beam, but such construction is expensive. Adequate shear strengthening results when the FRP strips are placed immediately below the slab and wrapped around the bottom edge of the beam. The d_{FRP} is then the distance from the bottom layer of steel reinforcing to the bottom of the slab. Additional guidelines on the subject are presented in Ref 6 and 7.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Surface Preparation

Effective rehabilitation techniques using bonded fiber-reinforced polymeric materials depend strongly upon the condition of the substrate to which composite materials will be bonded. To maximize this bond, it is recommended that at least the following surface preparation procedure be followed:

1. Remove all loose and damaged concrete material by mechanical means. Saw cutting, water blasting, and air hammers are effective, as long as "bruising" (added cracking) of surrounding sound concrete is avoided.
2. Repair the corroded reinforcing steel or prestress tendons by mechanically cleaning the rust; high-pressure washing is effective.
3. Restore the shape of the structure with a new structural concrete or mortar system.
4. Round all corner edges of the rehabilitated elements to a minimum radius of 25 mm (1 in.) to permit effective bends in the composite reinforcement.
5. Inject all cracks that are wider than 0.25 mm (0.01 in.) with structural resin.
6. Remove deleterious materials such as laitance, dust, oil, and so on by means of abrasive blasting. All residue from blasting should be removed with compressed air. When abrasive blasting is not an option due to environmental restrictions, grit blasting, where grits and debris are collected by a vacuum system, can also be used. Hydroblasting is an effective surface cleaning technique; when used, the concrete surface shall be allowed to dry prior to any subsequent repair step.
7. Remove all protrusions higher than 1.5 mm (1/16 in.) and fill all holes and depressions greater than 3 mm (1/8 in.) in diameter with structural mortar.
8. Apply a penetrating epoxy primer to the clean, dry concrete surface. Apply only when the ambient temperature is between 5 and 32 °C (40 and 90 °F), the relative humidity is less than 90%, the concrete surface temperature is more than 2 °C (5 °F) above the dew point, and the concrete moisture content is no greater than 4%.

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Composite Materials Applications

After allowing the epoxy primer to dry for a period of time as specified by the manufacturer, the rehabilitation procedure may continue, provided that the ambient temperature is between 5 and 32 °C (40 and 90 °F), the relative humidity is less than 90%, the concrete surface temperature is more than 2 °C (5 °F) above the dew point, and the concrete moisture content is dry (moisture content is less than 4%). Elapsed time between mixing and application of the first ply and also between any two successive plies shall be within a time period not exceeding the gel time of the resin.

A. Zureick and L. Kahn, Georgia Institute of Technology

Records

During the rehabilitation of concrete structures with composite materials, records of key data should be kept. The following is an example of the types of information that should be recorded:

- Name of the project
- Date of strengthening
- Ambient air temperature and relative air humidity measured in the shade
- Concrete surface temperature and relative humidity at the time of rehabilitation
- The compressive strength of the concrete to be strengthened
- The commercial designation, name of manufacturer, date of manufacturing, and the manufacturer lot number, as shown on the shipping label for each component used to form the binding resin matrix
- The commercial designation, name of manufacturer, date of manufacturing, and the manufacturer lot number, as shown on the shipping label for the reinforcing fibers, fabric, or prepreg, as applicable

Rehabilitation of Reinforced Concrete Structures Using Fiber-Reinforced Polymer Composites

A. Zureick and L. Kahn, Georgia Institute of Technology

Acceptance Criteria

A few days after the rehabilitation, the structure should be inspected visually and also by performing a tap test with a coin or a small piece of metal, as shown in Fig. 14. An automated version of this test can be performed with the instrument shown in Fig. 15. The structure also can be inspected much more accurately using thermography (Fig. 16). The strengthened structure should be free of any defects (e.g., voids, bubbles, and delamination). In the presence of such defects, a repair of the composite should be done. A valuable destructive test to measure bond strength is the direct composite pull-out test, conducted on an area adjacent to the actual rehabilitated area and performed after the manufacturer's recommended curing time period (Fig. 17). The test area should have the same number of plies and/or ply orientations as those of the rehabilitated areas, and should not affect the rehabilitation in any manner. The recommended number of composite pull-off tests is 3 for every 23 m^2 (250 ft^2) of rehabilitated area. These tests should demonstrate that failure always occurs in either the substrate or along the bond line with a minimum average tensile stress of 1380 kPa (200 psi). In addition, it is necessary to conduct tests for verifying the glass transition temperature and the tensile properties in the direction of interest. This can be done on field- prepared panels (Fig. 18) that have the same number of plies and fiber orientations and the same curing condition as those of the rehabilitated areas.

Maintainability Issues

Introduction

IN-SERVICE MAINTAINABILITY is a primary ongoing issue associated with composite aircraft structures. The increase in use of composite materials in aviation has been accompanied by more complicated designs and significantly loaded structures. Damage types experienced by composite structures, the methods of inspecting for damage, and the techniques for repair typically are more complex compared with those involving aluminum structures. As a result, performance and weight benefits inherent to composite materials can be reduced or lost if the cost associated with maintaining these structures is too high. This cost is directly related to the durability, damage tolerance, and repairability built in during the design process. There are a range of issues that need to be addressed in maintaining composite structures. A better understanding of, as well as improvement of, maintenance procedures will go a long way in maintaining composite structures more cost effectively.

Composite materials, mostly reinforced with glass fiber, began to replace aluminum secondary structure on aircraft in the early 1960s. Those first introduced were typically aerodynamic fairings and wing leading edges. As the potential benefits of composites were realized, other polymer composites reinforced with advanced fibers offering increased specific stiffness and strength, reduced weight, and improved corrosion and fatigue resistance over aluminum were successfully introduced. The most common base materials for these advanced fibers were graphite (carbon) and aramid. These materials were used in structures such as flight controls and engine cowlings.

These designs were lighter, thin-skinned sandwich structures that proved to be less damage resistant than those made of aluminum and introduced new damage phenomena that were complex by comparison. This complicated the maintenance actions of damage assessment, inspection, and repair. These problems, not foreseen at the design stage, made in-service damage a frequent occurrence, which was further aggravated by the lack of experience and materials needed to carry out corrective action. Out-of-service aircraft, expensive spare components, training liability for technicians, and expensive materials and facilities reduce or eliminate the cost benefits that composites are intended to provide through increased performance.

The most recent aircraft designs include graphite/epoxy solid composite laminates in primary structures such as floor beams and other critical substructures. These uses demonstrate continued confidence in the capabilities of composite materials. However, the effort needed to maintain composite components must be reduced to realize the complete life-cycle cost potential.

Maintainability is a function of the durability, damage tolerance, and repairability of the structure. Durability is the ability of the structure to maintain its strength and stiffness throughout its service life. Damage tolerance is the capability of the structure to sustain a level of damage and yet safely perform its intended operational functions. The initial design phase of these parameters has the greatest influence for maintainability and reliability.

Maintainability Issues

Types of Composite Structures

Over the past several years, advanced fiber reinforced polymer-matrix composites (PMCs) have emerged as a structural material to replace aluminum and titanium alloys. Composites, which were initially used as a direct replacement of metallic structures, have been utilized for many types of increasingly complex components. Advanced composites have been constructed with boron, Kevlar, and graphite fibers, with the predominant fiber of choice being graphite. Resins used in composite construction include epoxy, bismaleimide (BMI), and polyimide (PI), with epoxy resin used most exclusively.

Several configurations of composite structures are being used in military and commercial aviation applications. The three main configurations used in commercial aircraft composites are sandwich, stiffened-skin, and monolithic structures.

Sandwich Structure. Two forms of sandwich structures are found in aircraft applications: honeycomb panels and sandwich panels. Sandwich structures are the result of the bonding of thin face sheets separated by a low-density core (Fig. 1). This type of structure results in an efficient and light structure of high flexural stiffness. The face sheets are laminates of glass, graphite, aramid, or a combination of these materials in an epoxy matrix. The core is typically an aramid or fiberglass paper honeycomb, aluminum honeycomb, foam, or balsa wood material. Sandwich structures composed of a solid laminate plus an equivalent core thickness will be seven times the stiffness and almost four times the strength of the monolithic skin alone. However, thin- skinned sandwich structure is highly prone to impact damage and fluid ingression contamination. Aircraft components using sandwich core include control surface fairings, access doors, fuselage, and flooring.

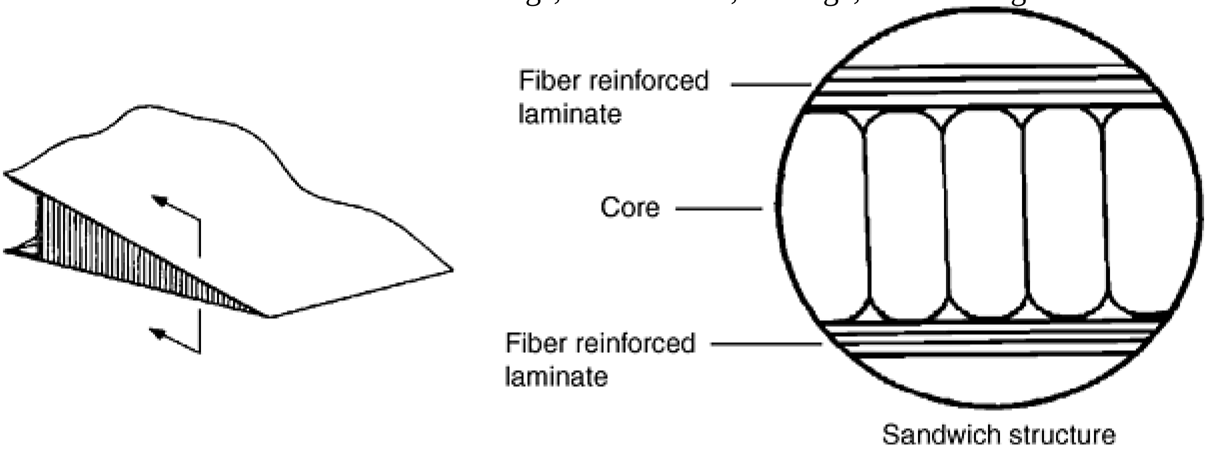

Fig. 1 Sandwich structure

Stiffened structure (Fig. 2), can be either strength or stiffness critical. This type of construction utilizes advanced composites as the skin material ranging from 8 to 20 plies. The stiffeners are typically constructed of composites and are either fabricated as integral to the skin or secondarily bonded, although mechanical fastening of the stiffeners is also used. The stiffeners currently utilized include hat, bead, and I- beam designs. The stiffeners range from 8 to 30 plies. Stiffened-skin structure is significantly more durable than sandwich structure and can approach the same stiffness, but will generally be slightly heavier. A well-designed stiffened-skin structure, designed with repair in mind, will typically provide superior maintainability compared with a sandwich structure. Aircraft components using stiffeners include fuselage, control surfaces, tail skins, wing panels, and wing skins.

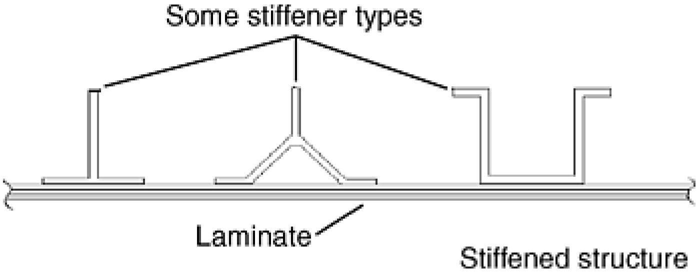

Fig. 2 Stiffened panels

Monolithic structure can be either strength or stiffness critical and are a form of stiffened structure. This type of construction utilizes advanced composites as the skin material and can be more than 100 plies. The monolithic skin panels are typically bolted to a composite or metallic substructure. Aircraft components using monolithic panels include main torque box, wing, and vertical tail.

Designing for Maintainability

The conceptual design phase is a time of greatest influence on maintainability. It is likely that a high level of maintainability will be achieved if a designer of a composite structure takes the following into consideration during the conceptual design phase:

- Understand that all composite structures will experience significant damage while in service.
- Understand all damage sources for the structure and design to minimize their effects.
- Understand the operating environment for the structure and design to accommodate this.
- Define the repair philosophy for this structure and develop all interim and permanent repairs simultaneously with the original design. If certain areas of the design do not lend themselves easily to repair, strongly consider an alternate configuration.
- Test candidate repairs during original development test programs. This will establish their effectiveness and provide a basis for maximum allowable and repairable damage limits.
- Consider only standardized repair techniques.
- Provide sufficient access to properly inspect and prepare the damaged area, fit and install repair parts, and use repair tools and bonding equipment. If adequate access is not possible, design for ease of removal and/or disassembly.
- Minimize the variety and amount of materials necessary to meet the requirements of both interim and permanent repairs.
- Establish minimum levels of damage resistance based on the type of structure, expected type of impact, and the level of impact energy.
- Design to reestablish the balance moment of flight controls by allowing for the increase in weight due to repair. Electrically servocontrolled flight controls do not have this requirement.
- Establish and verify level of nondetectable damage by test that will not endanger the normal operation of the aircraft structure for two lifetimes.
- Assess, based on the structure and its configurations, which methods of inspection are practical and usable to detect potential damage. No single nondestructive inspection method can locate and isolate all defects.
- Take into account material fatigue behavior, even though it is far superior to that of metallic structures.

Maintainability Issues

William F. Cole II, United Airlines; Mark S. Forte, Air Force Research Laboratory; Rikard B. Heslehurst, Australian Defence Force Academy

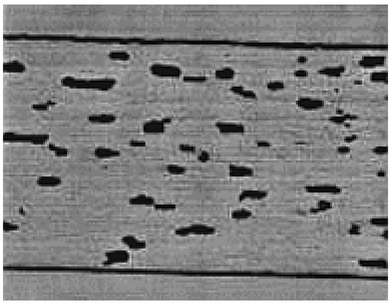
Sources of Defects and Damage

Advanced composites can be damaged from several manufacturing or in-service sources. The vulnerability of a particular composite structure depends on factors including type of construction, function, and location on the aircraft.

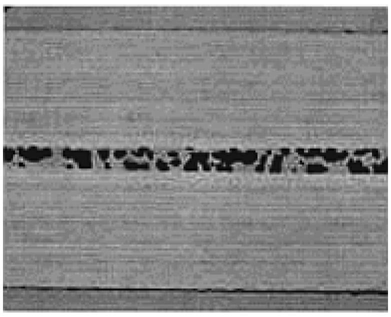
Manufacturing defects include voids, delaminations, surface damage, and misdrilled holes.

Void-type defects can occur in a laminate or the bondline of adhesively bonded structure, (Fig. 3). The most common cause of this defect is poor process control during fabrication. In the case of a composite laminate,

voids can result from lack of pressure during the curing operation or using incorrect cure cycle. Bonded structure can have excessive voids due to inadequate pressure during cure, lack of adhesive in the bondline, or improper fit with tooling or adjacent surfaces.



(a)



(b)

Fig. 3 Typical void defects in (a) laminates and (b) at the bondline

Delaminations are separations between laminate plies and can occur in any composite structure. The most common causes of this defect are poor process control, poor dimensional tolerance, faulty hole-drilling procedures, and inclusion of release film during fabrication. A majority of delaminations occur because the laminate is subjected to out-of-plane loading.

Surface damage can occur in a laminate or bonded structure, especially at an exposed edge. The most common causes of this type of defect are poor process control or incorrect handling of the composite. An example of surface damage due to poor process control is a structure not releasing from a tool in which prying for removal results in laminate or edge damage. Thin composite laminates are vulnerable to impact damage from dropped tools or from contact with heavy objects.

Misdrilled holes are typically the result of incorrect drilling procedures or faulty fixturing prior to the drilling operation. This type of damage can result in a repair of the hole or scrapping of the entire laminate.

In-service defects include cuts and scratches, penetration damage, abrasion and erosion, delaminations and disbonds, hole elongation, dents and crushed core, core corrosion, edge damage, and overheat damage.

Cuts and scratches can range from gouging of the resin to breaking of fibers, which can reduce the laminate structural strength. They typically occur as a result of impact or handling damage while the aircraft is on the ground.

Penetration damage is an extension of the previous category, with complete penetration of the skin and corresponding resin and fiber breakage (Fig. 4). This damage is likely to cause a reduction in load-carrying capability. This damage can occur as a result of severe impact or handling while the aircraft is on the ground, or in the case of military aircraft, ballistic impact.

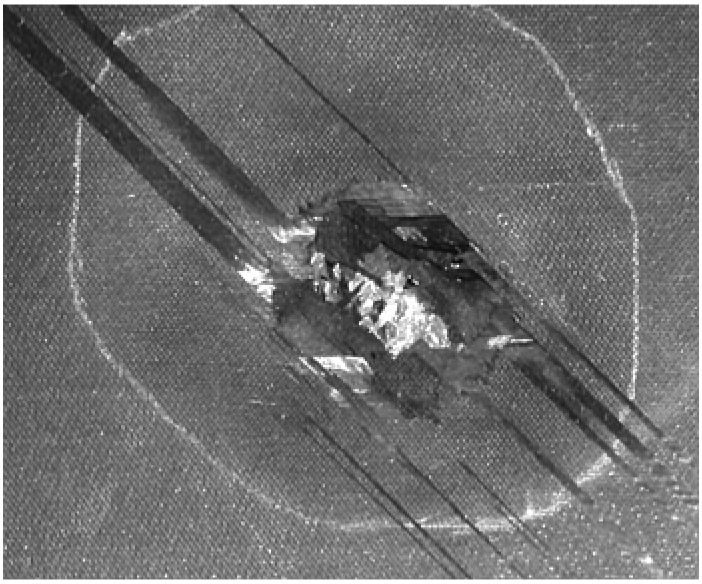


Fig. 4 Penetration damage

Abrasion and erosion typically affect leading- edge components that are exposed to airflow (Fig. 5). The damage occurs in flight as a result of air, rain, and/or grit impingement on the surface. Damage levels range from removal of coating to stripping of complete laminate surface plies.

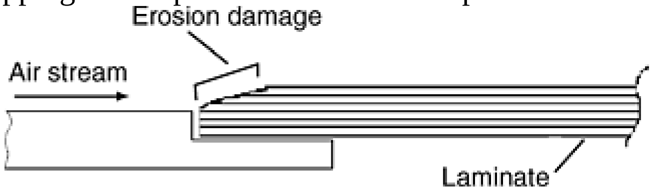

Fig. 5 Laminate edge erosion

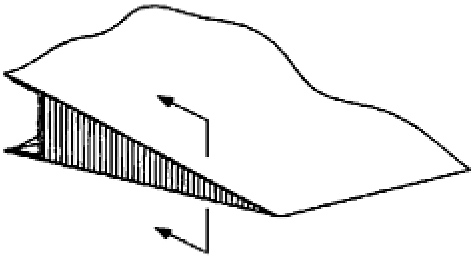
Delaminations and disbonds can occur in any laminate or bondline of a bonded structure. The causes of this defect are low-velocity impact (dropped tools), high-velocity impact (hailstones, runway debris), overload, and freeze/ thaw expansion. A majority of delaminations and disbonds occur because the laminate is minimum thickness and subjected to out-of-plane loading.

Hole elongation can occur in laminates with mechanical fasteners that have seen extended removal and reinstallation use. Other causes of damage include inadequate shimming and over- torqued fasteners.

Dents and crushed core can occur in sandwich structures. The causes of this defect are low-velocity impact (dropped tools) or high-velocity impact (hailstones, runway debris). A majority of dents and crushed cores occur because the laminate is minimum thickness and subjected to out-of-plane loading.

Core degradation is a result of cumulative effects on honeycomb substructure being exposed to standing water over a period of time (Fig. 6). The water typically enters the core through the face sheet or an edge member, often due to fiber breakage from impact damage, sealant loss, or missing surface finish. The aluminum honeycomb corrodes, while paper-type and resin-type honeycomb disbonds or loses material properties.



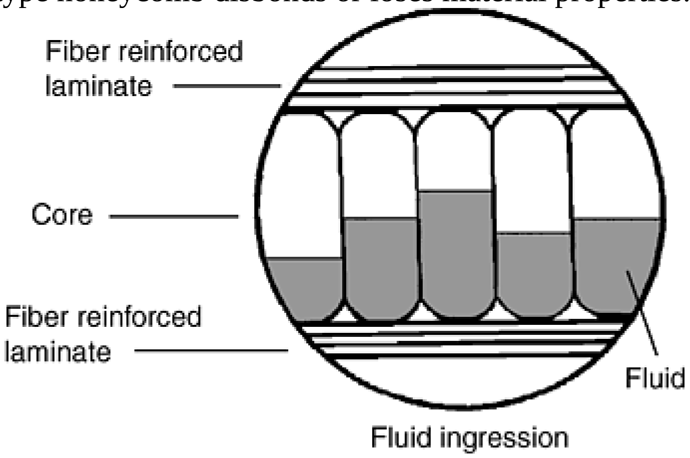


Fig. 6 Fluid ingression in honeycomb structure

Edge damage can result in disbonding, delamination, and fiber breakage. The most common cause of this type of defect is incorrect handling of the composite. Cured composite thin structures (laminates, edges, or corners) prove to be fragile and susceptible to impact damage from dropped tools or other heavy objects.

Overheat damage can occur in a laminate or bonded structure. The causes for overheat damage are hot gas impingement, fire, repair over temperature (Fig. 7), lightning strikes (Fig. 8), and battle damage that heat the composite over the intended use temperature, resulting in reduced mechanical properties.

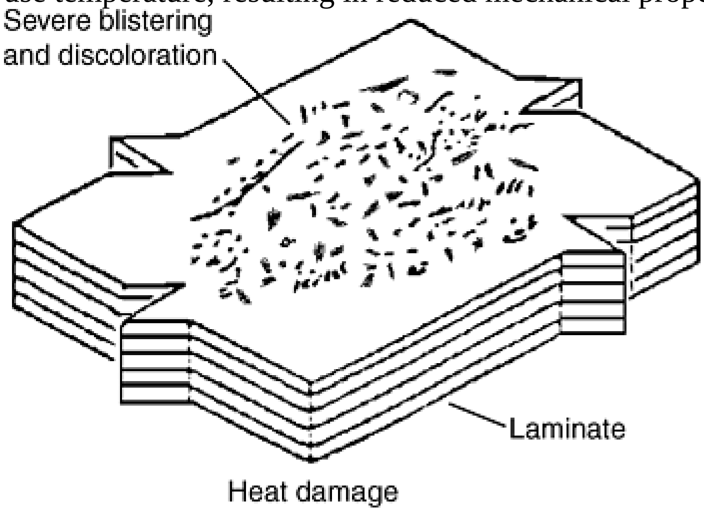

Fig. 7 Heat damage in laminate

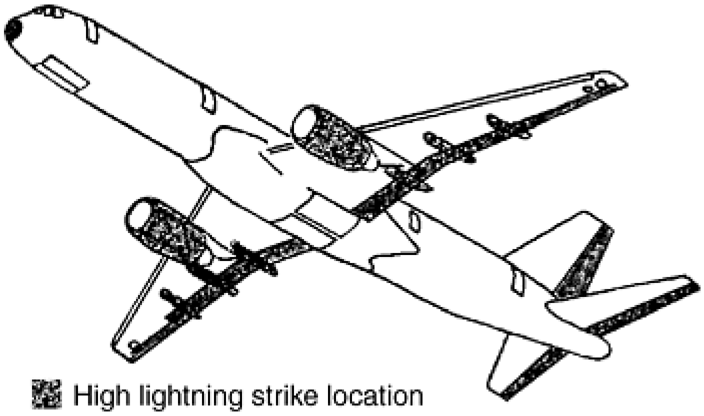

Fig. 8 Locations subject to high number of lightning strikes

Nondestructive Inspection Requirements

Nondestructive Inspection (NDI) methods are used in the repair of composite structures to locate damage, characterize the extent of damage, and ensure post-repair quality. The first and most important activity in a repair process is to identify the region of the defect or damage. Initial assessment of the damage is usually achieved by visual inspection. Visual inspection localizes the damaged area external surface. This is followed by a more sensitive NDI method that maps the extent of any internal damage. Detailed NDI is very important when dealing with composite structures because of the ease with which damage is hidden.

Nondestructive inspection methods currently available include:

- Visual, which includes optical magnification and defect enhancement
- Acoustic methods, which identify changes in sound emission
- Ultrasonic methods, such as A-scan and C- scan and also Lamb waves
- Thermography
- Interferometry
- Radiography
- Microwave
- Material property changes, that is, stiffness and dielectric strength

A detailed discussion of the various NDI methods can be found in the Selected References at the end of this article and in the article “Nondestructive Testing” in this Volume.

For the successful application of any NDI method, a selection process to identify the most suitable method must be in place with personnel trained and qualified in that method. The NDI selection process is based on configuration of the component and its construction materials, type and size of defects to be inspected, accessibility to the assessment area, and availability of both equipment and skilled operators. Table 1 lists the ability of selected NDI methods to find various defects in composite structures.

Table 1 Defects detectable by means of selected nondestructive inspection methods

1, Must be open to the surface; 2, unreliable detection; 3, dependent on defect orientation. DP, dye penetrant; UP, ultrasonic pulse echo; TT, through transmission; NR, neutron radiography; MI, mechanical impedance

The NDI operator and assessor must be familiar with several different inspection techniques and be able to set up equipment and effectively modify the standard diagnostic arrangements to suit the part being evaluated. Other requirements include having the skill to interpret the resulting NDI information, a knowledge of safety standards and procedures, and the ability to comply with MIL-STD-410 or its equivalent.

Three requirements for NDI to be successful in detecting the extent of damage in composite structures and components are:

- Suitable NDI equipment (calibrated and in good working order) and facilities, including personnel safety and environmental health procedures
- Adequately trained and experienced operators of NDI equipment to ensure that the results from any damage assessment survey are both accurate and reliable
- Available comparative specimens, because any NDI technique is comparative in nature, and results of an assessment usually are compared with a good or similarly damaged specimen. This is particularly important when calibrating NDI equipment.

Maintainability Issues

Design Recommendations

This section lists suggestions that can be used as guidelines when designing for the durability of a composite structure. Many of the suggestions provided would minimize the effects of the damage sources discussed in the previous section.

Adhesive bonding design guidelines include:

- Do not bond parts having significantly different coefficients of thermal expansion to avoid thermally induced residual bond stresses.
- Apply film adhesive at stiffener to skin interfaces to improve peel strength.
- Make bonded stiffener flanges wide enough to accommodate a row of structural fasteners that may be needed in making future repairs.
- Do not use sealants that become strong adhesives over time on joints that require separation for repair.
- Avoid structural eccentricities that can cause stress risers and lead to repair joint deterioration and failure.
- Confirm that any state-of-the-art automated processing methods used to manufacture a part lend themselves to in-service repair. Filament winding, for example, is not easily repaired using standard processes.
- Do not design components prone to mechanical impact damage (such as nacelles, flaps, and service doors) with thin face sheets.
- Reinforce and protect latch, corner, and edge areas from mishandling damage.

General composite structure design guidelines include:

- Consider breaking down complicated components into simpler subassemblies to make disassembly for repair and the repairs themselves easier. This will be a trade-off because structural efficiency and manufacturing part- count costs are both optimized by larger composite structures.
- Do not require the removal of components from the aircraft to gain access to equipment.
- Provide the maximum possible access for internal inspection and repair for hollow components.
- Provide adequate space for removal of hinge or actuator pins when using standard tools.
- Provide easy removal and replacement of access panels covering hinges, actuators, and ports.

- Design laminates having a fabric outer ply (particularly at fastener locations) to resist the cracking, splitting, and peeling often experienced with unidirectional outer plies.
- Accurately trim panel edges and locate holes using fixtures.
- Locate ground-handling fitting attachments to facilitate attachment of hoist fixtures during component change.
- Design robust attachments.
- Provide hole protection in access panels requiring frequent removal.
- Use galvanic compatible barrier plies when installing metallic hardware such as fasteners, fittings, metal-filled adhesives, and metallic core against graphite-based structures.
- Develop repair designs that do not degrade the design fatigue life of the structure.

Sandwich structure design guidelines include:

- Establish minimum face sheet thickness criteria based on realistic impact energy criteria and handling criteria.
- Protect the inner face sheet from damage by establishing a minimum core thickness and density consistent with the outer face sheet damage threshold. The core should be able to absorb the impact energy passing through the outer face sheet without the inner face sheet being damaged.
- Avoid the use of honeycomb core septums, because it is very difficult to remove all moisture with access to only one side during repair.
- Avoid the use of fasteners or tooling holes that penetrate into the core area to avoid creating fluid leak paths. If fasteners must be used, pot hole with filler material that will not crack over time.
- Use ramped core closeouts instead of square- edged core closeouts to avoid fluid leak paths. If this is not possible, seal the edge with a closure rib, composite wrap, or flexible sealant.
- Avoid low-pressure core-to-skin bonding processes to avoid fluid leak paths due to a porous bondline. This is a consideration for the processing of secondarily bonded precured skins.
- Provide adequate sealing to prevent moisture ingression.

Material selection guidelines include:

- Strive for commonality of materials; the use of exotic, high-performance materials may prove impractical or unacceptable for repair.
- Select a small number of repair materials that will be compatible with those used in manufacture. A lower-temperature cure repair material is preferable for repair.
- Choose materials and processing that result in low porosity when cured to reduce fluid ingression.
- Use higher-resin-content plies on the outer surface to reduce laminate porosity.
- Avoid the use of aramid materials in areas where moisture exists. Components with aramid plies are known to have problems with microcracking and moisture absorption.
- Use thicker laminates and, for sandwich applications, denser core materials to improve damage resistance.

Erosion and abrasion design guidelines include:

- Provide erosion protection on forward edges and avoid the possibility of positive steps in the air stream. This protection should be easily replaceable.
- Provide easily replaceable, sacrificial materials or coatings on wear areas to protect from abrasion.

Fasteners. Design considerations when using fasteners include:

- Use readily available, easily removed, standard fastener types and lengths.
- Use fasteners that are compatible in the galvanic series with the material of the contacting structure to prevent corrosion. Titanium and Monel (nickel-copper alloy), fasteners are used most often to join carbon fiber/epoxy-based structures.
- Use fastener systems that do not initiate damage to the structure upon removal and replacement.

- Drill fastener holes precisely so that they align when alternate parts are installed. Automated drilling or the use of drilling fixtures can ensure this.
- Use nut plates and reusable screws for panel attachment or where access to the far side is restricted.
- Do not cover fasteners with filler compound.
- Consider that blind fasteners will often require that stems be punched through for removal. If this is in a cavity where removal is not possible, these stems will move around in service, potentially damaging the composite structure.

Lightning-strike protection guidelines include:

- Avoid the use of aluminum honeycomb combined with graphite fiber face sheets due to the higher risk of lightning-strike damage.
- Provide easily replaceable conductive material with adequate conductive area at critical lightning-zone locations.
- Make all conductive path attachments easily accessible.
- Ensure that lightning-protection schemes, such as flame spray or metallic mesh, are easily restored during repair. If this is not possible for a particular protection scheme, consider using alternate protection options.

Thermal Degradation. Provide adequate materials or improved thermal insulation, such as heat blankets, for components used in environments of 120 °C (250 °F) or higher.

Maintainability Issues

Personnel, Facilities, and Equipment

Training/Skill Level Required. Trained personnel in a composite workshop are of the utmost necessity, particularly in the aviation industry where cured composite and bonded metallic patches require high levels of engineering design development and technician skills. Once the repair has been completed, any nonconformity in material and component properties are hidden until loaded. Furthermore, errors can be expensive to fix. All personnel must be qualified in the preparation and handling of repair materials and repair methods. Inspectors must have the same qualifications, as well as significant work experience. The quality of the repair, to maintain structural integrity throughout the life of the structure, is directly dependent on the design talents and workmanship employed.

Materials Storage and Handling. All incoming materials need to be handled and stored in accordance with the vendor's Materials Safety Data Sheet (MSDS) instructions. This is most necessary for hazardous and shelf-life materials, which are common in the composite and adhesive-bonding materials. The cold storage of shelf-life materials—in particular the composite prepregs, film adhesives, and two-part adhesives—is essential in order to maintain material property standards. The time duration that the material is out of cold storage must be well documented, and the appropriate reduction in remaining life made.

The thaw time of any materials held in cold storage is most important. When a material is taken from the freezer, it should not be removed from its protective sealed wrapping until all of it has reached room temperature. Otherwise, water vapor will condense onto the surface and be absorbed into the resin materials. This moisture degradation will have the same effect as using overaged materials, that is, reduced mechanical properties. However, the degree to which moisture continues to condense on the sealing package can give a ready indication of the “ready-to- use” status of the material. If water vapor no longer condenses on the bag, it is near enough to room temperature to open it.

When the materials are returned to cold storage, ensure that the packaging is airtight, even to the point of removing the air from the package. This again will stop moisture absorption. In general, storage temperatures

of–18 °C (0 °F), will provide the full storage life that is guaranteed by the materials supplier. Temperatures of–40 °C (–40 °F) will provide an indefinite life, but this is not guaranteed by the material suppliers. Finally, complete appropriate material storage documentation.

Repair Fabrication Rooms and Equipment. The two major processes in the repair of composite structures are damage removal and repair patch fabrication and application. Each of these processes must be done in separate rooms and with dedicated tooling to prevent contamination.

Environmental Controls for Work Areas. In a composite and adhesive-bonding workshop, the materials used are temperature and moisture sensitive. They are temperature sensitive because the material processing requires a time duration at elevated temperature to produce the finished product. High working temperatures can prematurely begin the curing process of resins and adhesives, thus shortening their working life. Humidity control is important as polymeric materials absorb moisture readily from the atmosphere, contaminating the material and possibly reducing the mechanical properties. Excessively low humidity and temperature will make the prepregs and film adhesive stiff and difficult to work with due to lack of tackiness. In the repair of flight critical structures, environmental controls must not be waived. If, however, field repairs are necessary, then the repair scheme is fabricated in a controlled environment (precured patch), sealed, and shipped to the field where it is attached as quickly as possible.

Access Control. Damage removal and clean rooms both are hazardous to personnel and have the potential to contaminate components. Access to these rooms should be restricted to personnel trained in health and safety procedures and composite processing.

Repair Documentation. From a quality-control perspective, four levels of repair documentation are required to ensure that the repair will be of the highest standard:

1. Equipment operations
2. Component tracking, including: initial NDI survey, damage details, repair action and scheme, moisture-removal requirements and method, damage removal action, repair fabrication details (including materials used), repair application procedure, cure details, and post-repair NDI action and results
3. Shelf-life materials tracking
4. Cure documentation (see Ref 1)

Health and Safety. Three main issues to be addressed in the environmental health and safety for composite structural repairs are:

Common Sense Approach: In all aspects of working with damaged composite structures and their repair, a common-sense approach to health and safety is expected. If there is the slightest concern, then appropriate safeguards and protective systems must be put in place. A good recordkeeping is very important. This includes the availability of up-to-date Material Safety Data Sheets, (MSDS), suitable storage requirements and facilities for toxic and harmful materials, appropriate relabeling (particularly when batches of materials are broken down into more usable sizes), and material disposal.

Protect the Worker: At all times the worker, that is, the person directly involved in damaged- component removal, composite structure machining and grinding, and the preparation of repair schemes and their application needs to be protected. This means that engineering management must ensure that the worker has a safe environment within which to work and is encouraged to follow safe work practices stringently.

Local, State, and Federal Legislation: Government legislation must be strictly observed at all times. Disposal action is steadily becoming a legislated requirement. Reference 1 details the specifics of the disposal requirements for toxic and hazardous composite materials. The details of legislation vary from one location or country to another. The appropriate authorities must be contacted for specific guidelines.

Sharp needlelike fibers are exposed when composite components are damaged. The needlelike spikes are a result of resin-stiffened fibers, and they easily protrude into skin or soft body tissues. Of particular threat are the fingers, hands, and eyes. The precautionary personal safety equipment required includes at least: disposable coveralls, face shields or goggles, and heavy rubber or canvas gloves.

There are a number of environmental and safety concerns when machining and/or grinding composite components. Fiber dust could be potentially hazardous to human health, both physically and chemically. Free-floating composite fibers are not seen as a particular carcinogenic concern (as opposed to asbestos) due to their fiber diameter to length ratio. However, workers should avoid breathing them. The microfibrils of aramid fibers are an unresolved concern. Therefore, the minimal safety equipment to be used includes: high-efficiency

particulate respirators, local vacuum or dust extractors, face shields and/ or goggles, appropriate gloves, and disposable coveralls.

Safety protection when working with uncured adhesives and resins, solvent cleaning, acid etching prior to bonding, and during the cure process include: disposable coveralls; gloves—surgical, cotton, or rubber depending on the application; vacuum hood or air extraction system; and face shields or goggles, if liquid resins and solvents are used. The major concerns are splashing of liquids and the absorption of vapors through the skin and other orifices of the body. The MSDS will specify the requirements for each material type. All of the processes that emit vapors should be performed with extraction systems outside the working space, in fume cupboards or in well- ventilated rooms. Note that many of these vapors are flammable. A further concern when working with uncured two-part resin systems is exothermic reactions. The mixing of two-part resin systems produces heat in the reaction. If this heat production (exothermic reaction) is not controlled, the resin mix may exotherm uncontrollably. This can lead to an explosive reaction or fire hazard. Follow the MSDS requirements and be observant to any heat buildup or unusual color changes. The hazards associated with the various types of adhesives and composite resins are provided in Table 2.

Table 2 Hazards associated with selected adhesives

Adhesive type	**Causes burns**	**Flammability**	**Explosion**	**Harmful vapors**	Harmful to skin and eyes
Solvent-borne		X	X	X	**X**
Water-borne				X maybe	**X**
Hot melts	X			X maybe	**X**
Powder form			X		
Curing rubber	X			X	
Epoxies		X		X maybe	**X**

Quality Control and Quality Assurance. In any composite-structures workshop, whether components are being manufactured or repaired, one of the most important process requirements, and usually the one most often neglected, is quality control. In terms of both manufacture and repair facilities, quality control is the process that provides the customer's full acceptance of the integrity of the product, its technology, and the producer.

The material and process quality-control aspects in a composite and bonded structure workshop deal principally with the actual materials used in the fabrication of the component or repair scheme and the process by which the fabrication takes place. This particular component of quality control covers the entire product or service process. In addition, the level of skill in the work force, both technician and engineer, is a fundamental part of material and process quality control.

To ensure that repair materials are of the highest quality and that the repair station is set up to maintain an appropriate working environment, certain quality-control procedures or guidelines should be in place. As a minimum, such guidelines would include:

- Supplied material quality checks and receiving inspections
- Materials handling procedures and storage facilities for shelf-life materials
- Clean room for patch repair fabrication and application
- Damage removal area with suitable dust-extraction equipment
- Humidity and temperature controls in the clean room, including positive pressure for dust control
- Controlled access to the clean room
- Consumables, environmental controls, and repair procedure documentation
- Appropriately trained technical staff, with skill levels set and ongoing training programs

Quality-assurance testing is the physical testing of a product to show or demonstrate that it meets its acceptance standards. That is, the product achieves the desired mechanical strength, stiffness, and durability properties, for which it is designed. Quality-assurance testing is the final proof of successful quality-control implementation. The types of quality-assurance tests required fall under three main areas:

- Material quality assurance
- Process quality assurance
- Component quality assurance

Material quality assurance is in effect prefabrication testing of constituent materials. Such testing is used to screen incoming materials to ensure that they conform to the manufacturer's documented standards, and that lifetime-expired materials can also be checked against that standard. Tests that can be used on prepreg composites and adhesives (or any resin material) include: composite prepreg tack test, adhesive flow tests (Ref 3), and other test methods provided in ASTM standards and Suppliers of Advanced Composite Materials Association (SACMA) test methods.

Cofabrication quality-assurance testing takes place during the actual fabrication of the repair scheme and its placement on the damaged area. The testing in effect is simple in that little expense and time is required, but such tests have a large impact on the structural integrity of the final repair. The testing procedure also ensures that all repair steps are completed and that critical steps are independently inspected prior to continuing with the repair. The testing process (both physical test and procedural checks) include backing ply count, water break test (Fig. 9), repair procedure checklist, and independent inspector's check.

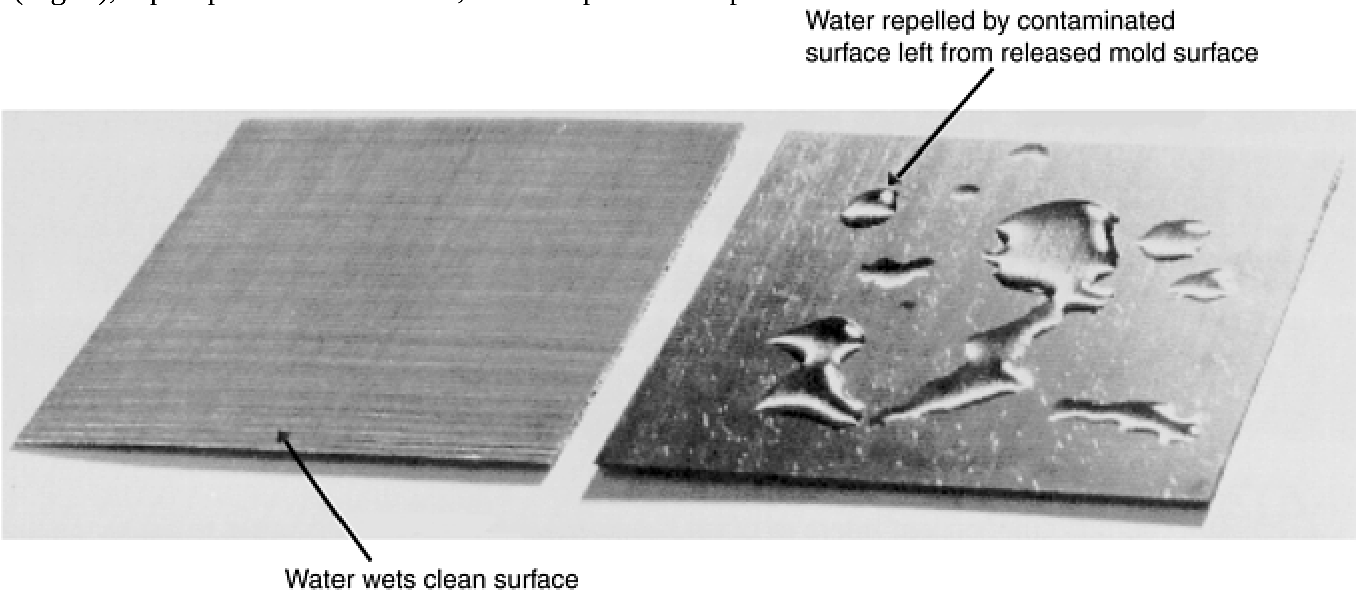

Fig. 9 Good (left) and poor (right) water break test results. Source: Ref 4

Finished-component quality-assurance testing is a postfabrication test procedure, which is either a mechanical test on the completed component for adequate material properties, (a proof-load test or comparative coupon test) and/ or a nondestructive test.

Mechanical property testing includes (for composites):

- Short-beam shear test—(ASTM D 2344 (Ref 5) or SRM 8-88 (Ref 6)
- Iosipescu shear test (Ref 7)
- Tension and compression tests—ASTM D 3039 (Ref 8), ASTM D 3410 (Ref 9), SRM 1-88 (Ref 10), and SRM 4-88 (Ref 11).

and (for bonded joints):

- Lap-shear test—ASTM D 3165 (Ref 12)
- Boeing wedge test—ASTM D 3762 (Ref 13)
- Postrepair NDI

Bonded Repair of Metal Structures Using Composites

Richard J. Chester, Aeronautical and Maritime Research Laboratory, Australia; James J. Mazza, Air Force Research Laboratory

Introduction

MODERN AIRCRAFT are becoming increasingly sophisticated and therefore more expensive to purchase. For this reason, aircraft are remaining in service for lengthy periods that, in some cases, exceed their original design lives. Some military aircraft are now expected to remain in service for 50 years or more; this would have been unthinkable when they were designed. To achieve such life extension, careful attention must be paid to managing both corrosion and fatigue, because they are the main problems associated with aging aircraft structure.

Composite bonded repair technology (Ref 1) enables cost-effective and durable repairs to be made to damaged or defective aircraft structure. This technology was developed in the early 1970s and is now routinely used for repairs to tertiary and secondary structure and noncritical repairs to primary structure (Ref 2). Some structurally significant repairs have also been made to primary structure (Ref 3, 4). Composite bonded repair technology is based on the use of advanced composite repairs or reinforcements that are adhesively bonded to the damaged structure. This contrasts with conventional repairs that are usually made from the same material as the parent structure (normally aluminum) and mechanically fastened to transfer the load into the repair material. The lack of conventional fasteners in a composite bonded repair is one of the main advantages. Fastener holes are points of stress concentration in a structure and may cause the initiation of new fatigue cracks. Adhesively bonded repairs have a much more uniform stress transfer mechanism, resulting in a stiffer joint, because the load is not transferred only at a few discrete locations, as is the case for fasteners. Composite bonded repairs are typically thinner, weigh less, and can be applied more rapidly than conventional repairs. They also do not suffer from subsequent corrosion during service, because the patch is immune to corrosion and the adhesive effectively seals the repair interface.

Because composite bonded repairs provide greater reinforcing efficiency than a mechanically fastened joint, it is often possible to leave the defect in the structure. Simple nondestructive inspection (NDI) methods can subsequently be used to confirm the effectiveness of the repair in service. Not having to remove the defect is one of the ways in which significant savings in repair time can be achieved. A major difference between mechanically fastened and adhesively bonded joints is that there is no NDI technique currently available that can provide a measure of the adhesively bonded joint strength or durability after the joint has been made. For this reason, it is essential that all adhesively bonded repairs be undertaken using quality management principles.

As well as repairing damaged structure, adhesively bonded composite materials can also be used to reinforce structure to reduce excessive deflection or stress and prevent the initiation of a defect. It is important that the details of the structure and nature of loading be understood to ensure that an effective reinforcement can be designed.

Due to the research carried out since the 1970s, the technology is now mature for relatively straightforward repairs. Research is continuing into its use on thicker structures that are highly loaded, highly curved structure and safety-of-flight-critical structure, where the defect has reduced the load capacity of the structure below design ultimate load.

This article aims to introduce the reader to the technology and explain some of the key steps that are normally encountered in the design, certification, and application of an adhesively bonded repair. In the space available, it is not possible to completely describe all aspects of this technology; readers interested in designing and applying such repairs are referred to the references for more complete details. Some examples are given of successful repairs to military aircraft, and finally, future trends and developments in this area are forecast.

Bonded Repair of Metal Structures Using Composites

Richard J. Chester, Aeronautical and Maritime Research Laboratory, Australia; James J. Mazza, Air Force Research Laboratory

Damage Assessment

An important precursor to the design phase is a careful assessment of the damage to establish if the repair design will be effective. Cracking, in particular, should be carefully inspected to determine the nature of the loads that are responsible. In many cases, tensile loads are involved; however, in some cases, shear or bending stresses may be present, and a repair may need to be specifically designed for these loads. Cracks should be inspected to determine if they are fatigue cracks, acoustically generated fatigue cracks, or stress corrosion cracks. Different design approaches will be required in each case.

The nature of the damaged structure is important. Considerations include material type and thickness, the nature of the loading, environmental conditions present, and local geometry, including curvature. The degree of support to the structure in the repair area is also important, together with the available length of the load transfer zone. If the structure is well supported or is sufficiently thick, a repair to only one side of the damage may be appropriate. For thin, poorly supported structure, a one-sided repair may induce bending, due to the shift of the neutral axis of the repaired structure, so a double-sided repair may need to be considered.

Accurate NDI is desirable to ensure the full extent and nature of the damage is known. If the defect is to be left in the structure, this information will be used during subsequent inspections to check for any defect growth during service.

Bonded Repair of Metal Structures Using Composites

Richard J. Chester, Aeronautical and Maritime Research Laboratory, Australia; James J. Mazza, Air Force Research Laboratory

Repair Design

Following a thorough assessment of the nature of the damage, an appropriate repair can be designed. In some cases, the designs of bonded composite repairs are deceptively simple, but some understanding of the technology is required if the repair is to perform its required function. Although strength and stiffness will be primary considerations during the design process, many other issues need to be considered to ensure that the repair is effective. Some of these are listed in Table 1. For any bonded repair, the designer must also recognize

the crucial importance of correct manufacture and application procedures (covered in the section "Repair Application" in this article).

Table 1 Partial list of issues to be considered during repair design

Static strength
Fatigue strength
Weight
Stiffness

Stress intensity following repair
Post-repair inspections
Durability under operating environment

Materials Selection and Engineering. There is no single repair material that will be optimal for every repair situation, and so the designer needs to select the best material for the situation (Ref 5). Materials that have been used effectively include boron/epoxy and graphite/epoxy composites (fiber-reinforced plastics, FRP), GLARE (a laminated metallic material reinforced with glass fibers in an adhesive layer), and conventional metallic materials. Fiber-reinforced plastic materials are most commonly used, because they are relatively resistant to fatigue damage and impervious to corrosion (Ref 1). Their high specific stiffness allows repairs to be made thin and with low weight, they can usually be molded readily to complex aerodynamic curvatures, and they can be readily made with tapered ends to reduce peel stresses. Potential FRP disadvantages include cost, availability, and the need to carefully insulate graphite/epoxy repairs to avoid galvanic corrosion of aluminum substrates. Boron/epoxy repairs do not cause galvanic corrosion and also readily permit the use of NDI methods, such as eddy current inspection, to check for growth of the defect underneath the installed repair material. As a result of thermal expansion mismatch between the composite and metal (Table 2), residual stresses are generated when composites are bonded to a metallic substrate with an elevated-temperature-curing adhesive. Boron/epoxy is often preferred to graphite/epoxy as a repair material, because it gives rise to lower residual stresses. Note that thermally induced residual stresses do not normally compromise the design of a composite bonded repair; however, it is important that they be considered during the design phase.

Table 2 Coefficients of thermal expansion of substrates and repair materials

Material	Coefficient of thermal expansion	
	10^{-6}/°C	10^{-6}/°F
Boron/epoxy (unidirectional)	4.5	**2.5**
Graphite/epoxy (unidirectional)	–0.3	**–0.16**
GLARE-3 3/2, 0.2 (longitudinal)	16.3	**9.1**
Aluminum (typical)	**23[(a)]**	**12.8[(a)]**

(a) In typical aircraft structure, the aluminum component is constrained by the relatively cool surrounding structure, and so the actual expansion is usually significantly lower than would be the case for free expansion.

GLARE has been demonstrated by the United States Air Force (USAF) for fuselage repairs and appears to have greatest advantage for applications where the operating temperature is normally low (high-altitude cruise conditions) (Ref 6). This is because at low temperatures, the residual stresses caused by composites are enhanced, while GLARE produces minimal residual stress. Disadvantages of GLARE include relatively low stiffness that results in comparatively thick and heavy repairs, difficulty in molding the patch to complex curves, and difficulty in performing NDI to check on growth of any underlying damage. These same disadvantages apply to the use of conventional metals for repair materials, but metals are more susceptible to fatigue and corrosion than GLARE.

The operating temperature is an important design consideration that can influence the choice of repair material. Apart from the low-temperature condition described previously, many high- temperature locations are present

around engines, bleed air (de-icing) locations, and on leading edges of military aircraft. The glass transition temperature of composite materials and the composite interlayers in GLARE need to be carefully checked to ensure that an adequate margin is allowed for safe operation under worst-case hot/wet conditions.

Adhesives used for bonded composite repairs are often structural film adhesives (epoxies, phenolics); however, some paste adhesives, such as epoxies and modified acrylics, have also been used successfully. The designer needs to consider whether the mechanical properties of the adhesive (shear modulus, shear yield strength, and strain-to-failure) are adequate for the repair application. Note that the lap/shear strength data usually provided by adhesive manufacturers are convenient for comparison purposes but are not pure shear (rather, mixed peel and shear) and, therefore, should not be used for design. The correct design value is the shear strain at yield, measured by the thick-adherend shear test (for example, ASTM D 3983 and D 5656). Good repair design will have the adhesive being stressed in shear with low peel stresses at the ends of the joint. Designs in which high levels of peel stress are present should not be considered; however, it is important to recognize that some adhesives are much better able to withstand peel stress than others. High-temperature adhesives (phenolics, polyimides), in general, are essentially brittle and so are much more likely to fail due to peel stresses than lower-temperature, toughened adhesives (modified acrylics and toughened epoxies). It should be noted that failure of a composite bonded repair may not be within the adhesive layer, but rather within the relatively more-brittle matrix resin of the composite repair material. Designing only to the adhesive strength may be unconservative, if actual repair failure occurs within the composite repair material.

The cure temperature is usually an important factor to be considered, because this directly affects the ability of the adhesive to function satisfactorily under the operating temperature. Cure temperature is also the critical consideration if residual stresses are deemed to be important, and cure time can sometimes be important where the repair must be completed quickly, due to operational requirements.

Stress Analysis. Bonded composite repairs are normally intended to restore the load path that the damage/defect has removed from the structure. For this reason, the design is typically undertaken so that the repair restores the lost stiffness, and checks are made to confirm that adequate strength levels have been achieved. Designing to restore strength with composite materials could result in the structure being overstiffened, which will result in extra load being attracted to the region. In practice, it is found that most simple repairs can be modeled approximately as a representative bonded joint, the solutions for which have previously been published (Ref 7, 8). The shear stress distribution in a typical repair is shown in Fig. 1.

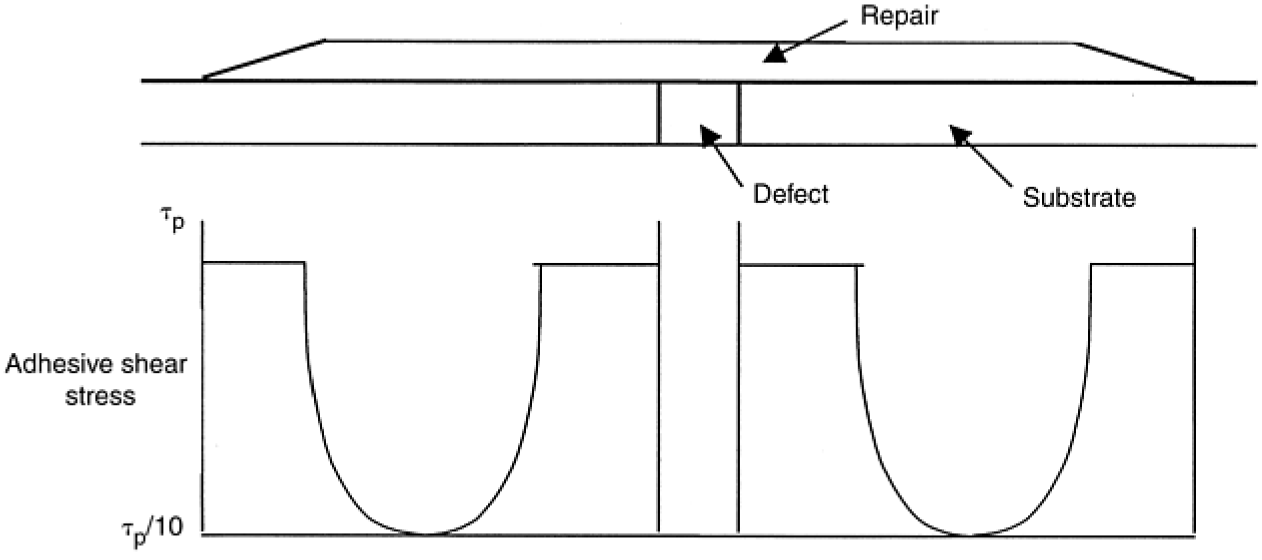

Fig. 1 Example of the shear stress distribution in a bonded repair where the defect remains in the structure and the substrate is restrained from bending

At the ends of the repair, the adhesive shear stress (τ_p) is high and may reach the yield stress at high loads. As the longitudinal strains in the repair and substrate adherends become equal, the adhesive shear stress reduces. A sensible design approach is to adjust the length of the repair to allow this stress to reduce to less than one-tenth of the plastic shear stress value. This provides necessary damage tolerance with respect to voids or other defects in the adhesive bondline and against failure by creep rupture.

The design should be checked for static strength using the maximum load the structure is expected to see in service (for aircraft this is the design ultimate load). Checks need to be made of the stress intensity at the defect

after repair to confirm that the repaired structure has an adequate margin of static strength. The maximum strain in the repair material needs to be less than the design allowable for the material, and a check must be made of the load-carrying capability of the adhesive in the joint. The maximum load to be transmitted by the joint is checked to confirm that it is less than the load- carrying capacity of the adhesive. This is related to the strain energy capacity of the adhesive (area under the stress-strain curve) and the influence of residual stresses in the joint. Where the repair will operate at low or elevated temperatures, these strength checks need to be made using the appropriate adhesive properties. As noted in the section "Materials Selection and Engineering" in this article, if the adhesive strength does not determine the joint strength, as may occur with composite adherends, this design strategy may be unconservative.

If the repair demonstrates adequate static strength, it should not be the weak link in the structure if maximum load is applied. Checks should also be made on the expected crack growth of the defect, using the postrepair stress- intensity factor and the fatigue load spectrum. Due to the efficiency of bonded repairs, it is usual to find zero or very low crack-growth rates following the application of a bonded composite repair. Using the fatigue spectrum, checks can then also be made to ensure that the adhesive is not likely to suffer fatigue damage and that the repair material is operating below the fatigue threshold. Simple repairs can be designed using this analytical approach, while more complex repairs (to thick structure or complex geometries) are likely to require the use of finite-element analysis (Ref 1).

Repair Application

Successful application of a bonded repair design is not necessarily difficult, but requires proper execution of a number of processing steps, including surface preparation for both the aircraft structure and the composite repair material, as well as heating and pressurization. Other considerations include the nature of the repair installation environment, handling of repair materials, health and safety issues, training of repair installers, and postbond operations. In all cases, it is important that installation procedures be considered during repair design and validation, because they directly influence the final properties of the adhesively bonded joint.

Surface Preparation. Preparation of adherend surfaces prior to bonding is the single most- important application process step for ensuring a successful repair (Ref 9). Surface preparation is necessary for the attainment of adequate initial bond strength and long-term durability in the service environment. Although the environment includes temperature extremes and exposure to many aircraft fluids and maintenance chemicals, moisture tends to be the biggest impediment to long-term durability, particularly for aluminum bonded joints. Nearly all failures in aluminum adhesive joints on aircraft have been initiated by moisture (Ref 10).

In the broadest sense, prebond surface preparation encompasses several steps required to provide a durable interface between the substrate and adhesive (or primer). These can include cleaning, deoxidizing, chemical and/or physical modification of the surface, and application of adhesive bond primer. Prior to surface preparation, existing inorganic and organic coatings or surface layers must be removed from the surface via locally approved processes. Cleaning, typically solvent degreasing, is required to remove oils, greases, hydraulic fluids, jet fuel, and other gross organic contaminants. This should be accomplished prior to and subsequent to coatings removal. Care must be taken to use degreasing solvents that can remove the likely contaminants.

After cleaning, metals are usually abraded, grit-blasted, or etched to remove loosely adhered oxides, to prepare a contaminant-free surface, and to generate a rough surface topography. Abrasion can be accomplished by a variety of means, including sandpaper and nylon abrasive pads, such as Scotch-Brite (3M Corporation). Grit-blasting, typically with fine alumina, is a good method for roughening surfaces and removing existing oxide layers. Care must be taken not to damage aircraft structure, with particular caution for fatigue-critical components, and removal of abrasive media and debris must be done in such a way that the clean surface is not contaminated. Etching with a strong acid or base can also be used to deoxidize, clean, and roughen metal components. After degreasing and roughening, the water break test (Ref 11) is often used to assess the cleanliness of the surface, although it does not guarantee that the surface is free of contaminants.

Adhesive bonding is sometimes conducted on surfaces that have simply been cleaned and roughened. However, this is not recommended, particularly for critical components or those intended for a long service life, because a clean, rough surface does not guarantee adequate initial bond strength and does very little toward providing a metal-polymer interface that can resist long-term moisture attack. Additional surface modification is necessary to create a robust interface capable of resisting moisture for extended periods of service. This modification is often referred to as the surface treatment step, whereas the precursor cleaning and roughening steps are often designated the pretreatment. The actual surface treatment can be accomplished via anodizing, etching, or application of a coupling agent. Many anodizing and etching processes are available for metal alloys (Ref 12). The anodizing processes grow a fairly stable, microrough oxide layer on the metal surface that allows for mechanical interlocking with an adhesive or primer. Etching treatments produce less microroughness, but also provide bond strength and durability via mechanical interlocking (Ref 13). The use of coupling agents is intended to produce adhesion via strong chemical bonds. Coupling agents, most often silanes with appropriate organic functionalities, are formulated to bond two dissimilar materials, such as a metal oxide surface and a polymer (primer or adhesive). This approach eliminates problems associated with acid use on aircraft, such as embrittlement of certain high-strength steels (Ref 14), health/safety issues, and possible corrosion if not properly rinsed away. Variants of the grit-blast/silane (GBS) approach have been used successfully by a number of organizations (Ref 15, 16). Silane coupling agent application is shown in Fig. 2 for a F-16 aircraft repair. A similar but improved approach based on sol-gel technology has been developed and is now beginning to see application (Ref 17, 18). Application of a corrosion- inhibiting adhesive primer is also required to maximize long-term moisture durability for all of the surface treatments, and its use is recommended in most cases. Primers, though, can be difficult to properly apply on aircraft, and they can present health/safety concerns. Environmental durability data for several surface preparations, as measured by the ASTM D 3762 wedge test, are presented in Table 3.

Fig. 2 Application of silane coupling agent (GBS surface preparation) during a F-16 aircraft repair

Table 3 Wedge test data (ASTM D 3762) for several surface preparations

Surface preparation	**Initial crack, mm (in.)**	Cumulative crack growth, mm (in.)					
		1 h	**8 h**	**24 h**	**7 days**	**28 days**	Failure mode[a]

(c) BR 6747-1, Cytec Fiberite chromated waterborne bond primer

Repair materials such as metals, GLARE, and precured FRPs must also be treated prior to bonding. Because the outer surface of the GLARE laminate is anodized and primed, it must only be degreased with a suitable solvent prior to bonding. Precured FRP materials must also be prepared by cleaning and roughening prior to bonding; however, because they do not have an oxide layer, there is no need for a chemical modification or treatment step to ensure a strong and durable bond, as is the case for metals. The primary function of the surface preparation is to remove contaminants, such as oils, mold lubricants, or general dirt. There are two main techniques used to accomplish this: the peel ply method and solvent cleaning and abrasion, often conducted after a peel ply surface has been exposed (Ref 19). Solvent cleaning to remove gross organic contaminants is conducted with the same type of solvents used to degrease metals. Abrasion can be accomplished using a variety of media, including abrasive papers and nylon pads. A grit-blast with aluminum oxide is the best surface preparation known for composites. This method is preferred, if at all practical for a given application, and its superiority has been confirmed by a series of tests at a number of companies. It results in optimal bond strengths with a minimum of scatter (Ref 20).

A peel ply can be incorporated, during manufacture, as the outer layer on the bonding surface of a composite laminate to be removed just prior to bonding (Fig. 3). In principle, a clean surface is exposed that is ready for immediate bonding. However, it is difficult to ensure that the peel ply has not left behind sufficient contamination to reduce the bond strength and increase the coefficient of variation considerably (Ref 21). The choice of peel ply material is important as well as controversial (Ref 22). The safest approach is to abrade or grit-blast after peel ply removal. The peel ply then prevents contamination of the bond surface until its removal just prior to bonding, and the abrasion ensures the peel ply itself does not contaminate the surface. The cleanliness of the prepared FRP surface can be checked using the standard water break test (Ref 23). The FRP should then be thoroughly dried prior to adhesive application. Primers are not typically used on FRP materials.

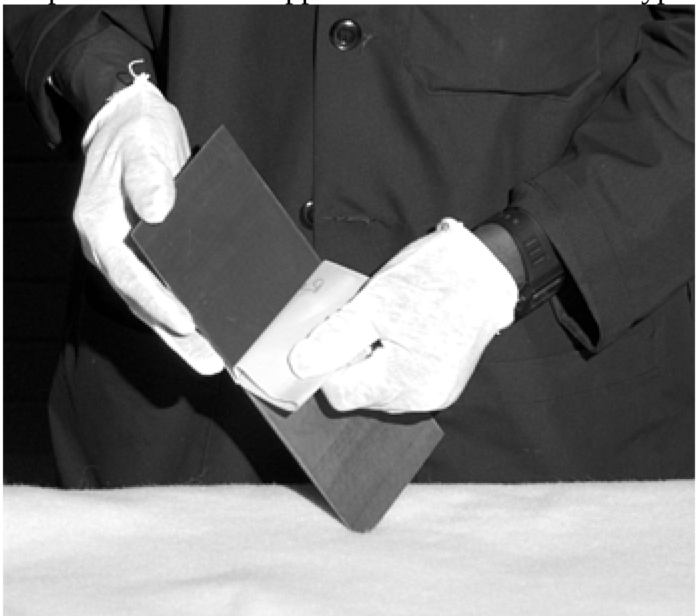

Fig. 3 Peel ply removal from composite doubler

After the aircraft repair area and repair material surfaces are prepared for bonding, adhesive is applied, and the repair material is mated to the aircraft within a predetermined time interval. Film adhesives are usually applied to the repair material, which is then taped in place on the aircraft. If paste adhesives are used, they are applied to both mating surfaces. Some means of bondline thickness control is required for pastes, such as glass beads or a scrim cloth, whereas most film adhesives used for repair already contain a carrier cloth. In all cases, the procedure used should be validated prior to the actual repair. Handling and application of adhesives should be done in such a way as to avoid contamination and minimize air entrapment.

Heating and Pressurization. If surface preparation is the single most important bonded repair application process, heating and pressurization are likely next. In fact, heat application is an essential part of many surface preparations. For instance, the GBS process requires controlled elevated-temperature drying of the silane immediately after its application to the metal surface. Heating may also be used to dry surfaces after rinsing acids or conducting water break tests. Controlled heating is also required to cure adhesive primers, and elevated

temperatures are often used to dry structure prior to repair. Of course, heating is required to cure many repair adhesives, and elevated temperatures are often used to accelerate the cure of ambient-curable adhesives. Many adhesives can cure over a range of temperatures, provided they exceed a minimum temperature for a specified time. It is often desirable to cure for longer times at lower temperatures to reduce the effect of coefficient of thermal expansion mismatch between aircraft structure and repair material (see the section "Materials Selection and Engineering" in this article). The actual cure cycle to be used should be validated with the design, because adhesive properties can vary for differing cures.

Pressure application is necessary to mate the repair material to the aircraft structure. Although pressure is not required to actually cure the adhesive, sufficient pressure is required to achieve desired bond strength and durability. Pressure causes the adhesive to flow and properly "wet" the bond surfaces; it ensures proper bondline thickness, and it helps reduce the extent of bondline voids and porosity.

Heating may be conducted by any of a number of methods, provided they are able to safely control the temperature in the repair area within prescribed tolerances for the time required, without contaminating the repair. Typical on-aircraft heating methods include electric-resistance heat blankets, infrared heat lamps, and hot air devices. Application specifics determine the method best suited to a given repair. Heat blankets are typically used to cure adhesives, whereas heat lamps are usually the choice for silane drying and precuring primers. All heating devices must be controlled by some means so that heat can be applied when and to the levels required. This is particularly important for adhesive cure, because controlled heat-up and cooling rates are usually prescribed. "Hot bonders" that automatically control heating based on temperature feedback from the repair area are normally used with heat blankets. These units or similar means can be employed to control heat lamps and hot air devices.

Achieving prescribed repair temperatures within desired tolerances can often be difficult on aircraft, because portions of the structure can act as "heat sinks." These regions conduct heat away from the repair site and become locally cooler regions where there is a danger that the adhesive may not fully cure. Thermal surveys of the repair area are important to ensure proper heating will be attainable. The surveys should be conducted on the actual repair area, using the equipment to be employed during the repair. They can determine the placement of insulation materials or the locations needed for supplemental heating to overcome "heat sinks," and they will reveal the required temperature readings for surrounding "monitoring" locations that can be used to determine the temperature in the repair area. The goal is to reduce the temperature delta in the repair area to an acceptable value considered during the repair design. In complex situations where large heat sinks exist, a sound philosophy is to monitor and control the hottest point, so as to avoid any damage to the structure, and then use the coldest point as the basis for ensuring complete cure of the adhesive.

Pressure application on aircraft may also be achieved by a variety of means. These include vacuum bag, inflated bladder, or various forms of mechanical pressure. The use of a vacuum bag is the most common, because it is almost always the most convenient. Vacuum bags are light, conform to almost any surface, apply uniform pressure, can remove volatiles from the repair area, and can hold a heat blanket in place (Fig. 4). To apply pressure this way, a bag is built over the repair area and air is extracted, allowing atmospheric pressure to be applied. In most cases, it is not desirable to achieve a full vacuum throughout the cure cycle, because the vacuum allows volatiles in the adhesive, such as moisture or solvents, to boil more readily, and it allows entrapped air to expand more easily. Often, high vacuum levels are applied initially to remove volatiles from the repair, then vacuum levels are reduced before the adhesive gels, in order to minimize porosity in the bondline. Levels corresponding to 34 to 69 kPa (5 to 10 psi) pressure are common. The process decision is influenced by the particular repair adhesive and should be considered during repair design. A common problem with the use of vacuum bags is that they also tend to draw air and contaminants into the repair area through leakage points in the structure, for example, from around and under fastener heads or from around intersecting ribs that cannot be completely sealed.

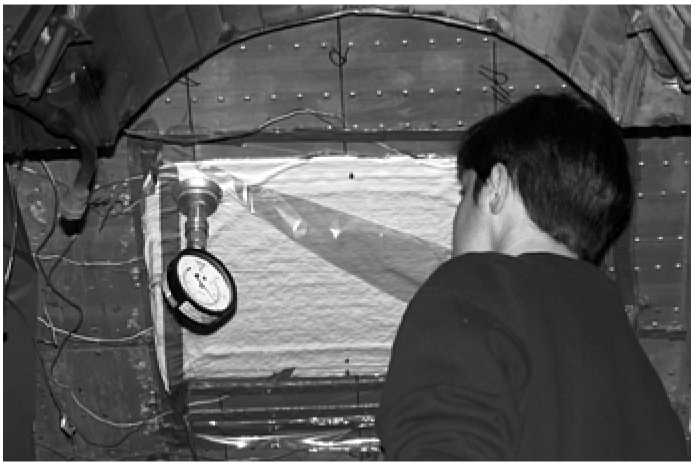

Fig. 4 Installation of vacuum bag containing heat blanket and thermocouples

Bladders inflated with air can be used to apply positive pressure (as opposed to vacuum) on a repair area. This may be desirable to minimize void formation due to the evolution of volatiles. However, this approach is not usually convenient, because bladders must be held against the structure in some way, and they require a frame or fixture to react against. If this fixture is fastened to the structure, pressure is limited to prevent damage. Mechanical pressure may also be applied by clamping or other means. Again, these forces must be reacted, and it is difficult to apply uniform pressure over a large area via clamps.

Precured FRP repair materials should be cured via positive pressure in accordance with manufacturer's recommendations. This is normally done in an autoclave to minimize porosity and achieve the per-ply thickness value envisioned by the design. Fiber-reinforced plastic materials can also be cocured with the adhesive during repair installation. This can be a convenient method for ensuring the repair material matches surface contours.

After the repair material is bonded in place, the edges of the repair should be sealed to slow moisture ingress. Adhesive “flash” that has squeezed out onto the prepared surface during bonding should be left in place around the periphery of the repair, with only excessive squeezeout carefully removed. The metal corrosion protection scheme should then be reestablished in the area surrounding the repair, and the edge of the repair should also be coated with sealant, such as Aerospace Materials Specification (AMS) S 8802 (Ref 24).

Bonded Repair of Metal Structures Using Composites

Richard J. Chester, Aeronautical and Maritime Research Laboratory, Australia; James J. Mazza, Air Force Research Laboratory

---

Repair Certification

A number of design, installation, and in-service inspection issues must be addressed in order to certify a bonded repair. Unfortunately, there is no widely accepted standard for certification. The problem that sets bonded repair apart is the concern over long-term bond durability in the service environment, particularly moisture, and the current inability to satisfactorily predict or nondestructively measure this durability. This is less important for repair of structure that is not flight-critical, because risks are lower, and these types of repairs are becoming accepted. However, a fail-safe approach is often taken for safety-of-flight-critical structure. This does not allow full credit to be given to the repair for restoring residual strength and reducing the fatigue crack growth rate. In

other words, it is assumed the repair can fail at any time. To receive full credit, there must be assurances that the risk of losing repair effectiveness is acceptably low, or a technique must be available to detect significant loss before it is a problem (Ref 25).

Certification Guidelines. Aside from the critical environmental durability issue, repairs can be designed on the basis that patch efficiency can be predicted, and they should be designed conservatively, with respect to the possible failure modes, to include the surrounding structure. In this regard, an approach similar to the one outlined by the USAF Structural Integrity Program identified in MIL-HDBK-1530 (Ref 26) can be used as the basis for certification. The environmental durability issue greatly increases the significance of quality control and associated testing, because quality is assured by complying with approved and validated process specifications. Validation of surface preparation procedures is particularly difficult, due to the current lack of a definitive test to accelerate the effects of service environment in a way that is quantifiable. Although not as complex as the issue of adhesive bond durability, validation of all the other aspects of repair implementation is also required to enable certification. This includes repair design methods, processes, and software and repair application methods and processes.

Nondestructive Inspection and Quality Control. Nondestructive inspection plays a role in determining whether a repair has been successfully installed and is performing as expected in service. Several different NDI techniques can be used to inspect bonded composite repairs. Ultrasonics can be used to readily detect disbonds between the repair and the parent structure, and defects within the adhesive bondline, such as large voids or delaminations within a composite patch or reinforcement. Ultrasonic bond testers using a low-frequency impedance technique can also detect disbonds and voids within a repair joint. Thermography is gaining increased acceptance as a rapid way of detecting the presence of disbonds and larger voids within bondlines. Also, simple tap tests can normally be used to provide a quick indication of the presence of a disbond under a repair, and inspection of the squeezeout after bonding can give an indication as to proper pressure application and bondline porosity. Eddy current methods are particularly useful for determining the length of cracks in metallic substructure under a composite repair and are most efficient for repair materials, such as boron/epoxy, that are electrically nonconductive. Further details of these and other NDI methods can be found in Ref 27 and 28.

Even with the large number of techniques available, NDI plays a supporting role that is necessary but not sufficient for assuring bondline integrity. This is because there is no NDI technique currently available that can measure the strength of a bond and therefore provide evidence of gradual adhesive bond degradation. When such a technique becomes available, it will be possible to confirm that the surface treatment procedures have produced a bond with the required level of strength, and then, while in service, the technique can be periodically used to confirm that no deterioration of the joint strength has occurred. The only way in which such assurance can currently be obtained is by quality management of the repair application. Critical aspects of quality management include:

- Effective training of design and technical staff
- The use of in-life materials that have been qualified and properly handled
- The use of validated design and application procedures (in particular, surface treatment procedures)
- Control of the repair environment and the use of validated procedures to ensure full cure of the adhesive and the absence of defects after the repair has been applied

The previously mentioned process, coupled with NDI and the judicious use of process control (witness) coupons, is the best method currently available to assure a successful repair that has long-term durability. This process has been applied successfully in the repairs described subsequently.

Bonded Repair of Metal Structures Using Composites

Richard J. Chester, Aeronautical and Maritime Research Laboratory, Australia; James J. Mazza, Air Force Research Laboratory

Repair Examples

Thousands of bonded repairs have been made to metallic aircraft structures using composite materials. Most have been applied to instances of metal fatigue cracking, although bonded repairs have been used to address damage caused by corrosion, stress corrosion, and other types of damage. The Royal Australian Air Force (RAAF) was the first to routinely use bonded composites to repair metal structure, and they have applied a large number of these repairs, including applications on several aircraft types (Ref 25). In particular, thousands of repairs have been installed on RAAF C-130 aircraft, saving nearly $100 million (Ref 2), with a successful history of over 25 years of service. The USAF has installed bonded composite repairs on a number of aircraft types, including C-141, C- 130, C-5, B-52, and F-16. The most notable application is the “weep hole” crack repair for the C-141 aircraft wings. This application and an example of the repair of a crack beyond critical length on an RAAF F-111 aircraft are discussed subsequently.

Example 1: USAF C-141 Weep Hole Repair. The C-141 aircraft lower wing skins are constructed of extruded 7075-T6 aluminum panels stiffened by integral risers containing weep holes to prevent fuel entrapment in the wings. In 1993, fatigue cracks were discovered at a large number of inner-wing weep holes, causing 45 of the approximately 250 aircraft in the fleet to be grounded and others to be restricted. All of the nearly 1500 inner-wing weep holes per aircraft were inspected using the bolt-hole eddy current NDI method, and more than 13,000 cracks were discovered. Oversizing holes eliminated over 80% of the cracks. In cases where a significant quantity or cluster of holes could not be cleaned up by oversizing, wing panels were replaced. In other cases, on about 170 aircraft where the maximum allowable oversize could not eliminate cracks, bonded composite repairs were accomplished.

A durability and damage tolerance analysis completed in the 1980s identified the wing weep holes as a potential concern. The C-141 manufacturer, Lockheed Martin, designed an initial bonded composite repair and accomplished a finite-element analysis (FEA). When cracking became a problem, Warner Robins Air Logistics Center (WR-ALC) built from these early efforts to produce a final repair design. A conservative approach was taken, assuming the riser was totally severed, and a coarse shell element analysis was used to evaluate the effect of several repairs in close proximity. The original 5-doubler Lockheed design was simplified to three, one on either side of the affected riser (inside the wing) and one on the wing skin below the riser (on the outer moldline). Figure 5 illustrates the wing configuration and 3-doubler repair. The outer doubler was later split into two for repairs over splice joints between wing panels, creating a 4-doubler repair in these cases.

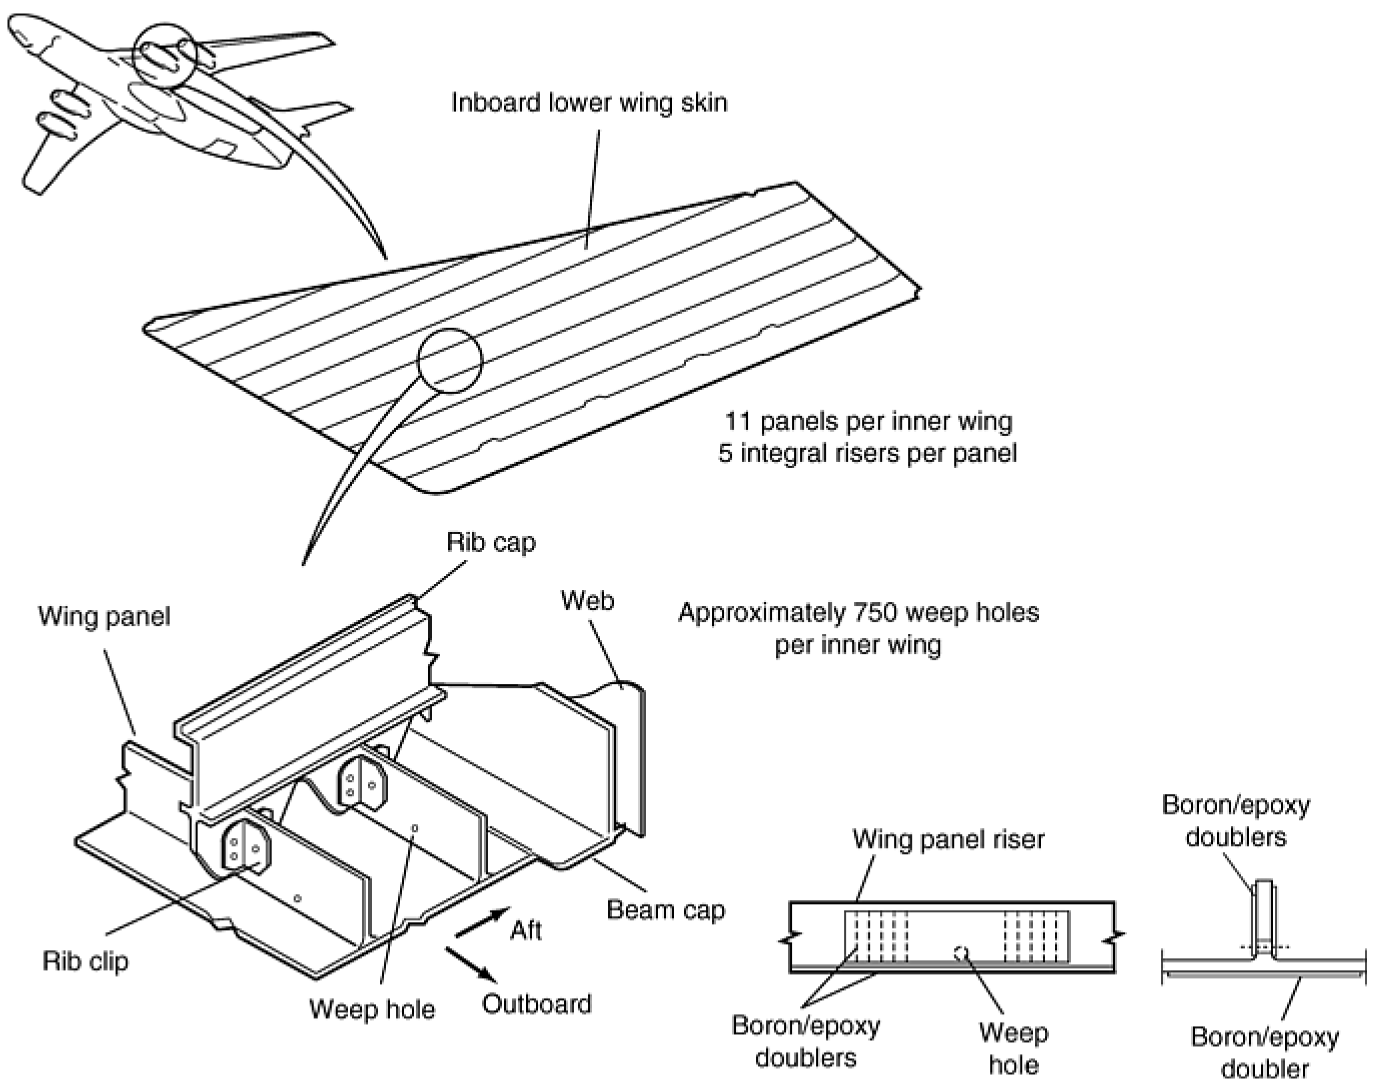

Fig. 5 C-141 wing configuration with weep holes; 3-doubler repair

Warner Robins Air Logistics Center's experience with composite repair of composite structure and various literature sources were used to size and shape doublers and determine ply stacking and stepoff. A detailed two-dimensional (2- D) shell element analysis of an assumed standard repair was accomplished to look at ply stresses and optimize doubler configuration, location, and quantity. The 3-doubler approach was verified at this time, and boron/epoxy was selected as the repair material. Although graphite/epoxy was considered viable, boron/epoxy was chosen, due to the desire to avoid galvanic corrosion issues in the event fasteners had to be put through the doublers. A considerable amount of detailed three-dimensional (3-D) FEA was conducted to further optimize the doubler and evaluate its impact on the surrounding structure. A segment of actual wing plank was repaired to identically match the 3-D model, instrumented and statically tested. Correlation was very good and even allowed reduction of spacing between repairs. Based on the detailed FEA, a damage tolerance assessment was performed. This was validated by fatigue testing to a critical flight spectrum of the area, indicating that the desired 15,000 flight hours could be achieved by repaired wing panels. Fatigue testing was conducted at ambient temperature and at–54 °C (–65 °F). Thermal shock and salt fog testing were also conducted on freestanding repaired specimens, with no negative effects.

Installation procedures for the precured doublers were developed in collaboration between WR-ALC and the Air Force Research Laboratory (AFRL). As expected, the key issue was metal surface preparation. Warner Robins Air Logistics Center's requirement for nonacid surface preparation was accommodated by selection of the GBS process developed by AFRL and based on a similar procedure used in Australia (Ref 15). The GBS procedure included the application of BR 127 (Cytec Fiberite, Inc.) adhesive primer. Although time-consuming, the GBS/primer approach proved to be very successful when implemented with strict quality control measures. The precured boron/epoxy doublers contained an untreated resin-rich nylon peel ply outer layer that was removed just prior to bonding. In most cases, no further treatment was provided. Silane was dried and primer was cured on the risers using a heat blanket placed on the outside moldline, whereas silane and primer applied

to the moldline were heated by means of heat lamps. Doublers were installed using one of three 120 °C (250 °F) curing modified epoxy film adhesives. Pressure was applied by vacuum bag at about 381 mm Hg. In most cases, heat was provided to all three bondlines simultaneously via a heat blanket located on the bottom of the wing skin in the vacuum bag over the outer moldline doubler. The ability to heat in this way had been previously established during thermal surveys on an actual C-141 wing.

The first repairs were made in August 1993. In less than two years, over 800 bonded composite repairs (representing over 2400 doublers) were installed by several organizations. In total, over 900 repairs have now been installed, over half by WR-ALC. Routine inspections are conducted using thermography, and none of the repairs installed using the GBS surface preparation have failed. Cost savings for the WR-ALC effort alone are estimated at approximately $40 million, based on avoiding the replacement of over 250 wing panels. This success has led to expanded applications on other C-141 primary structure. External doublers for weep hole repairs are shown in Fig. 6.

Fig. 6 Doublers installed on C-141 for “weep hole” repair

Example 2: RAAF F-111 Lower Wing Skin Repair. F-111 aircraft in service with the RAAF have recently been found to suffer from fatigue cracking in the outboard section of the lower wing skin (Ref 3). The cracking is caused by a stress concentration from a runout in the forward auxiliary spar to create a fuel flow passage. When the first crack was discovered, fracture mechanics calculations indicated that it was beyond critical length at design limit load. A conventional, mechanically fastened metallic repair was considered, but this was unattractive from an aerodynamic standpoint (excessive thickness). New fastener holes would not have been acceptable in this highly stressed primary structure, and the crack would have been uninspectable beneath such a repair. A bonded composite repair was the only alternative to scrapping the wing. It must be emphasized that because of its criticality this repair is not a typical example, but rather represents the limit of what bonded repair technology can achieve. Because of certification concerns (Ref 25), repairs to critical defects in primary aircraft structure are unlikely to become commonplace in the near future, and in this case, an extensive program was required to certify this repair.

Extensive and detailed 2-D and 3-D finite-element analyses were conducted, so that the stress distribution around the defect could be quantified. This revealed that the wing skin at this location was subject to secondary bending, and this was the explanation for the observation that the crack had initiated on the inside surface of the

wing skin. The model was validated with strain measurements from a full-scale wing test undertaken at the Aeronautical and Maritime Research Laboratory. In addition, three levels of specimen testing were undertaken:

- Small, inexpensive coupon-sized specimens were used to investigate the effects of impact damage, temperature, and moisture and load spectrum truncation effects.
- Panel specimens with a full-scale representation of the local wing geometry were used as structural details in a fatigue and environmental study.
- Large box specimens were used to represent the wing as a quasi-full-scale test article in testing static and fatigue strength and an examination of thermal residual stresses.

A repair was designed using boron/epoxy as the repair material, because this provides lower levels of thermally induced residual stress compared with graphite/epoxy and enables the ready use of eddy current NDI methods to confirm the length of the crack that was left in the wing. Cytec Fiberite FM 73 epoxy adhesive was selected and cured at the comparatively low temperature of 80 °C (180 °F) to minimize the thermally induced residual stresses (Ref 29). This cure cycle had previously been carefully validated for another complex repair (Ref 5). The surface treatment used was the GBS process described previously. Advantage was taken of nearby hard-points on the wing to make use of positive pressure during the cure. An inflated bladder was used to apply pressure to the repair, and the pressurization loads were reacted out via a rigid plate to the hard-points. A similar system was used in the earlier application of doublers to the upper surface of F-111 wing pivot fittings (Ref 5).

This lower wing skin repair was predicted, and subsequently proven in service, to substantially reduce the crack growth rate of the defect. Because most wings in the RAAF fleet have not yet developed cracks, these repairs are currently being applied to the fleet as preventative reinforcements to prevent the initiation of cracks in the future. This is an excellent example of how the technology can be used to extend the life of airframes. The repair to the wing is shown in Fig. 7.

Future Trends

The greatest future advance affecting the application of bonded composite repairs will arguably be the development of an NDI technique that can reliably and accurately measure the level of adhesive bond strength and long-term environmental durability. As mentioned in the section "Repair Certification," such a method will enable the management of repairs using risk analysis where the risk can be readily quantified by the NDI method. Unfortunately, due to the considerable technical complexity of this task, a practical NDI technique is unlikely to be available for many years. A more achievable goal is the development of a low-cost, accelerated test method that can be shown to accurately predict the long-term behavior of adhesively bonded joints. In the past, the Boeing wedge test (ASTM D 3762) has been proposed as such a test, after wedge specimens cut from the structure of aged airframes were found to correlate well with the observed behavior of the bonded sections of the structure. More work, possibly based on existing service durability data, is required to confirm that this method is able to reliably predict the long-term behavior of adhesively bonded joints made with a range of adhesives and processes.

Improvements are also possible in the development of adhesives and surface treatment processes. Adhesively bonded repairs can be produced with levels of durability approaching the best factory treatments; however, because of the greater difficulty of controlling the repair environment, very high levels of quality control are required for repairs when compared with the manufacturing situation. New adhesives that are significantly more tolerant of poor surface treatment could, for example, reduce the level of quality control that is currently required.

Another approach to the problem of long-term bond degradation is to assume that a small risk exists that a disbond may occur in the future and to construct a repair/reinforcement that is able to sense any such damage.

This so-called "smart patch" concept (Ref 30) makes use of modern electronic and sensor technology. It is envisaged that the sensors and electronics could be fully embedded within the patch. Piezoelectric films could be used to "harvest" power from the usual fatigue stresses in the structure, avoiding the need for a separate power supply. One approach is to compare the strains present in the patch to those in the parent structure, as a ratio describing the "patch state of health." If this ratio decreases (Fig. 8), it is an indication that a disbond may be growing under the patch. A single value representing this ratio could be stored in memory within the patch and then downloaded by means of a wireless technique to technical staff at a convenient time. Another concept being considered is to have embedded actuators inside the patch that would be capable of applying load to the bondline (without the aircraft being flown) to measure the load transfer into the repair. In all these concepts, it will of course be necessary to show that the smart systems themselves are highly reliable and have excellent long-term durability.

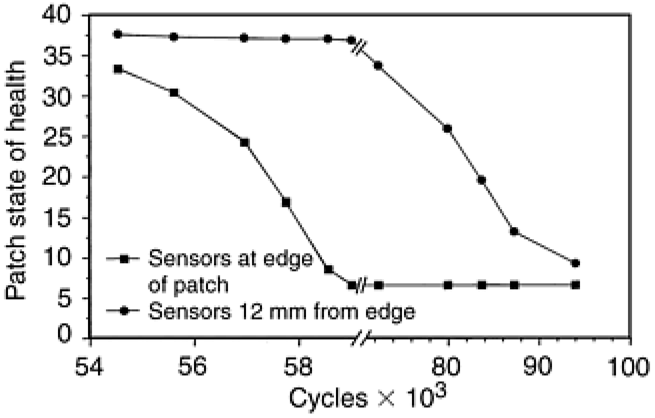

Fig. 8 Results from a demonstration "smart patch" showing a reduction in strain ratio ("patch state of health," the ratio of strains in the patch to those in the parent structure) as a function of fatigue cycles due to disbond growth under the patch. Source: Ref 30

Worldwide Repair Standardization

K.B. Armstrong, Consultant

Introduction

COMPARED WITH METALS, which have specified alloy content and which are covered by standard test methods, composites comprise a range of different fibers and resins, and the resins are of undisclosed formulations having a wide range of mechanical and other properties. Likewise, the test methods for composites are in the process of standardization with the International Standards Organization (ISO), but at present there are still some differences between the methods used by the fiber and prepreg producers and those used by the aircraft manufacturers. Efforts to introduce some degree of standardization are described in this article together with an indication of progress at the time of this writing. This work has been done by the Commercial Aircraft Composite Repair Committee (CACRC), a combination of previous Air Transport Association of America (ATA), International Air Transport Association (IATA), and Society of Automotive Engineers (SAE) committees with the support of the Federal Aviation Administration (FAA), SAE, and Airlines and Airframe and Engine Manufacturers. It is hoped that the standardization efforts of the aerospace industry may be of benefit in other areas and that other industries may make standardization efforts of their own.

In May 1988, IATA formed a Composite Repair Task Force (CRTF) at its Engineering and Maintenance Advisory Committee (EMAC) meeting in Geneva, Switzerland, with the aim of standardizing composite repairs as much as possible. The Society of Automotive Engineers (SAE) and ATA had similar committees at the time.

The first document resulting from CRTF was IATA DOC: GEN: 3043, "Guidance Material for the Design, Maintenance, Inspection, and Repair of Thermosetting Epoxy Matrix Composite Aircraft Structures," in 1990. Only epoxy systems were covered by this document because it was impossible in the short time allowed to include other matrix systems. Similar documents could be produced for other resin systems as required. The IATA CRTF was disbanded on completion of the document, and the original intention was that airlines should use it when purchasing aircraft so that manufacturers would know the requirements of airlines regarding design, maintainability, inspectability, and repairability of future composite structures and components. It was considered that a further effort should be made to standardize repair materials and techniques and training and inspection methods throughout the world and that the findings of the IATA CRTF needed to be implemented in a positive manner. The current airline practice of outsourcing maintenance made this even more important. At this stage, the ATA, IATA, and SAE Task Forces were combined to form the CACRC. The Society of Automotive Engineers provided the administrative support for the CACRC and have published all the documents it has produced. Many of these documents will be incorporated into Original Equipment Manufacturer (OEM) repair instructions as alternative means of compliance with FAA, Joint Aviation Authorities (JAA), and other regulatory requirements. This will help to standardize procedures around the world.

Repair Types and Materials

There is a need to recognize repair as a separate subject, needing different materials and techniques from manufacture, if operational delays and maintenance costs are to be kept to a minimum. It should be borne in mind that composites are now being considered more from a life-cycle cost point of view rather than pure

weight savings. Manufacturing cost and repair cost of a composite item throughout its service life will both need to be reduced. Manufacturers offer various repair techniques of different permitted sizes depending on the method, materials, and cure temperature used.

One of the problems of repair is that often it cannot be done by repeating procedures used in manufacture. Repair almost always needs to be carried out quickly with the minimum of equipment and often without tooling. Ideally, it also needs to be done without major disassembly of components such as rudders, flaps, and so forth. Experience has shown that if moisture is present in a honeycomb core, then heating to 180 ^{o}C (355 °F) can produce an internal steam pressure of about 1.2 MPa (180 psi). At this temperature the strength of the adhesive is seriously reduced, and disbonding between skin and core often takes place. In solid laminates, overheating can cause delamination between the plies. This means that repair needs to be performed at a lower temperature than manufacture (25–50 ^{o}C, or 45–90 °F lower), to avoid further damage, while retaining the resin glass transition temperature needed to meet design requirements.

It is essential during repair procedures to avoid causing further damage to a structure or component for several reasons:

- The permitted size of each type of repair is limited, and if the damage size is increased a more complex, expensive, and time-consuming repair may be necessary.
- The larger a repair becomes, the more likely it will be that some form of tooling will be required to maintain the shape.
- If the damage becomes too large, the part may be beyond economical repair.
- The larger the repair, the longer the delay that will be incurred in completing it.

The types of repair include:

- Wet lay-up liquid resins (cold or warm-cured) are available.
- Hot-cured, preimpregnated fabrics or tapes (prepreg repairs), which can take the form of precured or cocured patches. The precured patches have to be bonded with a suitable adhesive after they have been cured. A hot-curing film adhesive is usually used for this purpose, but a cold- or warm-curing adhesive can be used depending on the service temperature required from the repair. Bonded repairs (hot or cold cured) may be made with overlap joints, stepped lap joints, or scarf joints. All of these must be made strictly to the OEM repair instructions using only the specified type.
- Bolted repairs to solid laminate structures can be used with either titanium plates (in the case of the Harrier) or bolted precured composite sections. Bonded repairs are not often done on laminates more than 2 or 3 mm (0.078 or 0.12 in.) thick as overlaps are large and the weight of bolted joints is actually lower. However, there may be other reasons that require a bonded repair to be used. The OEM repair instructions must be complied with in each individual case.
- Bolted repairs to solid laminates are similar in appearance and concept to metal repairs, but their execution requires the use of the correct and special fasteners. These special fasteners require the use of the correct drill types and shapes and also the use of controlled feed drills and special lubricants (Boelube) to avoid overheating and backing plates to avoid breakout of the back skin as the drill goes through. Drills need to be sharpened frequently and reground accurately to achieve the close tolerance hole sizes required, especially when slight interference fits are specified. Bolt fitting must be done with great care to avoid delamination.

Special fasteners are needed to give an adequate clamping area and washers may have to be used to avoid scoring of laminates and to give clamping area to avoid crushing by nuts during torque tightening. Torque values for bolts need to be checked with the OEM instructions, as composites sometimes require slightly lower torque values. It is essential to avoid using higher torque values than those specified. As more solid laminate composite structure is used in fins, tailplanes, and wing structures, the use of bolted repairs will increase and special training will become necessary to ensure adequate quality. Original Equipment Manufacturer instructions give the information required on fastener type, drill type, and drilling procedures. It is usual to bond these parts with an adhesive in addition to bolting.

Training

The increasing number of applications of composite materials means that more and more people will become involved in their maintenance and repair, and the need for good training can only increase. It may be worth mentioning that experienced technicians are becoming difficult to find, and it may soon be necessary to look outside the aircraft industry for new people. This means two problems instead of one. Firstly, there is a need to find enough mechanically inclined people. Secondly, if they come from outside the aircraft industry and from outside the world of composites they will need to be trained, not only technically but also to accept the high standards of workmanship that will be expected of them. These high standards are also necessary in other industries using composites such as automobiles, boat building, railway carriages, space vehicles, and sporting equipment. Composites are also being used to build and to repair bridges, and these applications also need good quality, long-life repairs.

Worldwide Repair Standardization

K.B. Armstrong, Consultant

Major Standardization Issues

While a number of individual issues are involved, a review of the CACRC Task Group assignments gives an excellent overview of the major areas of concern in composite repair standardization. Each of these Task Groups has prepared recommended standard procedures and/or highlighted problem areas that need to be addressed. Topics of current work are given below, with some future needs.

Design. This group has produced AE-27 (Aerospace Information Report AIR 4928) Guide for the Design of Durable and Maintainable Composites and is working on a Life-Cycle Cost Model (Aerospace Information Report 5416) because there is a need to develop composite components with a lower life-cycle cost than metallic parts. Many small detail design changes can greatly increase the service life of composite parts, and this book should help designers avoid previous mistakes. AEs are automotive or aerospace engineering design manuals, handbooks, or guidebooks developed by SAE technical committees.

Repair Materials. The CACRC Task Group on Repair materials has issued one standard and is working on several others, as shown in Table 1. There is a need for a greater understanding of the importance of resin and adhesive mechanical and other properties to make the choice of alternatives easier when this is necessary.

Table 1 Aerospace Material Specifications for repair of polymer matrix composites

SpecificationNo.	Title
Issued	
AMS 2980	**Carbon Fiber Fabric and Epoxy Resin, Wet Lay-up Repair Material**
Work in progress	
AMS 2960	**Glass Fabric with Epoxy Resin, Wet Lay-up Repair Material**
AMS 3970	**CFRP Repair Prepreg 125 °C Vacuum Curing**

One material combination is in the process of qualification to AMS 2980 (Carbon Fiber Fabric and Epoxy Resins, Wet Lay-Up Repair Material), and it is hoped that other materials will be qualified. Qualification to AMS 2960 (Glass Fabric with Epoxy Resin, Wet Lay-Up Repair Material) and AMS 3970 (CFRP Repair Prepreg 125 °C Vacuum Curing) will follow later, and it is hoped that more than one material combination will be qualified to these specifications. The fiber type is expected to remain the same in each case, but could come

from a different source. The most likely difference will be the use of different resin systems, although with very similar mechanical and other properties.

Repair Techniques. The CACRC Task Group on Repair Techniques has issued several recommended repair practices and is working on others, as shown in Table 2. The group also is working on a technique for the repair of lightning strike protection systems. Work also is needed on techniques for the repair of thermoplastic composites and another for the preparation of bolted repairs.

Table 2 Aerospace Recommended Practices for polymer matrix composites repair techniques

AIR 5416	**Maintenance Life Cycle Cost Equations and Definition of Variables**
AIR 5431	**Tooling for Composite Repair**

Inspection. The task group on inspection issued ARP 5089: Composite Repair NDT/NDI) Handbook to address nondestructive testing techniques and is working on a generic set of Composite Reference Standards for use on all types of aircraft. It is intended to produce design drawings and manufacturing procedures for test blocks for honeycomb panels and solid laminates. A phenolic-based set of standard blocks is considered acceptable as representative of carbon, glass, and aramid composites. The group also is responsible for investigating improved NDI techniques.

Training. The task group on training has issued the following documents:

AIR 4844C	**Composite and Metal Bonding Glossary (updated annually)**
AIR 4938	**Composite and Bonded Structure Technician/Specialist Training Document**
AIR 5278	**Composite and Bonded Structure Engineers: Training Document**
AIR 5279	**Composite and Bonded Structure Inspector: Training Document**

There is a need in the training area to update existing documents to include repair techniques for thermoplastics and the preparation of bolted repairs to solid laminates.

Analytical Repair Techniques. This is a new group making good progress on its first document to provide a theoretical basis for the design of composite repairs. It would be helpful if this work included the design of bolted joints.

Future projects. There is a need for a nondestructive method of measuring adhesive bond strength and also a method of measuring the "bondability" of a surface, perhaps a measure of surface energy, after the surface preparation process has been performed. This could replace the "water break test" if found to be superior. At this point, these topics have not been allocated to any Task Group.

Worldwide Repair Standardization

Product Reliability, In-Service Experience, and Lessons Learned

Eric Chesmar, United Airlines

Introduction

SERVICE EXPERIENCE AND PRODUCT RELIABILITY have become increasingly important over time. When the use of composites has been compared to other materials, they are evaluated not just for weight savings and original cost, but for overall life cycle performance, including in-service reliability, maintainability, reparability, and durability. The value of reliability has risen as aircraft operators demand greater return on the large investment in aircraft, including lower maintenance costs.

The scope of this article is limited to nonproprietary and noncompetition-sensitive information related to aircraft applications. Those interested in specific aircraft or manufacturer data should contact the companies directly. In spite of these limitations, the experiences from past reliability and in-service problems can be found in various sources, such as publications by industry associations, textbooks, and symposiums. Although the specific design of any part determines the part's performance, the published literature contains consistently recurring failure modes, which will be presented as general types, and then specific component examples.

The following presents an overview of reliability and commonly used measurements. More importantly, the many failure modes that cause the negative performance are discussed. This catalog of failure modes is compiled from many types of sources: manufacturer service bulletins, reliability and customer service departments, literature reviews, demonstration programs, in-service evaluations, design guides, and surveys of commercial and military aircraft maintenance organizations. Lessons learned will also be described, while attempting to avoid overlapping the many other related topics in this Volume, such as maintainability, reparability, and materials choice.

Eric Chesmar, United Airlines

Reliability

The importance of operational (or in-service) reliability has been increased over the years as the use of composites has been compared to other materials choices, and the materials are evaluated not just for weight savings or original cost, but for reliability in service. Data on actual operational reliability is used to identify areas for improvements on existing aircraft and to identify design improvements for future aircraft. Reliability analysis at commercial airlines and airframe manufactures is required by Federal Aviation Administration (FAA) regulations for continued airworthiness. In addition to regulatory reasons, aircraft operators perform reliability analysis in order to optimize aircraft utilization and reduce costs and improve safety, and the aircraft original equipment manufacturers (OEMs) as a service to their customers to solve problems beyond their own capabilities and improve their product.

Reliability can be measured in many ways, but all result in performance that is less than trouble- free or maintenance-free. The trouble ranges from routine maintenance and servicing that ensures performance (such as lubrication), to active monitoring, to instrumented inspections at various intervals, to required overhauls at defined intervals, to mandatory scrapping of life-limited parts. Formal maintenance programs, as required by regulatory agencies, are specific to each model and can include any one of these tasks.

A general definition of *reliability* is the probability that a system or product will perform in a satisfactory manner for a given period of time when used under specified operating conditions (Ref 1). The elements of this definition are worthy of further examination for how they apply to composite structures as opposed to system components and line replaceable units, which account for most of the reliability studies. To be judged “satisfactory,” structures made of composites are expected by the aircraft operator to be equivalent to or better than the previous aircraft models or better than the same structure made in metallic materials; preferably they will require no routine maintenance. The “period of time” for structures is usually the life of the aircraft, or at least the interval between heavy- maintenance visits. The “specified operating conditions” for structures is usually the entire life cycle, including the aircraft's flying envelope, maintenance visits, and a component's time during maintenance, storage, and shipping. The elements of this definition are determined and specified in more detail during the design phase, together with concepts for maintenance, servicing, and repairs. These factors all influence the inherent reliability. The composite designer has the responsibility to translate the failure modes learned from past experience to a risk probability with associated inspectability and maintenance program, as well as to determine loads and design a part accordingly. One example of such a design process was that for Aerospatiale's ATR72 outer wing, certified in 1989 (Ref 2).

The field of reliability engineering has developed many measurements for reliability to describe the different impacts. In reviewing the total life cycle of an aircraft structure, measurements of “satisfactory performance” can be made at many different levels and different aspects, which reflect the repercussion of failure, such as a flight cancellation, delay, replacement, repair, servicing, repetitive inspection, or other maintenance action. At the highest level (the aircraft as a whole), reliability can be defined as the ability to complete the aircraft's mission, either a military sortie or a flight segment for commercial passenger or freight (e.g., 87% completed flights). Each type of event can be expressed as a percent (such as 97% on-time arrivals), frequency (e.g., 5 cancellations per year), or rate that normalizes based on use of the system, part, or aircraft (e.g., 0.0001 in-flight shutdowns per flying hour). For components, the most commonly used expression is the mean time between unscheduled removal (MTBUR), expressed in flight hours. Mean time to failure in flight hours is the removals without the no-fault-found. The units of measurements can also be calendar time, but in order to compare between different operators, they can be normalized for amount of use by dividing by flight hours or flight cycles.

One of the roles played by airline engineering and OEM customer service representatives is to identify and report the reasons for removal and failure modes. These reports form the basis for design changes, modifications, and improvements embodied in service bulletins, service letters, and production changes. To widen the experience base and increase the validity of these reports, the airline industry has worked together with aircraft manufacturers to establish standardized formats and variables for reliability reports (via the Air Transport Association and OEM reliability departments).

Additional information on reliability concepts is provided in the article “Reliability in Design” in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

Context of In-Service Experiences within Aircraft Operations

Many of the failure modes may seem insignificant, but for a variety of reasons can result in delays, cancellations, or other significant operational impact. This kind of operational impact is similar to that seen when any new technology or change is introduced, for example, lack of repair instructions, reliance on OEM advice, requirements for nonstandardized materials, tooling, testing, or skills. More details on these are covered in other articles, but they are significant in that they are usually a new failure mode compared to previous metallic designs. Furthermore, even though maintenance actions may be routine, they add up to significant resources, such as for paint, erosion, sealant, or minor wet lay- up repairs. The total maintenance life cycle includes not only the scheduled maintenance and inspection cycles, but also the daily walk- arounds, the shop repairs, repairs on-wing, and unscheduled inspections after damage. Failures or damage may occur at all times, but all may not be reported. Without reports on all the phases of the aircraft operation, the exact reliability and total life-cycle cost is incomplete. One should recognize this fact and understand the source of the reports and the missing data. Therefore, a review of published studies follows.

Don Joynes at Boeing made a study on the composite control surfaces (aileron, elevator, and rudder) on the Boeing 737-300, 757, and 767, which were introduced to service in 1982, 1982, and 1986, respectively (Ref 3). The study involved analyzing reported incident data for these components. The sample included about 1400 aircraft (7000 components), which had accumulated in excess of 15 million hours and 10 million flight cycles since they entered service, through July 1990. Figures 1, 2, and 3 show the incidents per airplane per year, major causes, and the zones affected. The category "Design and Wear," was defined to include general nonstructural items such as wear, panel-edge erosion and paint condition, peeling, and so on. It is important to note that even though these were considered "nonstructural" by the design engineers at the OEM, the impact on the operator can be the same as a "structural" damage if documentation inadequately describes the allowable damage. The reduction in incidents reported is not due to reliability improvements, but Joynes attributed it "to the airlines becoming familiar with the composite components, their maintenance requirements, repair methods, and increasing experience in making repairs." This indicates the subjective nature of these types of reports for use as a measure of in-service reliability.

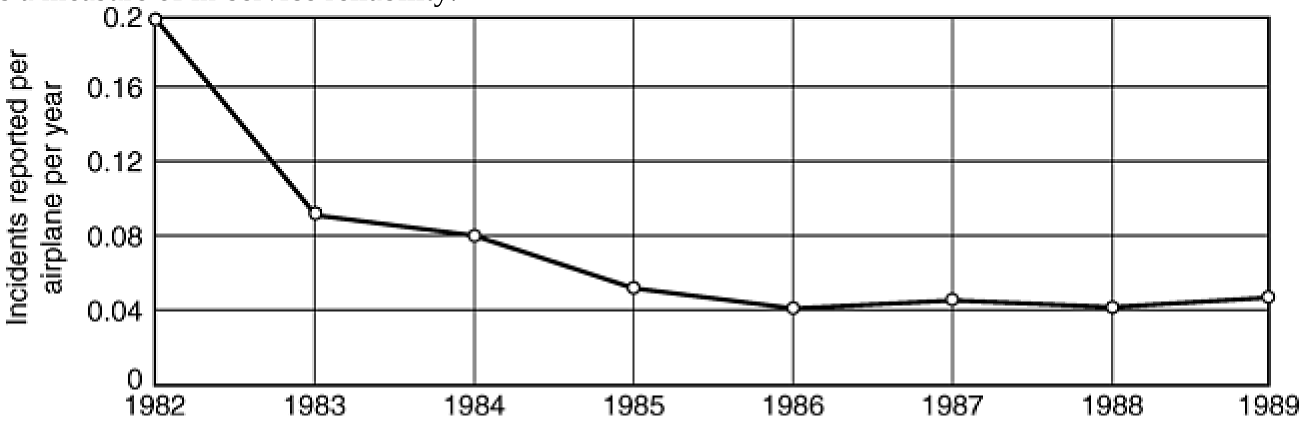

Fig. 1 Incidents reported per airplane per year for 737, 757, 767 control surfaces (aileron, elevator, and rudder). Source: Ref 3

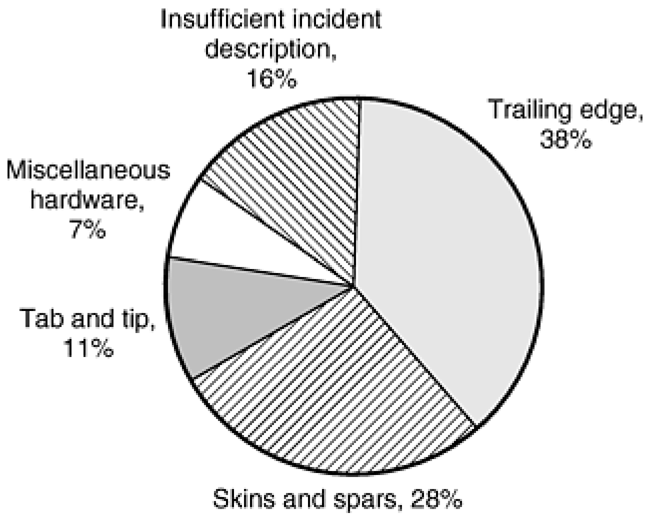

Fig. 2 Damage by zone for 737, 757, 767 control surfaces. Source: Ref 3

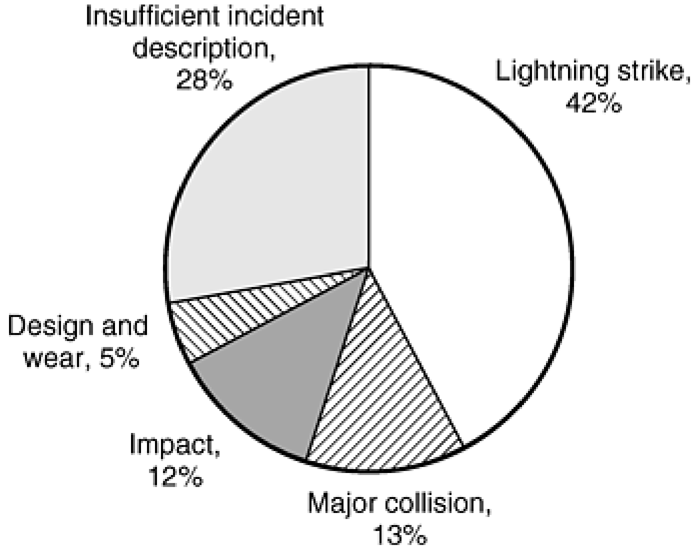

Fig. 3 Cause of major damage to 737, 757, 767 control surfaces. Source: Ref 3

In order to put the "OEM incident reports" in perspective with overall aircraft maintenance and to collect cost of all maintenance, a study was performed by British Aerospace (BA) at United Airlines (UAL) in 1998 by Dunkley (Ref 4). This study attempted to record all the maintenance actions at all levels of maintenance for the entire wing (BA's design responsibility in the Airbus partnership) and horizontal stabilizer. British Aerospace gathered data from UAL's records from all maintenance locations, including 4 years of line maintenance, 53 airframe annual visits (C-checks), and 5 each airframe heavy visits (or D-checks, approximately every 5 years). Based on the sample of 639 findings, the following causes were found: a large percentage of write-ups were due to paint erosion, numerous dents of unknown source, numerous cracks, few hail (six each) and bird strikes (three each), and no significant repairs or flight delays due to composites. None of the write-ups resulted in a query or report to the OEM, but were corrected using existing maintenance documents or the support of airline engineering. The study also noted the distribution of write-ups against the structure by material type (see Fig. 4).

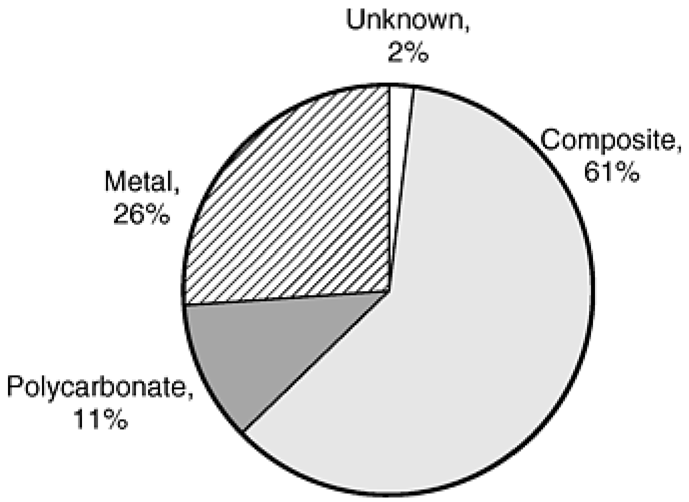

Fig. 4 Distribution of maintenance record write-ups (639 records total) by material type for A320 wings and stabilizer

Furthermore, even though maintenance actions may be routine, they add up to significant resources and costs, such as for paint or for minor wet lay-up repairs. Although some may be preventable with better designs, these repairs become an accepted and institutionalized "cost of doing business" for airlines. Customer service and engineering departments respond to problems brought to them, but the cost impact may be just as great for the "institutionalized" maintenance. Airline requests account for less than five percent of all the repairs.

Product Reliability, In-Service Experience, and Lessons Learned

Eric Chesmar, United Airlines

Failure Modes

Some efforts have been made by industry groups to identify commonly occurring failures. Examples include the Commercial Aircraft Composite Repair Committee (CACRC), National Aeronautics and Space Administration (NASA), National Research Council, the International Air Transport Association (IATA) in 1991 (and detailed in Ref 5), and the MIL- HDBK-17 Committee.

In 1998, the CACRC published the guide "Design of Repairable, Maintainable, and Durable Composite Structure" (Ref 6), which contains a compilation of failure modes based on survey observations and in-service experiences of airlines, OEMs, and repair stations (Table 1). The failure modes are organized by type and then the general zones, specific components, or structures they affect. One unique feature of this publication is the illustrations of design details and suggested solutions. This list of failure modes is reinforced by other surveys of operators, such as by National Research Council, NASA, and most comprehensively in the MIL-HDBK-17.

In reviewing studies of in-service damage, the term "failure mode" is subjective. Hence, some studies may not report minor, easily repaired or common wear, damage such as wear and tear, paint, and so on, although they are included in comprehensive lists. Major failure modes, which result in the component removal and repair or scrapping, are all that is reported in some studies, with no minor damage and wear and tear, which may be an

error of omission. A review of shop findings reveals that nearly all removed components have many other minor defects that are corrected during overhaul. In the subsequent review of many past studies, usually only the major failure modes are discussed to highlight their severity and the need to improve future designs based on experiences. Although the specific construction of each part is not always possible to disclose, by focusing on the failure mode and source, the lessons for the future can still be identified.

Table 1 Damage sources and areas affected

General category	**Specific source**	Aircraft parts affected
Foreign object damage in flight	Hail damage	**Radome, engine inlet cowls and interior engine components, wing leading edges, horizontal and vertical leading edges**
	Bird strike damage	**Radomes, engine inlet cowls, fan blades, leading edges**
	Engine failure or foreign object damage	**Nacelles, acoustic liners**
	Engine uncontained failure damage	**Fuselage, body fairing, lower wing panels, horizontal stabilizer leading edge**
	Tire separation	**Trailing edge flaps, lower wing to body fairings, landing gear doors, fixed wing panels**
Foreign object damage on ground	Hail damage	**Radome, engine inlet cowls and interior engine components, wing leading edges, horizontal and vertical leading edges**
	Runway debris	**Trailing-edge flap lower surface, environmental control system inlet, wing upper fixed trailing-edge panels, engine inlet cowls, lower fuselage aft of landing gear**
	Ground handling equipment damage	**Engine cowling outer surfaces, leading and trailing edges of wings and stabilizer, wing-to-body fairings, flap track fairings, radomes**
	Personnel mishandling	**Engine cowling near latches, access doors. Areas surrounding all latches should resist prying.**
	Shipping and transportation damage	**All removable components, especially without well-designed containers**
Environmental damage in flight	Lightning strikes	**Affected zones as specified by regulations; generally near attachment and detachment areas, such as radomes, engine cowlings, outer 18 in. of ailerons and elevators, rudder**
		Designs frequently sustain a strike that results in damage greater than allowable without repair.
		Avoid use of aluminum honeycomb with carbon facesheets.
	Overheat	**Engine cowling, parts near high-temperature ducts or borescope plugs, aft of air-conditioning exhaust**
	Moisture ingression	**Honeycomb parts, laminates during repair or high heat exposure**
	Erosion	**Radome, engine inlet cowl, leading-edge fairing**
Overstress	Overactuation due to system failure	**Actuated components such as flaps, powered doors**
	Buffeting, sonic fatigue, vibration	**High sonic areas such as near engines, i.e., flap track fairings, pylon panels**
Chemical contamination	Hydraulic fluid leakage	**Actuated components, fairings under hydraulic systems such as belly fairing, engine cowling**
	Jet fuel	**Components under fuel system, i.e., engine cowling, pylon**
	Paint stripper	**All painted surfaces, especially adjacent to metallic parts being stripped**
	Corrosion	**Improperly isolated aluminum attaching hardware, aluminum honeycomb with fluid ingression**

Source: Ref 6, 7

Ground Handling Damage. In all major studies and reports of production aircraft, ground handling damage is ranked as the largest cause of damage. In the early 1990s, Boeing investigated in order to understand the sources of damage and determine the extent of ground handling equipment damage. Eleven operators were asked about ground damage incidents during the period from 1990 to 1993 (Ref 8). The types of equipment that induced the 1,894 reported incidents are detailed in Table 2. The large number of “unknown” causes is a good indication of why it is so difficult for airline support operations to reduce these incidents—many of the people “at the wheel” in those incidents either fear retribution if they are reported or are unaware of the damage caused to composites. In addition, ramp employees are often driven to increase productivity through faster aircraft turn-arounds.

Table 2 Sources of ground equipment damage

Cause of damage	Percentage of incidents
Unknown	**41**
Jetway	**13**
Baggage cart	**7**
Catering	**7**
Belt loader	**6**
Tug/towbar/taxi	**6**
Loader	**5**
Maintenance	**5**
Cargo loading	**3**
Lavatory and water service	**3**
Container	**2**
Fueling	**2**

Source: Ref 8

The CACRC recognized the need to reduce ground equipment damage and sponsored a video (produced by Boeing) aimed at ramp personnel to increase awareness of consequences and appropriate actions. No one realistically expects that this damage can be totally eliminated by improved design; however, it must be recognized as the largest source of damage and taken into account when considering allowable damage, dispatch limits, battle damage repairs, repairability, ease of removing and installing parts, interchangeability, spare availability, and so on. The life-cycle cost associated with this fact of life has already motivated one airline launch customer to demand commonly damaged parts be made of aluminum to decrease flight delays and cancellations and to reduce life-cycle cost.

Moisture Ingression. The second major failure mode is moisture ingression, which primarily affects sandwich structure as opposed to monolithic (i.e., solid laminate) construction. Moisture absorption even at the equilibrium levels, in a laminate over sandwich or in monolithic, complicates the repair and is discussed widely in industry literature (see, for example, the article “Designing for Repairability” in this Section, Ref 9, etc.). This discussion concentrates on ingression that causes removal of the component. The problem is widespread due to the many sources of ingression and the many ways it affects the composite component. Water has been reported to ingress via the following means: cracked end potting, cracked paint, failed/cracked sealant, through fasteners, porosity in the skins of cloth or thin unidirectional skins, porous adhesive in lap joints, wicking through aramid fibers, and wicking along foaming adhesive and along metallic doublers. Once inside the sandwich, the fluid causes failures via various mechanisms. Water absorbed in the epoxy matrix or adhesive lowers its glass transition temperature and significantly degrades mechanical properties. Fluid also degrades the honeycomb cell wall, which increases the ease of water migration. Eventually, when a honeycomb cell is full of water, the expansion during freezing is strong enough to cause the skin to delaminate from the core. During repairs, water must be removed for any epoxy repairs to cure and bond properly, even at room temperature. Drying of water adds time to repairs. If water is not detected and sufficiently dried, the following elevated temperature cure generates steam that often causes delaminations, both in sandwich structures and in solid laminates (Ref 10).

Honeycomb sandwich structures have the potential to carry much more water weight than fibers and matrix. The empty space that makes honeycomb such an efficient structural element (by weight) also acts as a holding

tank for water. Most honeycomb thickness ranges from 10 mm (0.4 in.) for typical panels (rudders or fixed skins), to 25 mm (1 in.) for wing-to-body fairings, to 150 mm (6 in.) for full-depth core such as ailerons and flap wedges. An estimate for the weight of the 757 spoilers was made during their overhaul at UAL. Two hundred and fifty spoilers were x-rayed to find detectable amounts and weighed before and after replacement of one skin and honeycomb core. The average water weight per spoiler was 1.6 kg (3.5 lb).

To determine the extent of honeycomb parts with water, a joint study was made by UAL, University of Washington, Boeing, and Hexcel. Using infrared thermography, thirty-six UAL aircraft were surveyed from the ground, covering about 60% of the composite structures. Of the fifteen 767-200 aircraft between 12 and 15 years old, water was detected in an average of 15 parts. Closer analysis of the water patterns to find ingression point and an analysis of the design, materials, and processes used on the parts revealed there was no single mode on any one part, and all were types seen previously. These included: fastener penetration, cracking/wicking through potting around fastener, wicking through expanding foam core splice adhesive, porous prepreg skins, cracked sealant on honeycomb close- outs, and so on (Ref 11).

The U.S. Navy and U.S. Air Force have both reported that “honeycomb sandwich structures have had the most disbond problems in service.” The root cause for these military aircraft parts is suspected to be foreign object damage (FOD) or maintenance-induced damage, which produced a site for water to ingress (Ref 12). Use of aluminum for the type of honeycomb further exacerbates the problem due to the fast rate of corrosion. “Aluminum honeycomb sandwich structures caused major problems on Air Force and Navy aircraft because of moisture ingress, core corrosion, and for supersonic aircraft, debonding of skin to core adhesive due to pressure buildup in the core after moisture ingression.”

Manufacturing Defects. Although manufacturing of composites is discussed in more detail elsewhere, manufacturing defects are sometimes detected during in-service operations. Although these are not considered to be “failure modes” unless the defects are specifically documented as allowable damage/defects in the Structural Repair Manual, operators must treat them as any other damage discovered during inspections. Therefore, if not allowed, the defects have the same effect on an airline operation as damage. Furthermore, some defects will propagate, or affect long-term durability, such as peel ply not removed or resin-rich areas resulting in cracking and moisture ingression. Table 3 lists some of the manufacturing defects (Ref 9).

Table 3 Manufacturing defects in fiber composite laminates

Structure	Defect
Solid laminates	**Voids**
	Delaminations
	Disbonds
	Foreign body inclusions (e.g., release film)
	Resin-starved areas
	Resin-rich area (leading to cracks)
	Incomplete resin cure
	Incorrect fiber orientation (including wavy fibers)
	Incorrect ply sequence
	Fiber gaps
	Wrinkled layers
	Poor surface condition (i.e., poor release from mold)
	Tolerance errors (including mis-shimming)
	Misdrilled holes
	Surface damage
	Voids
Sandwich panels (in addition to the above)	**Poor core spliceDisbonds form skinsCrushed core**
	Core gaps
	Excessive thickness of polymeric surfaces and paint, leading to cracking and moisture ingress through surface laminate

Product Reliability, In-Service Experience, and Lessons Learned

Eric Chesmar, United Airlines

Part-Specific In-Service Experiences

Documentation of experiences with composite structural parts comes from many sources: demonstration programs, limited use research and development parts, reliability reports service, bulletins or service letters, surveys of maintenance organizations, telexes to the original manufacturer's customer service organization (usually from maintenance engineers for repairs), and anecdotal stories. Some examples are listed subsequently. Although the different sources and reports may be written for various purposes and emphasize different aspects, they all contain valid feedback on failure modes of composite structures. The author has gathered previously published reports, starting with the NASA Advanced Composite Energy Efficiency (ACEE) program, and then grouped by the specific components. Much more information can be found in each OEM's model-specific service bulletins and service letters.

NASA ACEE Program

Beginning in 1973, the ACEE program, the largest in-service evaluation program, was conducted by NASA Langley Research Center. The program's end goal was to reduce aircraft fuel consumption via the use of weight-saving advanced composite materials and to encourage the use and acceptance of composites in the aircraft industry. Other specific objectives were: "to establish confidence in the long-term durability of advanced composites through flight experience of numerous composite components on transport aircraft,""to

evaluate the effects of realistic flight environments on composite components," and to allow "airlines to develop inspection and repair procedures prior to making production commitments."

In 1979, NASA Langley and the U.S. Army initiated joint programs to evaluate composite components on commercial and military helicopters. Although helicopters accumulate fewer flight hours than do transport aircraft, the environments and fatigue loading are sometimes more severe for the helicopter components. The helicopters in which composite components were tested included the Bell 206L and the Sikorsky S-76 and CH-53. They were flown in Canada, Alaska, and the northeast, southwest, and gulf coast of the United States, with selected components removed periodically from service for residual strength testing. However, emphasis was on commercial aircraft because of their high utilization rates, exposure to worldwide environmental conditions, and systematic maintenance procedures. The ACEE program contracted many aerospace companies to produce composite versions of aircraft components already in production, put them in service with the modified inspection and maintenance program, periodically remove some of them either at planned or unplanned times for an in-depth inspection, and sometimes test them for residual strength. The in-service experience is summarized in Table 4. The discussion that follows is adapted from the previous edition of this Volume, which has more photos (Ref 13, 14, 15).

Table 4 NASA ACEE composite structures flight service summary

L-1011 Kevlar 49-Epoxy Fairings. The L- 1011 fairings were fabricated with Kevlar 49 fibers (in fabric form), F-155 and F-161 epoxy resins, and Nomex (E.I. DuPont de Nemours & Co., Wilmington, DE) honeycomb. The configurations of the center-engine fairing, under-wing fillet, and wing-to-body fairing are shown in Fig. 5, along with the various types of damage incurred. During the ten-year service evaluation period, the Kevlar 49-epoxy fairings installed on L-1011 aircraft were inspected annually. Minor impact damage from equipment and foreign objects was noted on several fairings, primarily the honeycomb sandwich wing-to-body fairings. Surface cracks and indentations were repaired with filler epoxy and, in general, the cracks did not propagate with continued service. Paint adherence was a minor problem, particularly with parts in contact with hydraulic fluid. Fastener holes in several fairings were frayed, primarily because of nonoptimal drilling procedures and improper fit. Elongated holes were also noted, primarily caused by improper fit and nonuniform fastener load distribution. There were no moisture intrusion problems with the Kevlar 49-epoxy fairings, and they performed similarly to production fiberglass-epoxy fairings. Additional details on the design, fabrication, and service evaluation of the Kevlar 49-epoxy fairings are presented in Ref 16 and 17.

B-737 Graphite-Epoxy Spoilers. The B-737 spoilers used three different graphite-epoxy unidirectional tape systems: T300-5209, T300- 2544, and AS-3501. The spoilers were fabricated with upper and lower graphite-epoxy skins, aluminum fittings, spar, and honeycomb core, and fiberglass-epoxy ribs (Fig. 6). During the 13-year service evaluation period, several types of damage were encountered, with over 75% of the damage incidents being related to design details. Damage was most often due to actuator rod interference with the graphite-epoxy skin, which was resolved by redesigning the actuator rod ends. The second most frequent cause of damage was moisture intrusion and corrosion at the spar- to-center hinge fitting splice, which could be resolved by redesigning the splice to prevent disbonds between the skin and spar cap. Miscellaneous cuts and dents related to airline use were also encountered. Damage from hailstones, bird strikes, and ground handling equipment occurred on several spoilers.

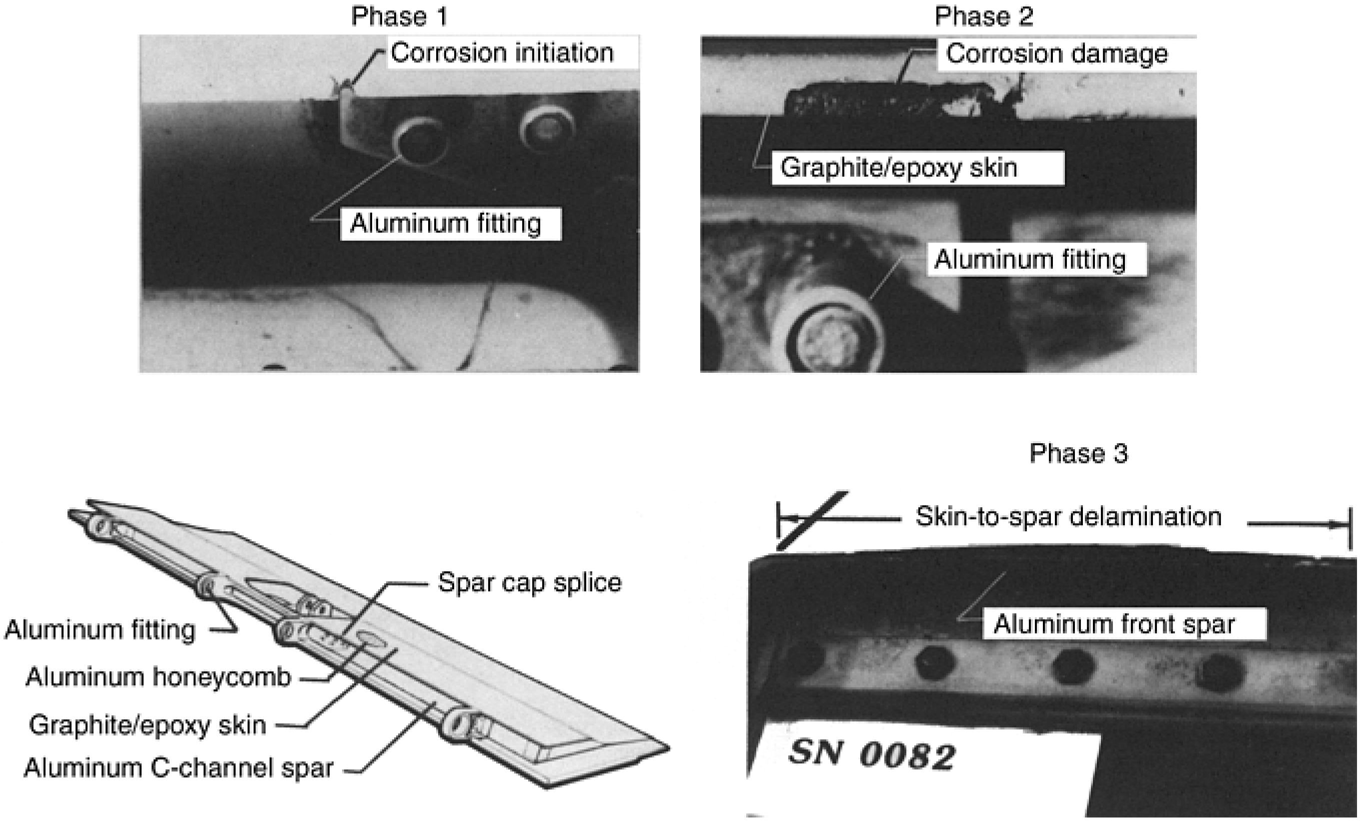

Fig. 6 Corrosion damage to B-737 graphite-epoxy spoiler

A typical corrosion damage scenario occurs at the spar-to-center hinge fitting splice (see Fig. 6). The corrosion damage can be characterized by three phases of development. Phase 1 involves corrosion initiation at an aluminum fitting or at the aluminum spar splice. The corrosion is initiated by moisture intrusion through cracked paint and sealant material. If the corrosion products are not removed and new sealant applied, the damage progresses to phase 2, where moisture penetrates under the graphite-epoxy skin along the aluminum C-channel front spar. Normal service loads combined with moisture contribute to crack growth and subsequent corrosion. If the phase 2 corrosion is not repaired, the damage progresses to phase 3, where extensive skin-to-spar separation takes place. Phase 3 corrosion can result in significant loss of strength and stiffness. Uninterrupted flight service of two to three years is required before phase 3 separation becomes significant. Residual strength tests were conducted annually to establish the effects of service environments on the graphite-epoxy spoilers. The spoilers were tested with compression load pads on the upper surface to simulate airloads. Trailing-edge tip deflection was measured as a function of applied load for each spoiler tested. The test results were compared with the strength and stiffness of 16 new spoilers. The strength for each spoiler through 12 years of service generally fell within the strength scatter band for the baseline spoilers. However, spoilers with significant corrosion damage that were tested after seven to eight years of service, respectively, indicated a strength reduction of up to 35%. The load deflection response of the spoilers, compared with that of the baseline spoilers, followed similar trends.

In addition to structural tests of the spoilers, measurements were made to determine absorbed moisture content of the graphite-epoxy skins. The moisture content was determined from plugs cut near the trailing edge. The plugs consisted of aluminum honeycomb core, two graphite-epoxy face sheets, two layers of epoxy film

adhesive, and two exterior coats of polyurethane paint. About 90% of the plug mass was in the composite facesheets, including the paint and adhesive. The moisture content was determined by drying the plugs and recording the mass change.

The data for plugs removed from spoilers after nine years of service indicated moisture levels in the graphite-epoxy skins ranging from 0.59 to 0.90%. The moisture levels for the T300-5209 and AS-3501 systems were similar to those for unpainted material coupons exposed to worldwide outdoor environments. However, the moisture content of 0.90% for the T300-2544 plugs was only about half that of the unpainted outdoor-exposure material coupons. Extensive ultraviolet radiation degradation of the T300-2544 unpainted specimens may partially explain the higher moisture absorption. Additional details on the design, fabrication, testing, and service evaluation of the B-737 graphite-epoxy spoilers are presented in Ref 18 and 19.

C-130 Boron-Epoxy-Reinforced Center- Wing Boxes. The design of the boron-epoxy- reinforced aluminum center-wing boxes installed on the two C-130 aircraft in 1974 included uniaxial strips of boron-epoxy bonded to the aluminum alloy skin panels and to the hat section stringer crown. The objective of this program was to compare the strength and fatigue endurance of the boron-epoxy-reinforced boxes and equivalent all-aluminum wing boxes.

The boron-epoxy-reinforced aluminum wing boxes performed excellently in service, with no damage or defects reported. No maintenance actions were required during a 12-year service evaluation period. On the basis of results of ground tests on a third wing box, the boron-epoxy-reinforced wing boxes are expected to have greater fatigue endurance than the baseline aluminum boxes. Additional details on the design, fabrication, and ground tests of the boron-epoxy- reinforced wing boxes can be found in 20, 21 22.

DC-10 Boron-Aluminum Aft-Pylon Skins. The boron-aluminum skin panels installed on the three DC-10 aircraft in 1975 were located above the aft-engine and encountered high acoustic fatigue loading and moderate thermal loads. Two of the skin panels were still in service after 11 years. However, one panel was removed from service after seven years because of corrosion damage (see Fig. 7); the outer layer of boron filaments on the inside of the panel was almost completely exposed. The panel contained a light residue of ester oil similar to turbine engine oil; however, the specific corrodent was not identified. A second panel also had some corrosion damage and a small crack, but was monitored closely during service to check for crack growth and further corrosion damage. The crack in the panel was probably caused by exterior mechanical damage during removal and reinstallation of the adjacent engine cowling.

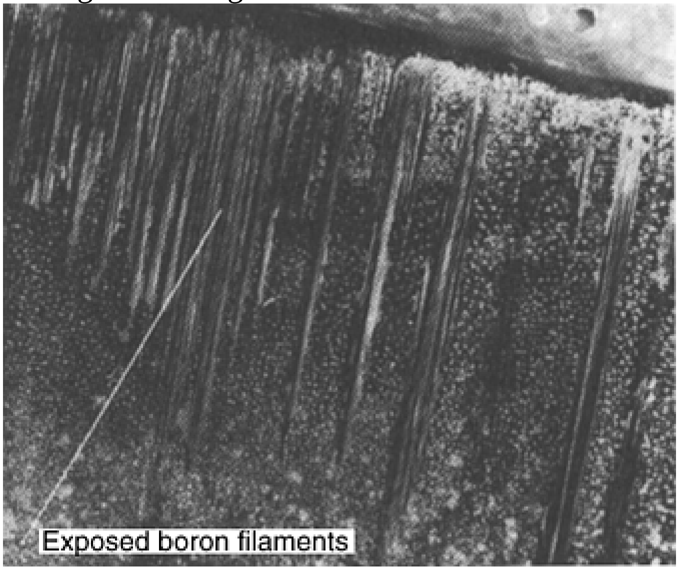

Fig. 7 Interior corrosion damage to DC-10 boron-aluminum aft-pylon skin panel

It was concluded that the method of corrosion protection used was inadequate. In general, the boron-aluminum panels did not perform as well as similar production titanium panels. Additional details on the DC-10 boron-aluminum skin panels are presented in Ref 23.

DC-10 Graphite-Epoxy Rudders. The configuration of the fifteen T300-5208 graphite-epoxy upper aft rudders installed on DC-10 aircraft in 1976 is shown in Fig. 8. The entire structure was co-cured in an oven at the materials supplier's recommended cure cycle for T300-5208. Expandable rubber was used inside the rudder to apply pressure against an outside steel tool.

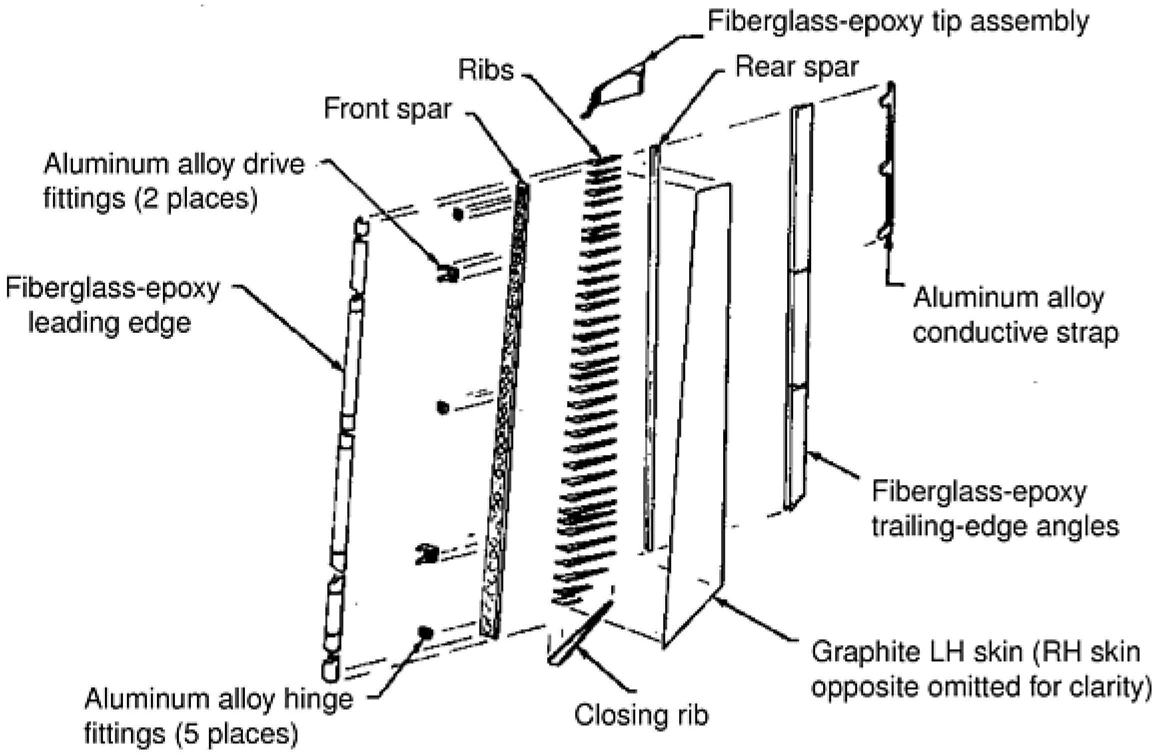

Fig. 8 Configuration of DC-10 graphite-epoxy upper aft rudder

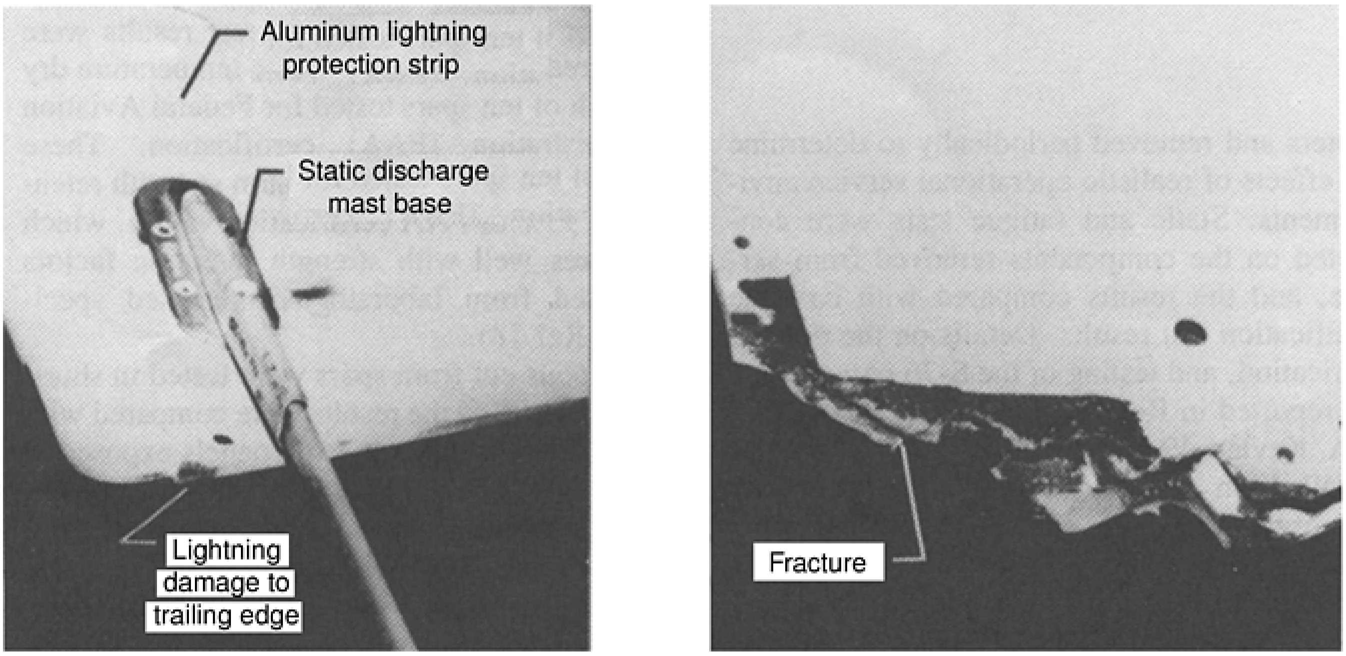
There were seven incidents that required rudder repairs, including three minor disbonds, rib damage due to ground handling, and damage due to lightning. Minor lightning strike damage to the trailing edge of a rudder and rib damage occurred while the rudder was off the aircraft for other maintenance. The lightning strike damage was limited to the outer four layers of graphite- epoxy, and a room-temperature repair was performed in accordance with procedures established when the rudders were certified by the FAA. The rib damage was more extensive, and a portion of a rib was removed and rebuilt (see Ref 24 for more details).

More extensive lightning damage was sustained on another graphite-epoxy rudder. Inspection of the rudder revealed that the lightning protection strap had been inadvertently left off after the previous maintenance check. The skin in the damaged area was eight-plies thick over an eight-ply spar cap. Fiber damage and resin vaporization extended through the skin forward of the spar, and the skin and spar cap aft of the rear spar were completely destroyed. Details of the repair procedures are given in Ref 25.

A graphite-epoxy rudder was removed from service for residual strength testing after 5.7 years and 22,265 flight hours on Air New Zealand aircraft. The load-deflection response indicated that this rudder had an initial stiffness higher than that of the baseline rudder, but a similar overall response. The baseline and the 5.7-year tests were stopped at approximately 400% limit load because of instability of the loading apparatus. Although the rudders were designed by stiffness considerations and only one residual strength test was conducted, the overall response of the rudder indicated that no degradation had occurred after 22,265 flight hours.

B-727 Graphite-Epoxy Elevators. The T300-5208 graphite-epoxy elevator was constructed with Nomex honeycomb sandwich skins and ribs, and laminated spars (see the article “Aircraft Applications” in this Volume). Following initiation of flight service of ten elevators in 1980, three B-727 graphite-epoxy elevators were damaged by minor lightning strikes and two elevators were damaged during ground handling. The most severe damage occurred when the static discharge of one B-727 penetrated the elevator of another B-727 during ground handling. Skin panels were punctured, resulting in four holes in the lower surface and one hole in the upper surface, and the lower horizontal flange at the front spar was cut inboard of the outboard hinge. Figure 9 shows typical lightning damage to the trailing edge of an elevator and trailing- edge fracture of another elevator caused by impact from a deicing apparatus. Damage from lightning strikes ranged in severity from scorched paint to skin delamination. All of the elevator repairs were performed by airline maintenance personnel.



Lightning damage
Ground handling damage

Fig. 9 B-727 graphite-epoxy elevator damage

The lightning damage was repaired with epoxy filler and milled glass fibers. The skin punctures were repaired with T300-5208 prepreg fabric and Nomex honeycomb core plugs. The front spar was repaired with a machined titanium doubler, which was mechanically fastened to the lower skin flange of the spar chord. The repaired graphite-epoxy elevators were reinstalled on aircraft for continued commercial service. Details of the design and fabrication of the graphite-epoxy elevators are given in Ref 26.

L-1011 Graphite-Epoxy Ailerons. After four shipsets of T300-5208 graphite-epoxy inboard ailerons (Fig. 10) were installed on L-1011 commercial aircraft in 1982, an additional shipset was installed on the L-1011 flight-test aircraft. During the four-year service evaluation period, no damage incidents occurred and no major maintenance actions were required. Minor paint touch-up was performed periodically, and loose fibers around one fastener hole on the flight-test aircraft were rebonded with epoxy. Details on the development of the graphite-epoxy ailerons are reported in Ref 27.

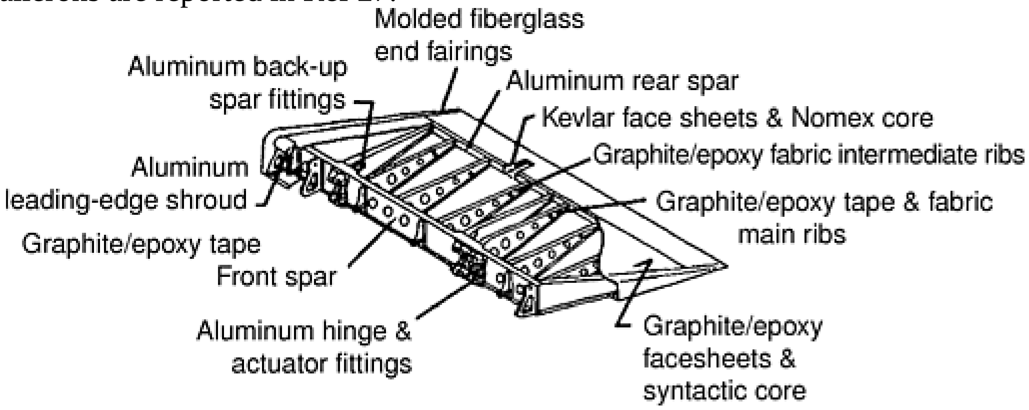


Fig. 10 Configuration of L-1011 graphite-epoxy aileron

B-737 Graphite-Epoxy Horizontal Stabilizers. The configuration of the five shipsets of T300-5208 graphite-epoxy horizontal stabilizers installed on B-737 aircraft beginning in 1984 is shown in Fig. 11. The graphite-epoxy stabilizer features stringer-reinforced skins, laminated spars, and Nomex honeycomb-reinforced ribs. This structure was the first certified primary structure for commercial airplanes. No damage incidents occurred and no maintenance actions were required on any of the stabilizers. Details on the development of the graphite-epoxy stabilizers are reported in Ref 28.

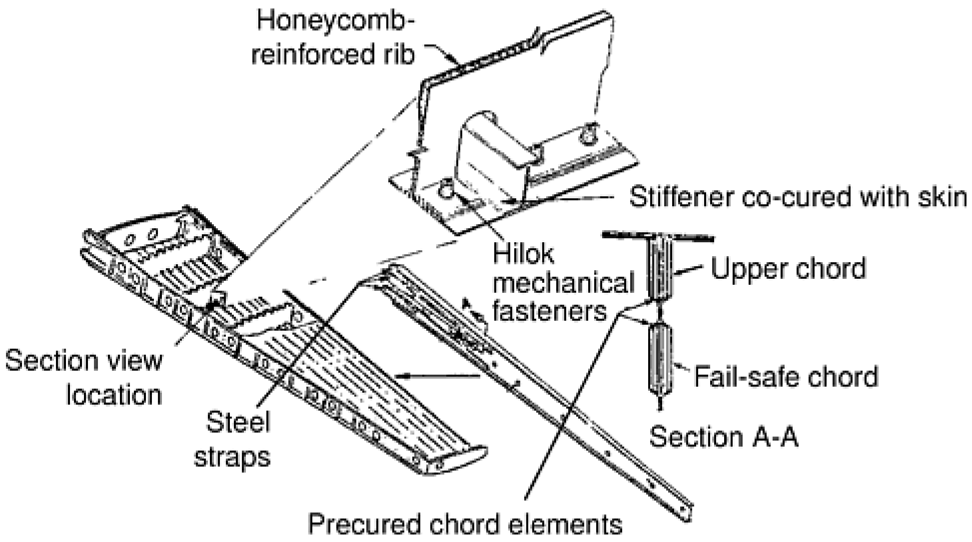

Fig. 11 Configuration of B-737 graphite-epoxy horizontal stabilizer

Helicopter (Bell 206L) Components. The four composite components evaluated on the 206L are shown in Fig. 12. Installation of the 40 shipsets of composite components was initiated in March 1981. Design-related and normal-use problems were encountered with some of the components, but service experience with the forward fairing and the vertical fin was excellent. Two graphite-epoxy vertical fins were struck by lightning. One fin was repaired and returned to service; the second fin was returned to the manufacturer for residual-strength testing. Service experience with the Kevlar 49-epoxy litter door was good, but underdesigned metal hinges caused problems. New hinges were installed on all the litter doors. A design-related thermal distortion problem occurred with Plexiglas (Rohm & Haas Company, Philadelphia, PA) windows in the litter doors, necessitating redesign of the window attachment to the door. The baggage doors had the poorest service record; the major problem was disbanding of the outer Kevlar 49- epoxy skin from the Nomex honeycomb core, to which the outer skin had been co-cured with no additional adhesive. Poor resin filleting was the primary cause of the skin-to-core disbonds, which could probably be prevented by using a film adhesive between the skin and core.

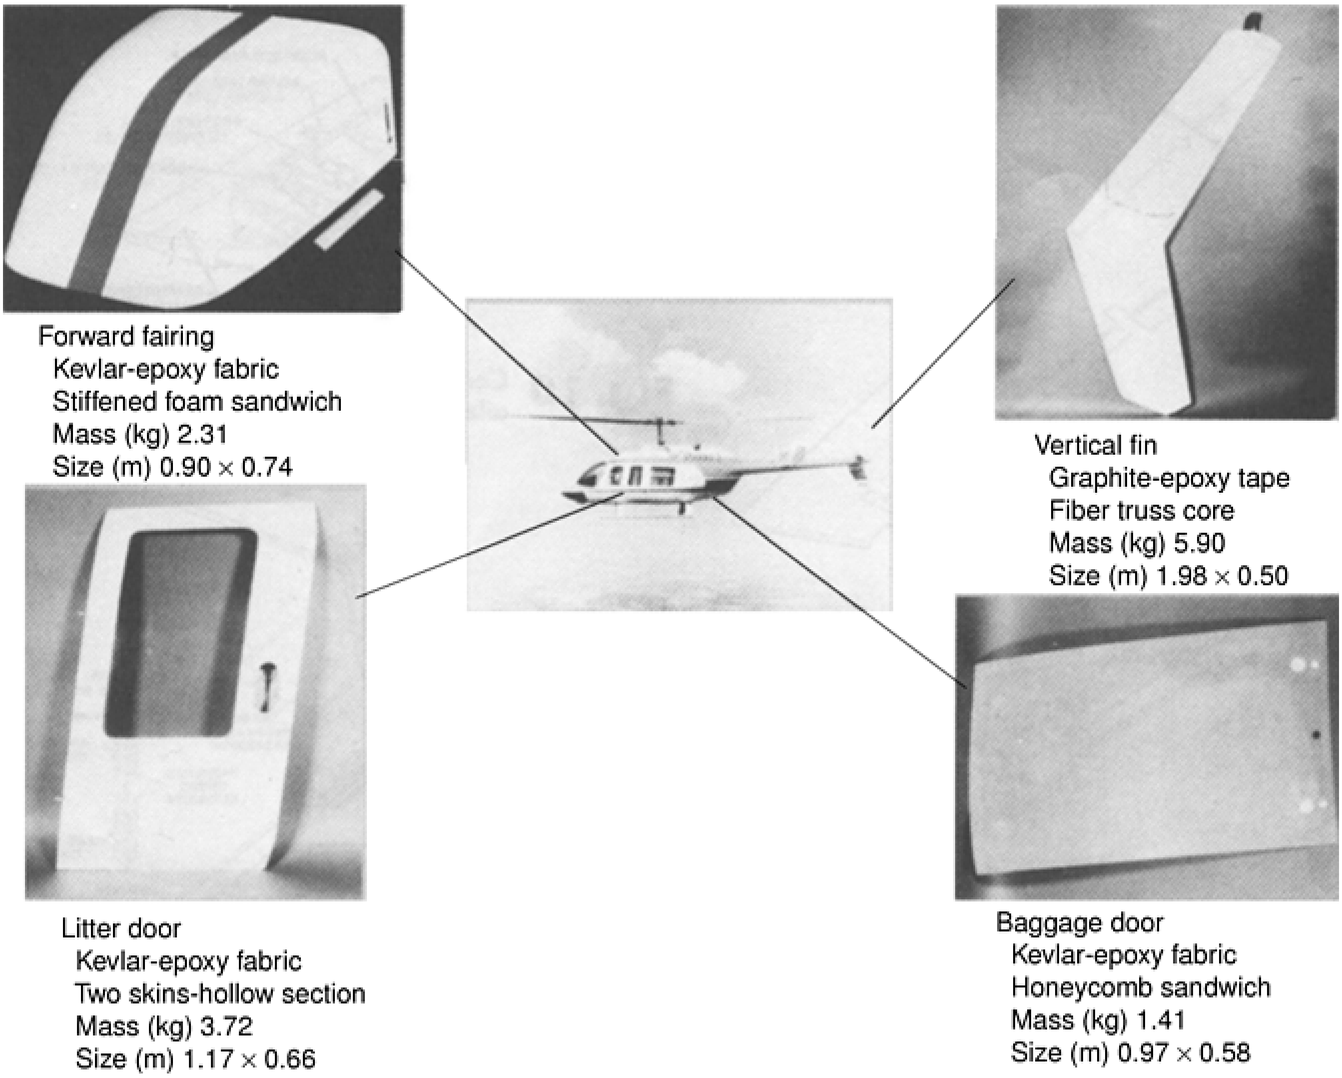

Fig. 12 Composite components in 206L helicopter

Residual-strength tests were conducted on 24 components removed from service in the Gulf of Mexico, eastern Canada, Alaska, and the northeastern United States. The service times ranged from 12 to 34 months, and flight times ranged from 668 to 3387 h. All the flight-service components, except two baggage doors with disbonds, failed at loads higher than the design requirements. Additional details on flight-service performance of the 206L components are reported in Ref 29.

S-76 Components. The two composite components evaluated on the S-76 were tail rotors (graphite-epoxy spar, glass-epoxy skin) and horizontal stabilizers (Kevlar 49-epoxy torque tube reinforced with full-depth aluminum honeycomb and graphite-epoxy spar caps, Kevlar 49-epoxy skin, Nomex honeycomb sandwich core). These were baseline designs for the S-76 and went into commercial production.

Three horizontal stabilizers removed from service for residual-strength testing met baseline proof load requirements. Seven tail rotor spars were removed from service for either static or fatigue testing, and test results were compared to the baseline room-temperature dry strength of ten spars tested for FAA certification. These components exhibited minimum strength retention of 93% of FAA certification values, which compares well with strength retention factors projected from laboratory-conditioned specimens.

Coupons cut from spars were tested in short- beam shear, and the results were compared with those from coupons cut from panels exposed in an outdoor exposure rack in Stratford, Connecticut. The average short-beam shear strength of the spar coupons was 5% lower than that of the coupons machined from the outdoor ground-exposure panels. The spar coupons had service times ranging from 37 to 51 months, and the panel coupons had exposure times ranging from 35 to 49 months. The foregoing results indicate excellent in-service performance for all the S-76 composite components. Additional details on the evaluation program are reported in Ref 30.

CH-53D Cargo-Ramp Skin. A ±45° Kevlar 49 fabric-5143 epoxy composite skin was installed on the aft end of a CH-53D cargo ramp for U.S. Marine Corps service evaluation in 1981 to assess the wear, impact, and damage

resistance of Kevlar 49-epoxy in an environment where ground impact occurs frequently. The skin panel was 508 × 2032 mm (20 × 80 in.) and ranged in thickness from 1.0 to 2.0 mm (0.04 to 0.08 in.). Because of the location and thinness of the panel, the potential for damage was significant. However, no damage or service-related problems were reported following annual inspections.

Other Part-Specific In-Service Experiences

Elevators and Ailerons. In Joynes' 1990 study of the 737-300, 757, and 767 models, the aileron and elevator control surfaces had the most reported incidents. “Being closest to the ground, they present the greatest opportunity for collisions with ground equipment, stands, and so on, and also the greatest area for falling-object damage. The elevators are particularly susceptible to damage from runway debris,” sometimes disturbed by engine exhaust and tires. “Lightning strike damage also occurs more frequently to the elevators because they are subjected to both direct strikes and to the attachment of swept strikes off the wing, engine nacelles, or fuselage that stream aft over the horizontal stabilizer” (Ref 3). Elevators have suffered from a moisture ingression problem due to the thin skins they are often designed with, such as on the 737 and A320, as stated in Airbus Service Bulletin.

Rudders. Joynes reports that the majority of the rudder damage on 737-300s, 757s, and 767s was due to lightning strikes, impacts due to collisions with other aircraft or hangers, or uncoordinated surface movements while the aircraft was near workstands (Ref 3).

Nacelles. Nacelles, in general, due to their location, suffer from several frequent damage modes: damage by ground vehicles, erosion, lightning strike, heat damage on inner and outer skins, and fluid ingression (Ref 6).

Engine inlet cowls are a structure complicated by the need to incorporate noise attenuation to meet lower engine noise requirements. These acoustic panels have a perforated outer skin that necessarily allows water in the honeycomb and must use materials very resistant to water. If drainage is not designed or manufactured properly, water will accumulate to cause other damage (such as service bulletins for the CF6-6 and CFM56). On some designs, the acoustic panels use materials that are difficult to bond or not durable under impact, such as stainless steel mesh or coarse weave graphite cloth. Due to their low bond strength, these materials delaminate easily after impact or under environment stress or corrosion (Ref 6).

Fan Cowls. One early service demonstration study was conducted by Rolls-Royce on an RB211-524 engine (Ref 31). A substitute was designed for the aluminum-skinned unit using skins of T300 graphite. A left-hand and right- hand fan cowl were installed on a commercial turbine engine and examined after 5795 hours and 2663 cycles. Visual inspection found paint erosion, disbond of edge erosion protection, disbonding of door lands, fiber splintering at leading edge, damaged connecting plates, and dents on the outer skins. The “majority of the damage sustained was … of a minor nature.” X-ray inspection revealed honeycomb cell wall buckling near the dents and fluid ingress near the visible skin damage. Testing on sections cut from the cowls showed no change in four-point bending, flatwise tensile strength, thermal analysis, and a moisture content of 1.2% by weight. Rolls Royce concluded, “In view of the many small areas of local impact damage, the absence of delamination and … unbond gives confidence that composite components and bonded assemblies of this type can withstand normal environmental condition.”

Thermal degradation of nacelles is quite common in nacelle composite due to failures of other components, such as bleed valves, anti-ice systems, high-pressure bleed air ducts, and unplugged borescope ports. Normal operation of various exhausts, such as from the engine inlet anti-ice system, can result in hot air flowing over the fan cowl or reverser and leading to delamination. A polyimide demonstration fan cowl was evaluated in service by Lufthansa. The cowl was found to have a large amount of hydraulic fluid that diffused through the skin. The root cause of the damage was identified as thermal degradation and matrix cracking. During an effort to investigate nacelle temperatures, Lufthansa ran a short monitoring program on an A300-600 aircraft with CF6-80-C2 engines. Temperatures recorded on the inner surface of the fan cowl were found to be much higher than the manufacturer's designed continuous service temperature (Ref 32).

Other failure modes identified that are specific to fan cowls include: mishandling damage around the latch cutouts, erosion, punctures of the inner skin by clamps on engine accessories, and ingression of oil/hydraulic fluid. Use of aluminum honeycomb with graphite skins seems to increase the lightning damage (Ref 6).

Fuselage Fairings. Many aircraft models are reported to require many repairs and maintenance to the belly fairings, due to the high exposure to vehicle damage or runway FOD, and due to lightweight designs. However, one failure that is easier to prevent is fluid ingression, especially from leaky hydraulic components mounted

above the panels. Armstrong reported early in the B-747 service that some of the fairings collect moisture (Ref 31). One specific case was described in AE-27 and the Airbus Service Bulletin A320-53-1116. The belly panels were constructed of honeycomb sandwich with one ply aramid cloth on the inside skin. The inner skin was not protected by any fluid barrier, such as a polyvinyl fluoride film or paint, and allowed the ingress of hydraulic fluid, fuel, and water. This is a common failure mode with honeycomb panels on many aircraft models, even with protection schemes, which will degrade with time, allowing ingression into thin permeable skins.

Radomes. Radomes have been cited in many studies as a troublesome part, because they are in a vulnerable location on the nose of the aircraft, and there is the additional complication that they must have transparency to radar waves. The MTBUR reported by various sources ranges from 1,000 to 40,000 flight hours. Keith Armstrong reported that radomes needed repair after…"rain and hail erosion and penetration, overshoe deterioration, lightning strike, and impact with ground service vehicles." (Ref 31). At UAL, an internal study on removal reasons from line aircraft found similar failures, as shown in Table 5. This study was based on almost 400 radomes removed during three years of nonmaintenance visits on UAL's DC10, A320, 727, 737, 757, and 767 fleets. At UAL, of all the composite removable components in all fleets, radomes are the worst in causing delays and cancellations, in removal rate, and in the number of spares.

Table 5 United Airlines radome removal reasons, three year

Reason for Removal	**Number**	Percent
Bird	14	**3.5**
Boot	18	**4.5**
Color scheme wrong	22	**5.5**
Cracked	3	**0.8**
Damage found	26	**6.5**

Fibers exposed	15	**3.8**
Hole	31	**7.8**
Lightning strike	86	**21.6**
Moisture	16	**4.0**
Paint chips	63	**15.8**
Pinhole	40	**10.1**
Radome noise	2	**0.5**
Static burn	34	**8.5**
Total	398	100.0

Spoilers. Slightly predating the ACEE, Vought established a program for a four-year study with 28 composite spoilers on the S-3A. The objective of the program was to establish the practicality of advanced composite materials. Flight-service test complements laboratory test result and serves to validate the long-term structural integrity of the material design and manufacturing process. They also recognized the necessity to obtain management approval from both the manufacturer and the airline user for production and fleet usage. The 41 incidents of in-service damage are summarized in Table 6 (Ref 33).

Table 6 S-3A composite spoilers in-service damage

Problem	**Number of incidents**	**Percent of total**	Cause
Blister above center hinge fitting	24	58	**Design**
Spar exfoliation corrosion	9	22	**Manufacturing**
Miscellaneous cuts and dents	6	15	**Airline use**
Trailing-edge delamination	2	5	**Environment**
Total	41	100	

Source: Ref 33

By far the worst failure mode has been due to moisture intrusion in the honeycomb. In the NASA ACEE program, the B-737 Spoiler, made of graphite skins with aluminum honeycomb and fittings, was reported to have a design flaw where moisture and corrosion entered the overlap between the spar and the hinge fitting after sealing protection (paint and a fillet sealant) failed in places. After 15 years in service, types of damage

found included (in order of frequency): dents from actuator, moisture intrusion with corrosion where the skin and spar overlap, miscellaneous cuts and dents, hailstones, bird strikes, and ground handling equipment. Even though "design changes and improved sealing methods could prevent corrosion damage," the "improved"sealing methods have never materialized (Ref 15). Reliance on sealant or paint to never crack has been demonstrated to eventually have some percentage of failures, which are sometimes as small as pinholes. Additionally, the water intrusion can lead to failure of the skin- to-core bondline.

757 Spoilers have also been a recent example of moisture intrusion. Although the root cause was identified as manufacturing noncompliance with sealing in accordance with the drawing, disassembly also revealed water ingression at tooling holes and hinge fittings. The water propagated rapidly through porous foaming adhesive and along the fiberglass septum (Boeing Service Bulletin 757-57-0047).

Empennage and Primary Structure. Most operators report relatively few problems with composite fixed horizontal stabilizers and vertical stabilizer. The primary airframe structures have had very few occurrences of damage (Ref 34). The CACRC "Guide for Design…" has described the A320 vertical stabilizer as a "success story" for composites, saving weight and requiring little unforeseen maintenance (Ref 6). Service bulletins written against the tail have been minor.

Metallic alloy structures make up the vast majority of the airframes in the Air Force aging aircraft. However, more-recent aircraft have significant quantities of primary flight controls (C- 17) and primary airframe structures (B-2, F-22) constructed from carbon-fiber-reinforced polymeric composites. Limited Navy and commercial aircraft service experience with composite laminate primary structures has indicated very few occurrences of damage in primary structures. The committee recommends that the Air Force undertake long-term research to monitor potential deterioration of composite structures, including the development of improved nondestructive evaluation methods, and to develop or improve maintenance and repair technologies, especially for composite primary structures.

In addition to the ACEE program, a paper was published in 1980, early in the life of the eight A-7 composite wings (Ref 35). After only 2.2 years and an average of 682 flight hours, no major problems were found. The following "minor" effects were reported, and the associated corrective actions:

- Small delamination. Injected with paste adhesive
- Suspected crack along rear spar. Paint sanded down, and crack found only in the aerodynamic filler material
- Blind fasteners installed with wrong grip length
- 13 mm (0.5 in.) crack in the upper cover at the access door support structure
- "Herringbone" cracks were detected in the upper and lower surfaces. Paint sanded down, and cracks found only in the aerodynamic filler material
- Delamination in leading edge of the lower skin. Repair with bolted doubler picking up nearby fastener

Product Reliability, In-Service Experience, and Lessons Learned

Eric Chesmar, United Airlines

Lessons Learned

With any maturing technology, dispersal of the technology is related to the comfort level and acceptance. "Lessons learned" is an effort to document and pass on to future users of the technology the experiences and mistakes of the past, and therefore encourage the use of and reduce the risk of the technology. These lessons are often learned by the users while the aircraft are in service, but need to be absorbed by the designers and decision-makers at the OEMs, and then implemented whenever possible on production aircraft or new aircraft. The CACRC compiled some lessons oriented toward increasing durability, which have been summarized in Table 7 (Ref 6). The most comprehensive compilation of lessons for all stages of the lifecycle is found in *Composite Materials,* MIL-HDBK-17, Volume 3, Chapter 9 (Ref 36).

Table 7 Lessons learned for in-flight durability

Design aspect affected	Lesson
Solid laminate	**Avoid abrupt termination of bonded solid laminate stiffeners; design flanges of stiffeners wide enough to accommodate bearing loads for fasteners; avoid bonding materials with different coefficients of thermal expansion.**
Honeycomb sandwich	**Establish minimum skin thickness criteria based on realistic impact energy levels; avoid self-adhesive prepregs when bonding to sandwich core; avoid fasteners penetrating into the core; potting around fasteners sufficient diameter; potting susceptible to cracking over time, or to moisture absorption; avoid square-edge honeycomb; avoid geometry and tools with local areas of low pressure, leading to porous bondline.**
Materials selection	**Avoid prepregs with high porosity when cured, such as solvated impregnation, and especially when cured only with vacuum pressure; take care with aramid fibers, especially in thin skins that are more susceptible to microcracking and moisture absorption; avoid surface finishes that can crack after subjected to combined stress of thermal, aging, and cyclic fatigue, or reduce the amount used.**
Erosion	**Provide erosion protection on leading edge and forward facing, such as radomes; erosion protection on forward edges with positive step; use easily replaceable, sacrificial**

	materials or coatings.
Lightning strikes	**Affect zones as specified by FARs, generally near attachment and detachment areas, such as radomes, engine cowlings, outer 18 in. of ailerons and elevators, rudder; allow for easy access to bonding jumpers and attachments; designs frequently do not sustain a strike without damage greater than allowable. Use sacrificial protection instead of sacrificing laminate; avoid use of aluminum honeycomb with carbon facesheets.**
Thermal durability	**Aircraft systems, especially powerplants, experience increase in operation temperatures with age. Do not underestimate temperature margins near engines; provide materials with adequate temperature capability; use insulation blankets, which have superior durability and repairability, instead of insulating/fire resistant coatings.**

Materials. Even though the materials and process used in composite structures are still evolving, many of the failure modes can be attributed to materials or their inappropriate processing and design. However, these materials are still in use due to the economics of their continued use, which is often driven by the expense of changing or qualifying a new material. The two most obvious examples include: high-porosity prepreg cloths (Ref 37), and surface finishes that crack and chip (Ref 6).

Furthermore, the failure modes observed in service do correlate to degradation mechanisms for the materials. In a report on “Accelerated Aging of Materials and Structures,” the National Research Council identified the four most significant degradation mechanisms: matrix cracking, thermal degradation and oxidation, hygrothermal degradation, and phase separation or macrostructural changes (see Table 8). The root cause of many of the current failure modes is in those areas identified in the column “missing information,” which is a fruitful area for future materials research. The National Research Council summarized nicely: “The principal barriers to increased use for new high-performance materials are acquisition, manufacturing, certification, life-cycle cost, and incomplete understanding of failure mechanisms and the interactions” (Ref 39).

Table 8 Aging materials lessons learned

Degradation mechanism	**Most important variables**	**Modeling approach**	**Ways to accelerate tests**	Missing information
Matrix cracking	Processing parameters Temperature cycle range Static and fatigue loading Moisture/thermal cycle Number of cycles Ply thickness Residual stresses	Damage accumulation models	Increase temperature cycle range Increase applied stress Increase frequency	**Effects of moisture** **Rate effects**
Thermal degradation and oxidation	Temperature Oxygen concentration Exposure time Mass-transfer	Reaction kinetics models	Increase temperature Increase oxygen concentration	**Chemical degradation models** **Effect of matrix cracking**

	models			
Hygrothermal degradation	Exposure temperature Moisture concentration Heating rate	Moisture diffusion models	Increase exposure temperature Increase moisture content Cycle moisture sorption	**Effect of moisture on residual stresses** **Description effects** **Moisture gradient effects** **Effect of matrix cracking** **Effect of imposed stress**
Phase separation/microstructural changes	**Exposure time** **Exposure temperature** **Moisture content**	**None**	**Increase temperature** **Increase moisture content**	**Microstructural characterization methods** **Solubility methods**

Source: Ref 38

In the military aircraft, lessons for materials are embodied formally in aircraft specifications. For example, the U.S. Navy currently prohibits the use of honeycomb sandwich structure and aramid/epoxy. The Navy also has prohibited the use of polyimide and bismaleimide resins, because of potential for corrosion in the presence of jet fuel and salt (Ref 12). In a 1997 study, the Committee on Aging of U.S. Air Force Aircraft reported on the need "…to continue to monitor the performance of their composite components." Potential degradation mechanisms to monitor for future composite structural applications include (Ref 34):

- The development of transverse matrix cracking resulting from mechanical, thermal, or hygrothermal stresses
- The growth of impact damage under fatigue loading
- The growth of manufacturing-induced damage, especially from fastener installation
- The development of corrosion in adjacent metal structures

Design Opportunities and Documentation. Although such lessons learned have been documented for many years in various places, they have been difficult to implement, and known mistakes are often repeated by copying previous designs. One obvious opportunity to take advantage of the lessons learned from past experience is during the design process for new aircraft models or redesign for a new fleet. Recently, aircraft manufacturers have attempted to use a team approach to design, involving designers, production, and the airline customers. If given the opportunity, this is the time during the aircraft life cycle when the airline customer can most easily influence the design and therefore, the maintenance and airline operating costs.

The OEM can incorporate lessons into general design guidelines, new test requirements, or materials specifications. Boeing uses documents called Design Requirements and Objectives (DR&O), which translate both mandatory Federal Aviation Regulations (FARs) and nonmandatory targets into specifics. One change for these DR&O for composites was an increase in the hail resistance, specifically the minimum thickness for the sandwich skins. Don Joynes stated in 1990, "To reduce time-consuming replacement of the fixed upper panels, a new hail and impact damage criteria was established that increased the thickness of the outer upper skin for production airplanes" (Ref 3). An example of new and revised specifications and design guidelines was presented by R. Thevénin in response to airline requests for more durable composites. Several specifications were described: EN2563 for testing for mechanical degradation from fluids, AITM 2-0037 for fluid tightness of the completed structure, AITM 1-0029 for resistance against erosion, improved potting compounds, and larger area of potting around fasteners, ABD0076 for elimination of a layer of pore filler, and AIMS 10-01-000 for material qualification for surfacers (Ref 40).

Another method of capturing the lessons of the past is to create a living document containing a generic, state-of-the-art design. The B.F. Goodrich-Aerostructures company has incorporated all the lessons they have learned from their hardware in a "best practices" nacelle design (Ref 41). The advantage with this approach is that there is continual feedback from customer service groups, continual updating of the design, and the design is not associated only with specific engines or aircraft models. This type of document also avoids the pitfalls of relying on existing designs or copying the experience of individuals.

Introduction to Failure Analysis

Patricia L. Stumpff, Hartzell Propeller, Inc.

Introduction

ADVANCED COMPOSITES are being used as structural materials in automotive, recreational, aerospace, and other industries due to their low weight and inherent structural stiffness. As these materials continue to be used, it is inevitable for premature failures to occur as a result of manufacturing defects, unexpected loads, environmental exposure, and in-service damage. The need to understand and analyze these failures has led to an increased interest in determining whether the techniques and procedures used for failure analysis of metallic materials can be applied to composite materials as well. Analysts have been trying to establish, modify, and amend metallic failure analysis procedures to fit the procedures required for conducting failure analysis investigations of composite materials. This work has resulted in significant strides in this area since the 1980s. While failure analysis of composite materials is similar to that of metallic materials, the anisotropy of composites, the frequent use of adhesive bonding for joining dissimilar materials and structures, as well as the potential for composites to fracture in different and multiple failure modes, sometimes make their analysis much more complex. Therefore, while much has been accomplished in this regard, there is still much that needs to be done.

Introduction to Failure Analysis

Patricia L. Stumpff, Hartzell Propeller, Inc.

Overview of Failure Analysis

Any failure investigation begins with obtaining background information about the manufacture of the part and its service history. Part manufacturing information includes things such as part drawings, materials, manufacturing process specifications utilized, and any materials and/or manufacturing changes. Service history includes information regarding part usage, service time prior to failure, the number of failures, changes in the number of failures as a function of time, expected loading, and service environment.

After the background information has been obtained, the laboratory investigation can proceed. The purposes of the laboratory investigation are to determine if the material was manufactured according to the specifications and to identify any potential problems that may have played a role in the failure of the part. The laboratory investigation begins by conducting a thorough visual analysis of the failed parts to verify the type and location of the damage and to initiate ideas as to how the failure may have occurred. Appropriate nondestructive evaluation should also be conducted in order to verify all visual determinations of damage and to find other damage that may or may not be visible. It is necessary that all damage to the component be found and evaluated, in order to understand the failure mode and sequence. The next step in the investigation is verification of the materials and processes. This includes taking measurements, wherever possible, to ensure that the part exhibited dimensional conformance. Next, sections should be removed to verify material chemistry. Cross sections are extracted and mounted to evaluate ply type, count, and orientation. Glass transition temperature and degree of resin cure should be determined using thermal analysis techniques to ensure that the part was processed as required. Fracture surfaces should be removed and analyzed using both optical and scanning electron microscopy in order to determine failure initiation sites, crack growth directions, environmental influences, defects, and failure modes. Chemical analyses of potential foreign materials or contaminants may also be conducted.

If the laboratory investigation up to this point does not yet adequately explain the failure, additional testing can be conducted to further define the failure cause. Additional testing could include such things as mechanical testing to verify material strength and modulus, and/or stress analysis to determine the maximum failure stresses and potential sequence of fracture. The failure analysis is concluded when the cause of the failure has been adequately explained.

The sequence of conducting these investigative efforts is as important as the information actually obtained. This is because there can be a loss of relevant information that cannot be obtained later, once sectioning of the part has begun. Additionally, the information obtained from the previous analyses may be needed or useful in conducting subsequent analyses. The investigative sequence for conducting a failure investigation has been identified as the failure analysis logic network (FALN), and is shown in Fig. 1.

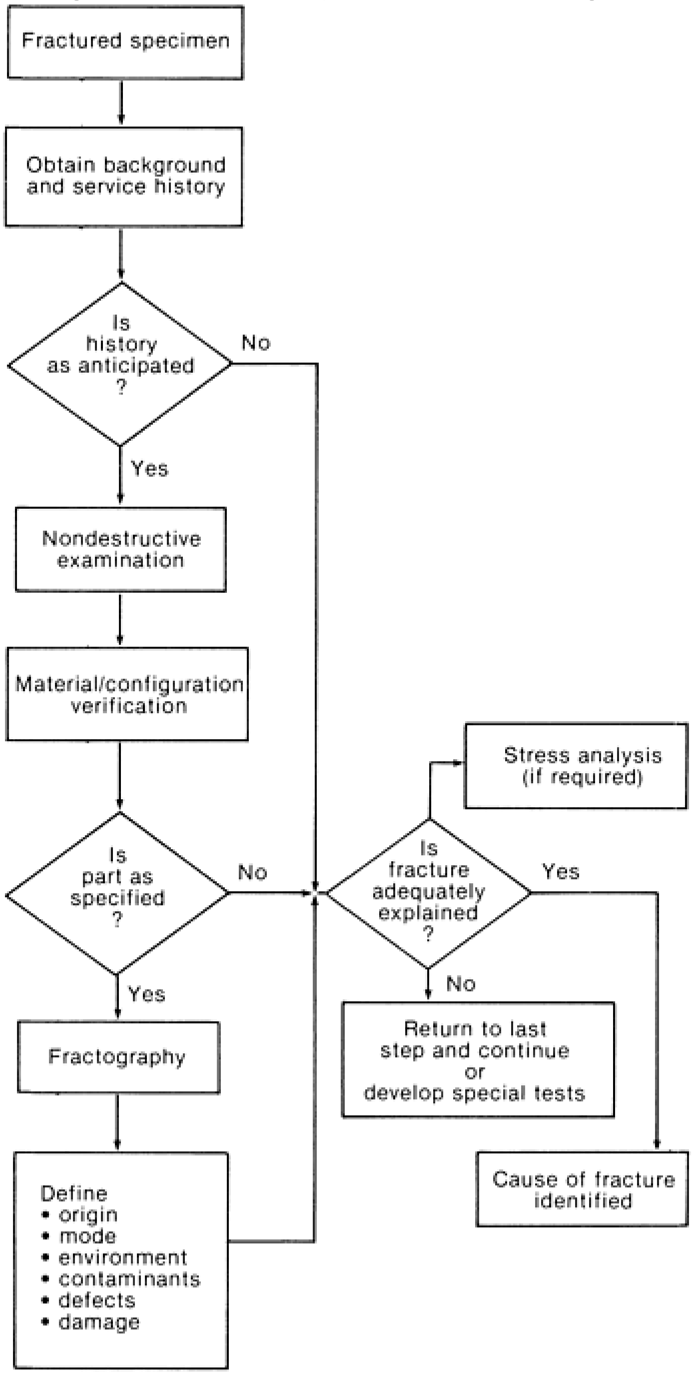

Fig. 1 Failure analysis logic network (FALN) for determining sources of failure in composite parts. Original FALN was developed by Boeing.

Introduction to Failure Analysis

Patricia L. Stumpff, Hartzell Propeller, Inc.

Coverage of this Section

This Section has been significantly overhauled since the last edition, mainly because of a significant increase in the understanding and actual use of the analytical procedures and techniques developed in prior years. Although it is not possible to describe in detail all the analytical procedures and techniques that might be useful in any investigation, it is hoped that this Section will at least provide the analyst with some general guidelines for conducting an investigation.

Most of the information in this Section is geared toward organic-matrix composites, although there is some information on failure analysis and fractography of ceramic- and metal-matrix composites (CMCs and MMCs). It is hoped that many, or at least some, of these procedures and techniques, which were originally developed for organic-matrix composites, can be applied to CMC and MMC materials as well.

The remainder of this Section is divided into nine articles. The first article, “Failure Causes,” details the types of failures in composites, including those due to material and manufacturing defects, mechanical, thermal, and residual stresses, and environmental exposure.

The second article, “Failure Analysis Procedures,” gives a general overview of the investigative sequence, as well as many of the specific techniques that can be used in an investigation. These techniques include both nondestructive techniques, such as x-ray and ultrasonics, and destructive techniques, such as cross-sectioning, thermal analysis, fractography, and mechanical testing. In addition to defining the technique, the article gives numerous examples of the types of data obtained and how those data can be used in a composite failure investigation.

The third article, “Visual Analysis, Nondestructive Testing, and Destructive Testing,” is devoted to obtaining information relative to the current damage state of the component. Nondestructive analysis techniques, including visual examination, ultrasonics, x-radiography, and tape replicas, are discussed in relation to their usefulness in determining the location and severity of all damage.

The fourth article, “Microscopy,” details the procedures for obtaining part cross sections. Cross sections are necessary in order to determine the material and processing conditions used to manufacture the part, including fiber, resins, and adhesives; ply type, count, and orientation; fiber, matrix, and void-volume fractions; fiber/matrix adhesion; material crystallinity; and material defects such as porosity, delaminations, and microcracking. The article also details several different techniques used for sample preparation of different materials, including information regarding thin section preparation. It describes the use of reflected bright-field, dark- field, polarized, and transmitted light, as well as phase contrast, differential interference contrast, modulation contrast, and optical staining in the analysis of material microstructure.

The fifth article, “Thermal Analysis,” is devoted to detailing specific thermal analysis techniques utilized in composite failure analysis. Thermal analysis techniques, such as differential scanning calorimetry, thermomechanical analyses, dynamic mechanical analysis, and dielectric analysis, are generally used for determining the prior processing history, thermal exposure, and environmental service history. These analyses are used to help define the time/temperature exposures experienced by the composite either during manufacture or in service.

The sixth article, “Fractography,” provides fractographs that help define the specific features used to determine the crack initiation site, crack growth direction, fracture mode, material/manufacturing defects, and environmental conditions at the time of failure. This article gives just a glimpse of the numerous fractographic features encountered when working with composite materials, although features from a broad range of materials and failure modes are provided. There is also a short discussion provided with each fractographic feature to describe what the feature tells an analyst about the failure.

The seventh article, “Case Histories,” is devoted to describing three composite failure investigations. The purpose of this section is to provide the analyst with a description of how the procedural sequence and specific techniques were used in conducting several specific composite failure investigations.

The eighth article, "Fatigue Properties and Quantitative Fractography of Metal-Matrix Composites" is devoted to fatigue testing and the fractography associated with metal-matrix composites.
The ninth and final article, "Failure Analysis of Ceramic-Matrix Composites," is devoted to the fractographic analysis of ceramic-matrix composites, including characteristic failure modes, fractography, and failure mechanisms.
It is hoped that the information presented in this Section will be useful to the composite failure analyst and encourage future work in these areas. There is still a significant amount of research that needs to be conducted in the areas of visual, metallographic, and fractographic analyses before the analyses of composite materials and structures are as routine as the analysis of metals.

Failure Causes

John E. Moalli, Exponent Failure Analysis Associates

Introduction

AS WITH MOST ENGINEERING MATERIALS, the failure of composite materials, no matter how complex, can be divided into three discrete arenas: improper design, improper manufacturing, and improper use of the end product. Each of these categories can be further subdivided, but it is rare that a failure cannot be assigned to one or more of them. This article looks at these failure causes from a broad perspective so that the composites designer, manufacturer, and user can readily see some of the more common issues associated with these unique materials.

Design

Design is sometimes described as a circular process that involves conceptualization of a product, construction of a prototype, evaluation and testing of the prototype, and return to the conceptualization/design phase to correct any deficiencies discovered during testing. Clearly, this is a great simplification, with each of these phases representing multiple steps. For example, in order to design and build a prototype, one must come up with dimensions that satisfy the relevant design criteria (Ref 1).
In composite materials, sizing the part based on its ability to support loads can be a challenging process, as stress analysis in composite materials is complicated by the inherent anisotropy of the material. In certain nonsymmetric laminated structures, it is possible to require 21 independent elastic constants to describe fully the component of interest, that number being reduced to 9 and 4 constants for three- and two- dimensional orthotropy, respectively (Ref 2). This is not to say that anisotropy should be avoided. In fact, it is anisotropy that allows composite structures to be designed so efficiently; the structure can be tailored to have different strengths in different directions to effectively handle directionally dependent loads and stresses.
It is important to note that not only are composite materials anisotropic because of the macrostructures (fiber orientation and laminate sequence), but also because of the anisotropy in the materials from which they are made. For example, many synthetic polymeric fibers have different moduli in tension and compression. Failure to consider this can lead to failures if one assumes that composites made from these materials will behave identically in push/pull situations. Even a unidirectional laminate in flexure will require special analytical consideration with different tensile and compressive moduli, as the neutral axis will no longer be coincident

with the centroidal one. Equally important is the fact that the compressive and tensile strengths may be different, and the associated failure criteria may have to be examined separately.

Anisotropy is not limited to mechanical properties; composites often have directionally dependent thermal characteristics as well. It is not uncommon to have a factor of 10 difference in longitudinal and transverse thermal expansion coefficients (Ref 3), a variation dominated by the thermal characteristics of the constituent materials. Some graphite fibers, in fact, have negative longitudinal thermal expansion coefficients; they actually shrink when they are heated (Ref 4).

When considering internal thermal (often called residual) stresses from a design standpoint, it is critical to remember that the reference, zero-strain temperature is the curing temperature, not the ambient one. In laminated composites, the variation in ply orientation can cause thermally induced internal stresses to be quite large; ignoring these stresses and considering applied stresses only can promote overloading and resultant failure. Thermal stresses resulting from external conditions should use a different, appropriate reference temperature. For example, attaching a composite structure to a material of different composition can lead to applied stresses from differential thermal expansion and should use the attachment temperature as the reference condition.

Analysis of composite materials also needs proper consideration of product-dependent inhomogeneities including holes and notches, the presence of which can lead to structural failure at stresses well below nominal ultimate strength. Even the edges of composite plates with plies oriented at significant angles to each other need to be considered; the large ply stress gradients are not always considered and sometimes lead to premature failure.

Finally, analysis can be further complicated by selection of appropriate failure criteria. Those familiar with design based on load-limit-type analyses may find that, in many occasions with composites, strain limits are a more appropriate selection. For example, in composite pipes carrying aggressive media it may be important for the resin not to crack as the fibers will no longer be protected; this will likely occur at a strain level much lower than ultimate. If the pipe is designed solely from a strength standpoint, premature cracking of the resin may result.

As part of the design process described previously, prototype components should be fabricated and tested in actual end-use conditions. All expected load conditions should be evaluated, including transient or impact loads; it is well known that in certain composite structures, compressive strength after impact can be substantially reduced. Cyclic loads can also have detrimental effects, and fatigue damage created by them should be tested for and examined carefully. Carbon fiber reinforced composites generally display better fatigue resistance than glass reinforced ones; this is often attributed to the lower matrix strains in the higher-modulus carbon fiber reinforced material at a given stress level (Ref 5).

The time-dependent nature of extended loads must also be considered, as composites can be susceptible to both creep and stress relaxation. Finally, it is important to evaluate prototypes under representative environmental conditions (temperature, chemical, and ultraviolet exposure). For example, exposure of composite pressure vessels to acidic conditions has led to premature failure from environmental stress corrosion of the glass reinforcement (Ref 6).

Manufacturing

Manufacturing processes for composite materials are quite varied, from hand lay-up of laminated structures to computer-controlled processing of sheet molding compound, and failures can and do result from manufacturing errors. In the context of this discussion, manufacturing includes both processing of the composite and assembly of final components.

Typical processing-related failures include improper mixing and curing of matrix resins, which can have a number of effects on composite properties. An overcured resin can become embrittled, crack prematurely, and expose the reinforcement to environmental conditions it might not otherwise be exposed to. An undercured resin may be too soft and not transmit loads efficiently to fibers. Improper resin curing and mixing can also affect the chemical and thermal resistance of the matrix material.

If the composite is manufactured in such a way as to induce substantial voids in the resin, the flexural, transverse tensile, compressive, and interlaminar shear strength can all be negatively affected. Excessive voids can also reduce the environmental resistance of the composite. Because the end-use requirements of composite structures are so different, allowable void contents vary as well. Applications that demand minimal voids are usually autoclaved or vacuum bagged.

Since the strength and stiffness of composites is mostly governed by the reinforcing fibers, placement of them within the composite can be critical. In a thin, unidirectional laminate, for example, a variation in fiber orientation as small as 15° can reduce the laminate strength by a factor of 2. In some cases, random fiber placement is desired to produce a more isotropic structure. Flow-induced fiber orientation from processing can reduce isotropy, increasing strength and stiffness along the flow direction and reducing them transverse to the flow direction.

Errors related to assembly and fabrication of composites can also lead to failure. Composite materials are often bonded together with adhesives, the curing of which can affect strength and ultimate performance. Proper curing, as well as minimization of voids and contaminants, are important items to monitor during adhesive bonding.

Other types of mechanical joints also need to be monitored carefully during assembly. For example, excessive applied torque in bolted joints not only can cause visible bearing failures, but subsurface interlaminar failures can also be induced. Because these failures are not readily observed, they tend to be more insidious as they can propagate without notice.

As mentioned previously, the temperature at which a bonded or adhesive joint is made can also be a factor in composite failure. If the joint connects materials with dissimilar thermal expansion coefficients and is made at a temperature significantly different than the service temperature, significant stresses can be induced from differential thermal expansion.

John E. Moalli, Exponent Failure Analysis Associates

Improper Use

Although the incidence of misuse in composite materials should be similar to conventional ones, the results can be quite different. An impact, not expected in typical service conditions, may dent a metallic component that can be used thereafter without consequence. The same impact in a composite structure can cause an internal delamination that can propagate unseen and contribute to subsequent premature failure. For example,

application of force with blunt objects to composite pressure vessels may leave little visible sign of external damage, but can cause subsequent failure of the vessel after filling to service pressures. For this reason, it is often necessary to inspect critical parts for nonvisible damage and also to make composite designs more robust than their traditional counterparts.

Failures from misuse can also be caused by not following specific instructions associated with the composite component. For example, buried composite tanks need to be installed in the ground in a very specific way, as they rely on the surrounding soil for support and stiffness. If they are not properly installed (misused), they tend to fail prematurely. For products such as these, designers and manufacturers should ensure that use instructions are clear and simple to comprehend.

Failure Causes

Failure Analysis Procedures

Patricia L. Stumpff, Hartzell Propeller, Inc.

Introduction

FAILURE ANALYSIS procedures for composites are generally similar to those used for other material systems. As with any thorough analysis, the investigation should follow a series of chronological steps that includes at least:

1. A review of available in-service records
2. A review of required materials and processing methods, print requirements, and manufacturing records
3. Visual analysis, documentation of damage and any other nondestructive part evaluation
4. Verification of materials, including the fiber/ resin/adhesive systems
5. Determination of fiber, matrix, and void volume fractions and verification of the lay-up, ply type, and orientation

6. A review of the processing parameters used to manufacture the component, including the type of equipment, pressure, times, and temperatures used to effect the proper cure
7. Fractographic analysis, including failure origin, crack growth direction, environmental influences, and failure mode
8. Mechanical testing and stress analysis as warranted to adequately determine failure cause

The purpose in following a specific test sequence is to try to avoid the loss of necessary evidence that may come about during the destructive evaluation of the component. The techniques to be used in these analyses are described in more detail in this article.

Patricia L. Stumpff, Hartzell Propeller, Inc.

Review of Available In-Service Records, Materials and Processing Methods, Print Requirements, and Manufacturing Records

Available service records are a good source of information to determine:

- How long the fractured component has been in service
- Whether or not the component was properly maintained during its service history
- If and when the component had ever been repaired or overhauled
- The types and magnitudes of the loads the component experienced at the time of failure, and whether or not those loads were typical or atypical for that part
- The environment experienced in service, and whether or not that environment was as initially anticipated during the design phase
- Whether or not there have been any other failures similar to the current failure of this particular component

A review of the materials and processing methods, print requirements, and manufacturing methods will entail a determination of the fiber/ resin/adhesive systems, the type and number of plies and their orientation, the dimensional requirements and tolerances of the part, and the pressures, temperatures, times, and cure cycles used to process the materials into the finished component. A review of this information should provide answers to questions regarding whether the design, materials, manufacturing or processing methods, loads, environment, maintenance, or repair procedures might have been implicated in the failure event.

Failure Analysis Procedures

Patricia L. Stumpff, Hartzell Propeller, Inc.

Visual Analysis and Nondestructive Examination

Visual analysis is usually the first step in the nondestructive evaluation process. The purpose of a visual examination is to document all damage and to determine how the component may have separated, and from this information, to try to discern which specific fracture or fractures initiated the failure event. The purpose in defining the initiating fractures from subsequent ones is to reduce the number of surfaces needing further evaluation in order to determine failure cause. Figure 1 depicts the three different stages in the failure of a helicopter rotor. The area labeled “A” depicts a fatigue initiation region; the area labeled “B” depicts a region

of translaminar bending failure; and the area labeled “C” depicts an area of fiber crushing during final fracture. These three distinct regions are visually apparent on the fracture surface and are indicative of the different types of loading on the part during the failure event.

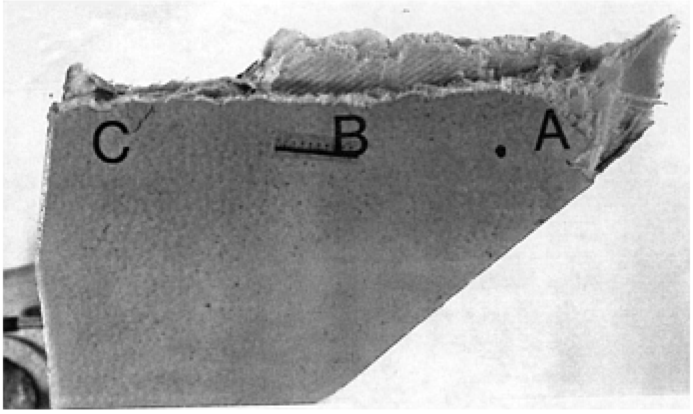

Fig. 1 Three different failure modes exhibited on the surface of a fractured, translaminar helicopter rotor. A, fatigue initiation; B, translaminar bending; C, fiber crushing during final fracture

Although most translaminar fractures are visually apparent, composites, because of their laminated construction, will also exhibit interlaminar fractures that may be hidden from view. As a result, nondestructive evaluation of the component to find these interlaminar fractures often represents a particularly critical step in the analysis of composite structures.

The most successful nondestructive inspection methods for composite materials include through-transmission ultrasonics (TTU), pulse- echo ultrasonics, and dye-penetrant enhanced x- radiography. In the first two methods, internal damage is detected by placing an ultrasonic transducer on either one (pulse echo) or both sides (TTU) of the component and measuring the attenuation of 1 to 25 MHz acoustic waves transmitted into it. Signal attenuation levels are then measured, grouped together, and assigned different gray levels or colors on the scale of the chart recorder. The greater the level of signal attenuation, the more internal damage in the component. Figure 2 depicts an ultrasonic inspection record from a section of a damaged radome. In this case, the signal is highly attenuated in the dark, damaged region, identified as section A, where a delamination has occurred. No signal attenuation, however, was noted in the light-colored area shown in the center of section B, meaning no damage exists in that region. Moderate attenuation of the signal can be noted in the darker areas surrounding the undamaged area in section B. Moderate attenuation of the signal is probably indicative of some minor form of damage to the composite, such as resin micro-cracking or fiber-matrix separation.

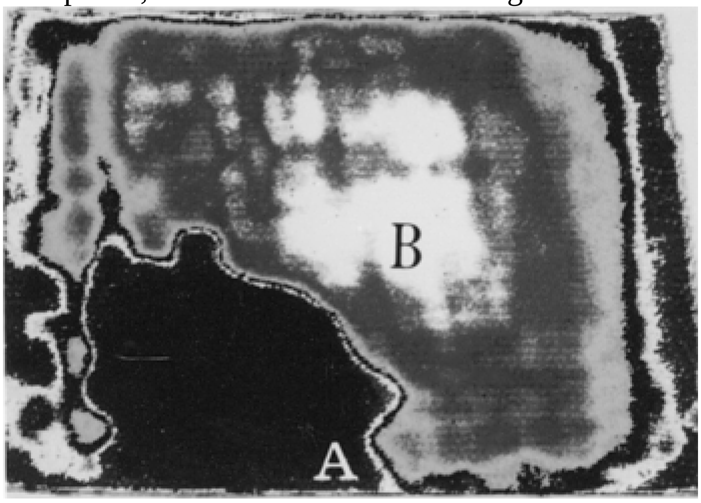

Fig. 2 Ultrasonic C-scan evaluation of a delaminated section of an aramid/epoxy radome. A, damaged region; B, undamaged region

The detection of damage in composites using x-radiography is carried out in the same basic manner as it is for metals, except that prior to the x-ray inspection, a radiopaque penetrant is wetted into the open surface cracks to enhance damage visibility. In general, x-ray equipment operable in the 10 to 50 kV, 5 mA range with

diiodobutane penetrant yields the best results. Figure 3 details the damage evident in the 45° plies of a composite specimen following tensile loading in a mechanical test frame. The radiograph was taken following the addition and penetration of the radiopaque penetrant from the edges toward the center of the specimen. The use of penetrant to enhance this type of damage is often important in defining the depth of the interlaminar damage in a specimen prior to ultimate failure.

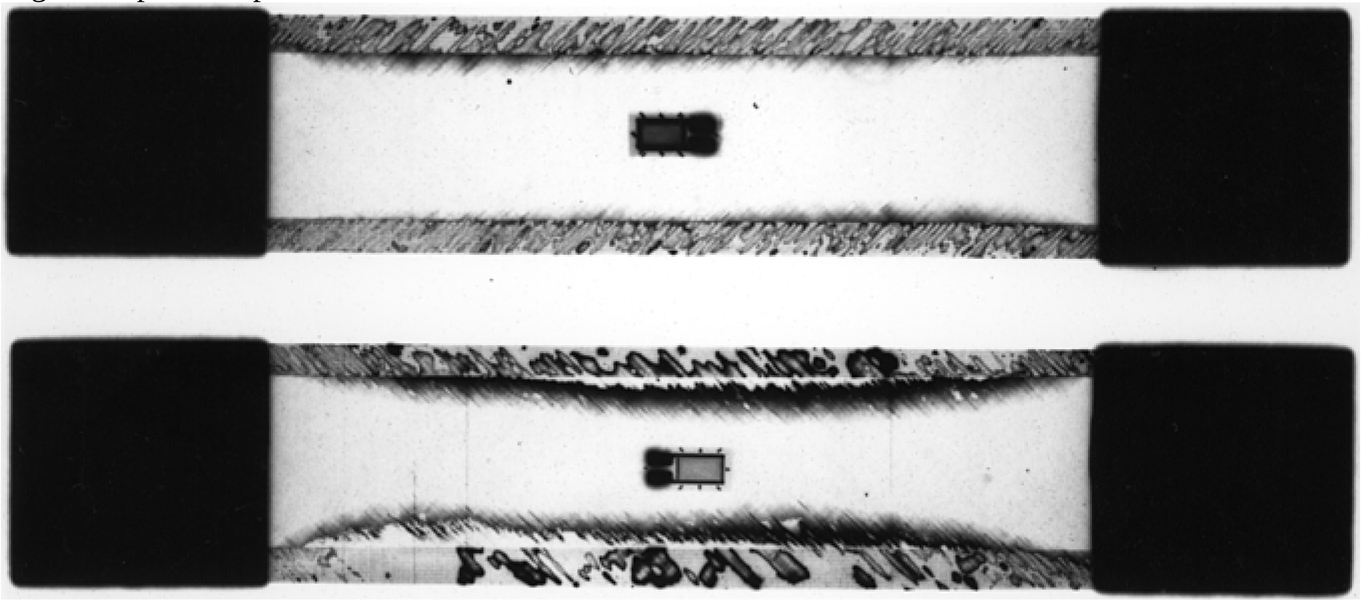

Fig. 3 Penetrant-enhanced radiograph revealing the microcracking and edge delaminations in a tensile test specimen

In addition to dye-penetrant-aided x-radiography, standard x-ray analysis can provide information regarding ply counts, ply orientations, and ply drop-offs. Foaming of resins or adhesives will also be apparent, as will water ingression into core details. The orientation, cell size, and web materials of honeycomb cores (particularly nonmetallic cores) can often be determined with x-ray inspection.

The use of any of these nondestructive evaluation techniques requires that some forethought be given to the type of failure likely to be encountered. With both ultrasonic methods, as well as with x-radiography with radiopaque penetrant, liquids will penetrate into the fracture surfaces. These liquids may alter the chemical nature of the fracture surfaces that may have initiated and/or propagated the failure. In those cases where surface-analysis techniques, such as x-ray photoelectron spectroscopy (XPS), are to be used later on to define the type of contamination on the fracture surface, the water or penetrant should be prevented from entering the fracture surfaces by sealing the exposed ends of the fracture with a water-resistant tape.

Failure Analysis Procedures

Patricia L. Stumpff, Hartzell Propeller, Inc.

Verification of Materials and Processing Methods

The first step in the destructive portion of the investigation is to verify that the correct materials and processing methods were used in the manufacture of the component. These analyses include verification of:

- The fiber, resin, and adhesive systems
- The size, type, number, location, and orientation of all plies and adhesive layers
- The cure cycle used to cure the component

Verification of the resin and adhesive systems is usually conducted using a technique known as Fourier transform infrared (FTIR) spectroscopy. Each resin or adhesive used in the composite exhibits a unique infrared

spectrum, as depicted in Fig. 4. The spectrum obtained for the resin or adhesive in the component is then compared to reference spectra in a materials database. This analysis generally reveals the specific material type and delineates materials such as epoxies from bismaleimides. Additionally, if enough database profiles are available for comparison, the uniqueness of the FTIR trace may even be able to verify a specific resin and its manufacturer, for example, Cytec FM 73 epoxy. The spectrum obtained during this analysis may also exhibit peaks that are not indicative of the material being analyzed; peaks that may be indicative of a potential contaminant that may be related to failure cause. The FTIR technique is also used to verify the fiber type as well, although visual analysis is often all that is required to identify fiber systems such as carbon, glass, boron, and aramid.

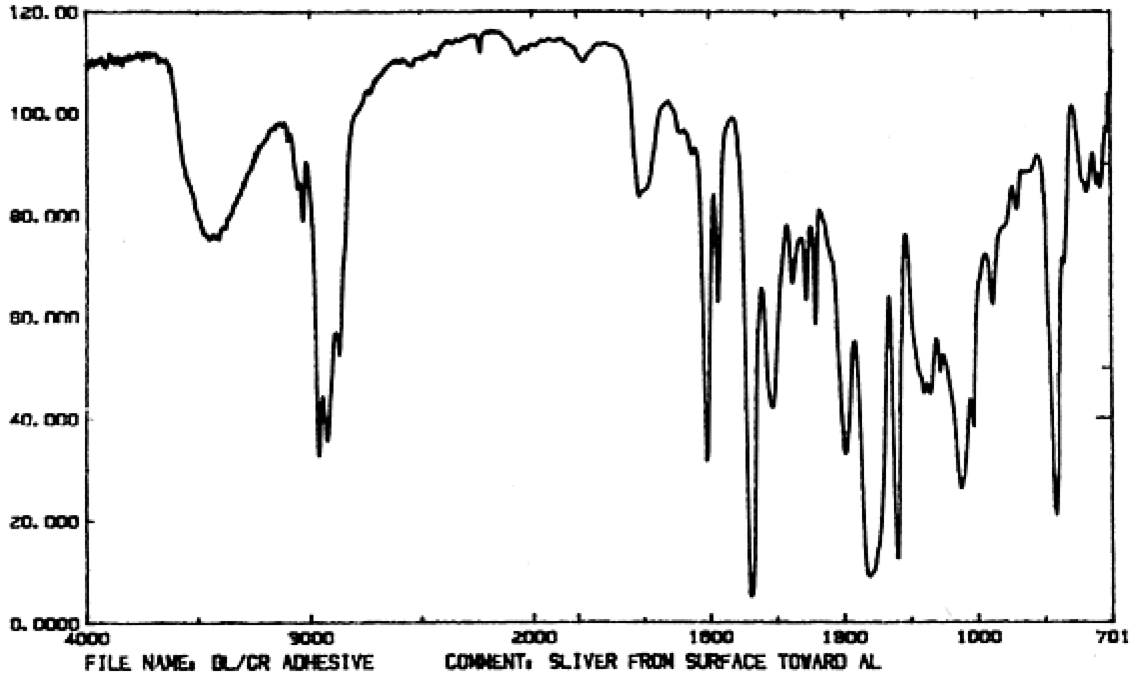

Fig. 4 Fourier transform infrared (FTIR) spectroscopy trace of an adhesive from a composite component

Following verification of the material, the next step in the investigative process is to determine glass transition temperatures and degrees of cure for all resin and adhesive systems. The assurance of a full cure is generally obtained by measuring both the glass transition temperature (T_g) and the residual heat of reaction (ΔH). These measurements are conducted using thermomechanical analysis (TMA) and differential scanning calorimetry (DSC), both standard thermodynamic instruments.

The T_g is defined as the temperature at which the matrix undergoes a transition from a glassy to a rubbery state. It is measured by inputting heat into the test sample and monitoring the rate of change of one of several materials properties, such as thermal expansion or stiffness, as a function of increasing temperature (see Fig. 5). The T_g can also be defined as the temperature at which the tangents to the curve, before and after the transition, intersect. The specimens used for determining the T_g of the material, however, must be completely dry prior to the start of the test. This is because any moisture in the composite will generally lower the T_g and give a false reading. Specimens can generally be dried out by placing them in a vacuum oven set at 60 to 95 °C (140 to 200 °F), depending on the T_g of the material, until no weight loss is noted. (It should be noted, though, that predrying TMA samples prior to T_g determination may raise the T_g of the sample over the level seen at the time of the failure. In this case, the T_g may not be representative of the in-service condition of the failed part.)

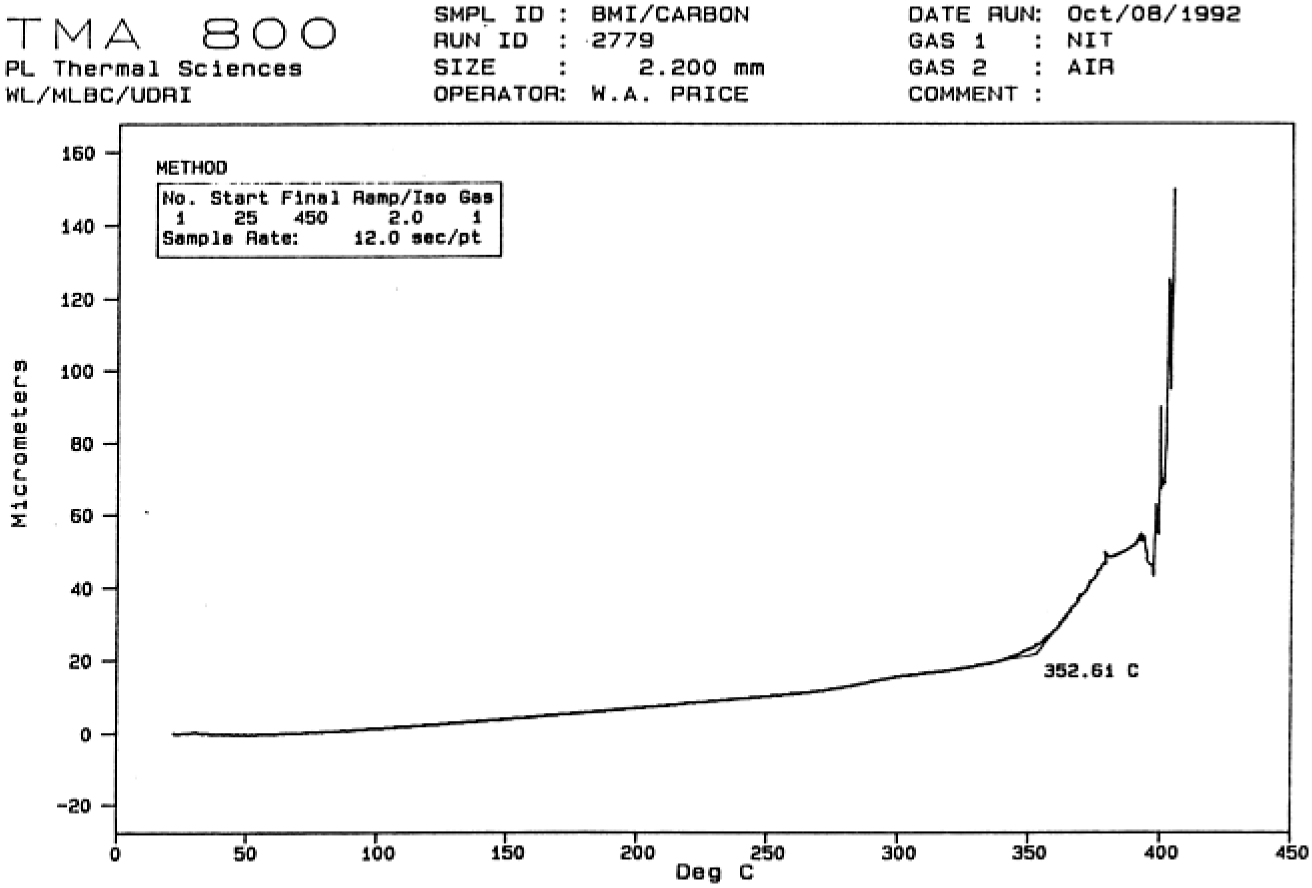

Fig. 5 Thermomechanical analysis (TMA) trace of a carbon/bismaleimide composite

If the T_g is still lower than expected after the specimen has been fully dried, then a DSC test should be conducted by inputting heat into the sample and measuring ΔH. The ΔH is basically the area under the curve on the thermogram in Fig. 6. A test specimen that has a thermogram with ΔH indicates that the specimen was not fully cured. Further analysis of the area under the curve reveals the degree of undercure in the specimen. This is done by comparing the ΔH for the test sample against that required to cure a similar amount of the original prepreg material. The two samples are each individually heated and the ΔH calculated. The ratio of the two ΔH values per gram of material is then used for determining the ratio or percentage of cure in the test sample. (It should be noted that using DSC to determine the extent of cure [and the completeness of the cure] will work well only for systems with well-defined reaction endpoints. Other systems are more difficult to characterize by this method.)

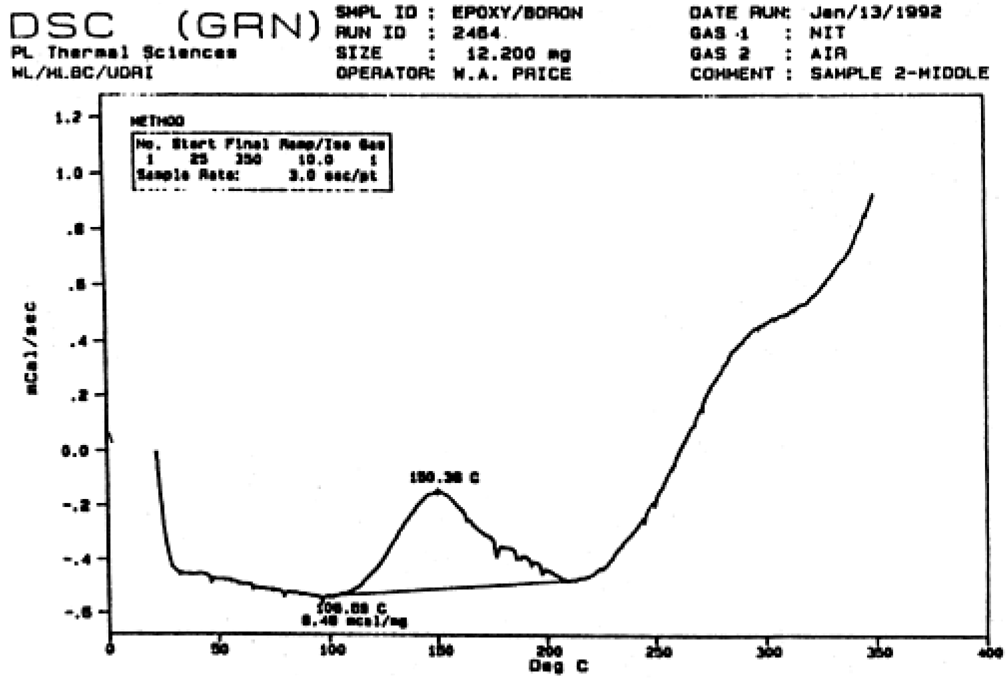

Fig. 6 Differential scanning calorimetry (DSC) trace of an undercured boron/epoxy laminate

---

Patricia L. Stumpff, Hartzell Propeller, Inc.

Determination of Fiber, Matrix, and Void Volume Fractions and Verification of Ply Lay-Up and Orientation

Composite failures can also be the result of improper fiber, matrix, and void volume fractions or incorrect ply lay-up and orientation. For determination of the fiber, matrix, and void volume fractions, two techniques are often used: the chemical matrix digestion method, and the microstructural analysis method. In the chemical matrix digestion method, the composite is first weighed in air and water to determine the density, using the Archimedean principle (that is, that a body immersed in fluid undergoes an apparent loss in weight equal to the weight of the fluid it displaces). The composite is then put into hot nitric acid until the resin is gone and nothing remains but the fibers. The fibers are then weighed, and a calculation is made to determine the volume percentages of the fibers and the resin, using standard density measurements. Fiber, resin, and void volume percentages can be determined as follows:

$$V_f = 100\frac{W_f/\rho_f}{W_c/\rho_c}$$

$$V_r = 100\frac{W_r/\rho_r}{W_c/\rho_c}$$

$$V_v = 100 - \left(100\frac{(W_r/\rho_r)+(W_f/\rho_f)}{W_c/\rho_c}\right)$$

where V is volume percent, W is weight, ρ is density, and subscripts f, r, v, and c are fiber, resin, void, and composite, respectively.

Fiber, matrix, and void volume fractions can also be determined by metallographic means, by taking several cross-sectional samples (Fig. 7) both near and away from the fracture surfaces and using image analysis techniques to determine average percentages of each constituent.

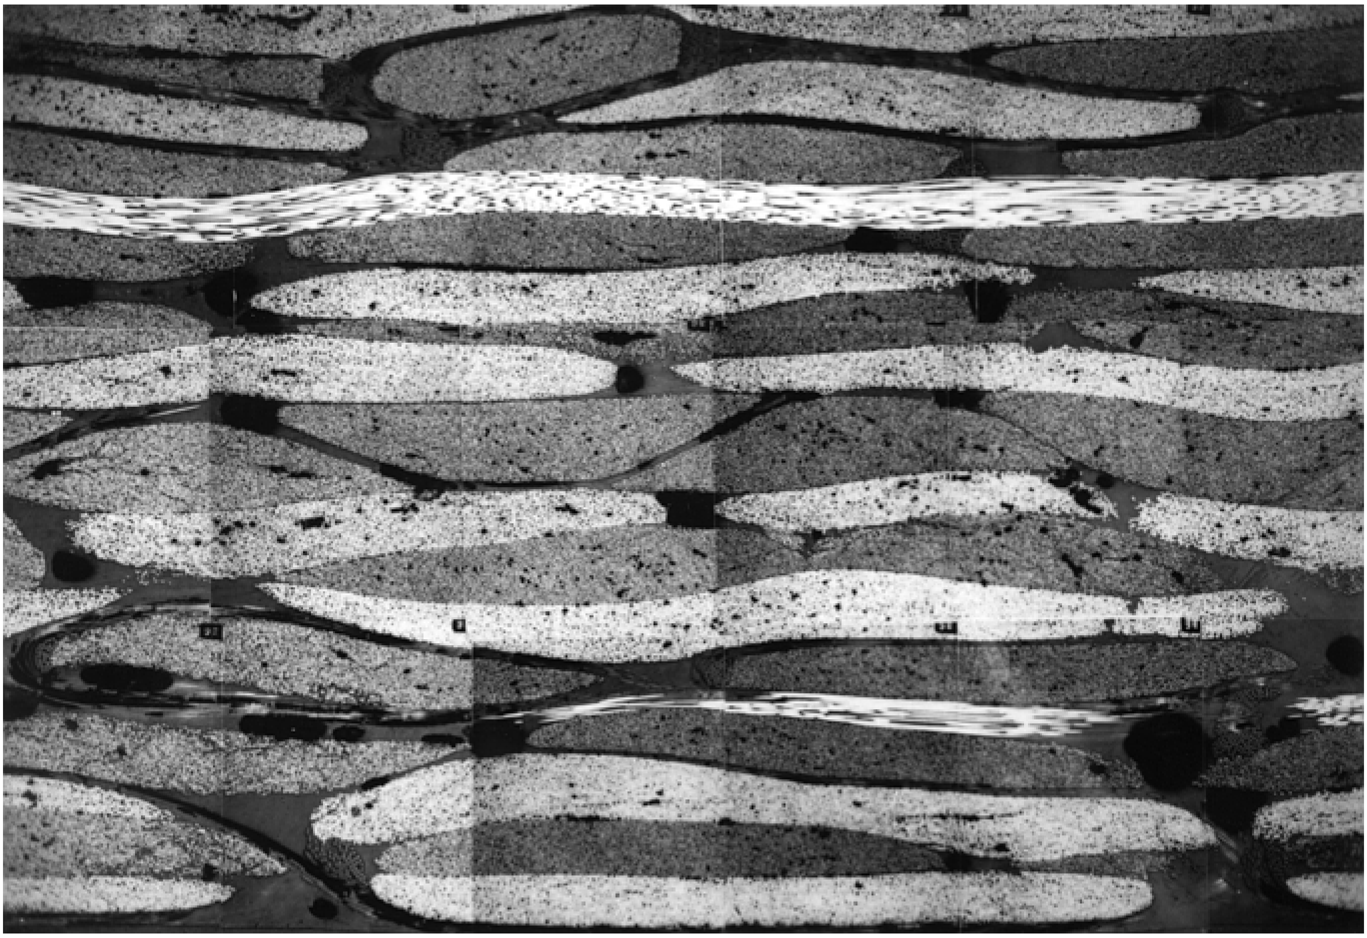

Fig. 7 Micrograph of a cross section obtained from a carbon/epoxy, resin transfer molded component

Improper ply lay-up and orientation can also be the cause of failure in composite materials. The number and orientation of plies can be examined through simple metallographic cross- sectioning procedures. The metallographic sections are cut so that they are perpendicular to the 0° or 90° plies, in order to enable relatively easy identification of the ply orientation and lay-up. Sections are then mounted using a cold mounting epoxy resin, so as not to expose the matrix material to the high temperatures used in hot presses. Mounting may not be necessary for laminate samples or for sandwich constructions if the skins are of interest. However, the examination of the core requires mounting for best results. Grinding of the samples is accomplished using standard metallographic techniques similar to that used for metallic specimens. Polishing is best accomplished with wheels covered with cloths without appreciable nap, such as nylon or silk. Diamond lapping films (9 μm) provide a good rough polish in advance of the final steps. Polymer-coated wheels can be used in lieu of cloths with alumina suspensions for final polishing steps. Etching is generally not required, because of the distinct optical differences that exist between most fiber-matrix systems. An exception to this, however, is fiberglass, for which a dilute hydrofluoric acid etch may be necessary to enhance fiber visibility.

The resin-rich regions between the plies often help in the identification of ply lay-up. Additionally, because the fibers in each of the different angular plies exhibit a different profile (round, elliptical, and so on), the orientation of the plies is also usually determined using a simple formula. Known as the fiber ellipse aspect ratio, the angles of the fiber and hence, the plies are determined from the equation:

$$\sin\theta = \frac{2b}{2a}$$

where b is the short transverse radius of the ellipse and a is the long transverse radius of the ellipse. Using cross-sectional metallography for ply orientation verification does not distinguish ±45 plies, unless the cross section is taken at a 45° angle from the normal direction of the laminate surface.

Patricia L. Stumpff, Hartzell Propeller, Inc.

Review of Composites Processing Parameters

Knowing the exact processing methods used in the manufacture of the component is also useful when evaluating failure cause. Knowing whether the part was manufactured using vacuum bag, press, or autoclave techniques enables the analyst to better understand how the microstructural characteristics of the composite may have affected the overall mechanical properties of the component. For example, autoclaved components generally exhibit better fiber, resin, and void contents and have better consolidation and higher mechanical properties than either press-molded or vacuum-bagged components. In addition to knowing what type of temperature/pressure system was used, the actual cure cycle for the component should be examined to ensure that proper pressures, ramp rate, times at temperature, and cool-down cycles were as specified by the materials supplier.

Failure Analysis Procedures

Patricia L. Stumpff, Hartzell Propeller, Inc.

Fractography and Surface Analysis

Fractography. Composites can exhibit either relatively simple or extremely complex failure modes. Complex failures may include one or more interlaminar, intralaminar, or translaminar fractures, and hence, many fracture surfaces may need to be examined. To reduce the number of surfaces for examination, a decision must be made as to which surfaces are likely to give the most useful information. This decision often represents one of the most difficult tasks involved in composite failure analysis. Generally, the selection of which surfaces to examine depends first upon the predominant failure mode exhibited by the component and second, the necessity to examine the secondary fractures in order to explain the primary fracture.

In general, fractography is used to determine failure mode, initiation site, crack growth direction, and all environmental influences on the failure. For now, it is sufficient to say that translaminar fractures can exhibit tensile, compressive, shear, flexural, or fatigue failure modes, while intra- and interlaminar fractures can exhibit both overload and fatigue in mode I tension, mode II shear, and mixed-mode failure. Additional information regarding features associated with specific loading conditions, as well as crack initiation and propagation direction and features related to environmental exposure, can be found in the article “Fractography” in this Section.

Surface Analysis Techniques. A number of chemical techniques can also be used to define surface contaminants noted during the fractographic evaluation. Some of these techniques include XPS, FTIR spectroscopy, secondary ion mass spectroscopy (SIMS), and Auger electron spectroscopy (AES).

In XPS, a sample is irradiated with x-rays, causing each element to emit photoelectrons at specific energies, thus identifying the elements present. All elements, except hydrogen and helium, can be detected by this method. Fourier transform infrared spectroscopy is a technique for identifying the basic compound or chemical family in which a foreign contaminant might belong. The technique uses a mechanism whereby infrared radiation is absorbed by the material at distinct frequencies associated with characteristic molecular vibrations in the molecules. The result is an infrared spectrum that reveals the characteristic infrared radiation frequencies that relate to the specific chemical bonds. Secondary ion mass spectroscopy is based on energetic ion beam impact of the contaminant, with subsequent ionization and removal of the surface atoms that are then detected with a mass spectrometer. A plot of intensity versus atomic mass units is generated. This technique is used when XPS cannot provide sufficient sensitivity or chemical information regarding the contaminant, but does

not work very well on nonconducting composite surfaces. Auger electron spectroscopy is a technique based on the induced Auger electron emission characteristic energy for each element. Many instruments are capable of performing both AES and XPS, but because AES requires a conductive specimen, its application is limited in composites.

Failure Analysis Procedures

Patricia L. Stumpff, Hartzell Propeller, Inc.

Mechanical Testing and Stress Analysis

Mechanical testing is often used in an investigation to determine the effect of various defects or environmental influences on the material. For example, mechanical testing may be required to determine the reduction in compressive properties of a skin or spar that exhibited excessive fiber waviness, high levels of porosity, weak fiber-matrix interfaces, or impact damage that resulted in an undetected delamination. Similarly, tensile or fatigue testing might be required if it is determined that the maximum or minimum loads experienced by the component were more than expected, if the number and/or orientation of the plies was different in the part than specified in the design, or if there was an undetected fatigue load noted on the part. Mechanical testing of composite materials is generally conducted using typical ASTM standards. Some of the more common test methods for composites include:

ASTM No.	Title
D 790	Standard Test Methods for Flexural Properties of Unreinforced and Reinforced Plastics and Electrical Insulating Materials
D 2344/D 2344M	Standard Test Method for Short-Beam Shear Strength of Polymer-Matrix Composite Materials and Their Laminates
D 3039/D 3039M	Standard Test Method for Tensile Properties of Polymer-Matrix Composite Materials
D 3410/D 3410M	Standard Test Method for Compressive Properties of Polymer-Matrix Composite Materials with Unsupported Gage Section by Shear Loading
D 3479/D 3479M	Standard Test Method for Tension-Tension Fatigue of Polymer-Matrix Composite Materials
D 4255/D 4255M	Standard Guide for Testing In-Plane Shear Properties of Composite Laminates

Further information regarding mechanical test methods can be found in the article "Lamina and Laminate Mechanical Testing" and in other articles in this Volume.

Stress Analysis. In most cases, an accurate understanding of the loads and stress levels in component operation is one of the critical ingredients involved in defining the source of failure. Although fractographic and visual methods of analysis may identify the origin, direction, and mode of crack propagation, stress analysis is the technique that most often provides the quantitative explanation for the failure cause. Through this analysis step, engineers involved in future or corrective redesigns are provided with direct feedback regarding the actual loads experienced by the component, poor design practices and configurations, and the effectiveness of the analysis methods used in the design.

Stress analysis procedures for composite materials can be relatively complex, and because they are fabricated by the lamination of highly anisotropic plies, a nearly infinite variety of directional moduli and strengths can be achieved. Because of this tailorability, a different set of materials properties must be considered for each failure examined. As a further complication, because of their laminated and anisotropic construction, significant variations in stress can exist within the laminate itself. As a result, consideration must be given to failure at the microstructural, or individual ply, as well as the gross, or overall, laminate levels.

Typically, analyses at the individual ply level provide the greatest level of detailed information. This method basically predicts materials properties by modeling the composite as a plate built up from individual plies. The calculated properties may include the effect of hygrothermal expansion, moisture diffusivity, and density of the

composite, but are, in general, estimated from individual fiber and resin properties using micromechanics equations. Through this method, the stiffness characteristics of the overall laminate can be determined for the general case of in-plane and/or flexural loads. Based upon this stiffness, the gross stress generated for any given load can be calculated.

However, as noted previously, consideration must also be given to the stresses carried by each individual ply. These stresses depend on the modulus and orientation of each ply and can be determined using basic lamination theory. One of the chief advantages of lamination theory is its ability to quantify these stresses and to examine them on an individual ply level. Although lamination theory provides a powerful tool with which to examine the stress state operating within a composite, there are several disadvantages. The most notable of these is in its application in predicting the onset of failure. Such predictions are achieved by evaluating the stress within each individual ply against semiempirical models that define the maximum stress envelope to which a ply can be exposed without failure. However, predictions of the onset of interlaminar and intralaminar failure using such criteria have not been entirely successful. One of the reasons for this lack of success centers around the fact that standard lamination theory is unable to predict the three-dimensional state of stress that exists in laminates near free edges and other discontinuities, such as holes, cut-outs, and ply drop-offs.

Various approaches can be used, however, to predict the three-dimensional state of stress within a laminate. Typically, these methods, including finite-element analysis, generalized plane strain, three-dimensional elements, and approximate strength-of-materials methods (Ref 1), are relatively specific. Using these methods, failure criteria based on principles of fracture mechanics (Ref 2) have been somewhat successful in predicting the onset and growth of interlaminar and intralaminar matrix damage, including fatigue effects.

The prediction of catastrophic failure at the laminate level has followed two distinctly different approaches. The first, which may be referred to as a statistical approach, uses coupon test data to determine the maximum allowable strains for each laminate design. From this, traditional methods of stress analysis can be applied, load versus area, to determine the occurrence of failure, without regard to individual ply or interlaminar stresses. In this case, failure occurs when the statistically determined maximum allowable strain is exceeded. The second approach to predicting translaminar failure involves a more mechanistic approach in which the load redistribution due to intralaminar and interlaminar matrix damage is taken into account. In its simplest form, this approach can be applied directly with lamination theory and has been referred to as the global ply discount method (Ref 3). Applications of this method rely on a predetermined definition of characteristic intralaminar and interlaminar damage. Using the lamination theory, the state of stress surrounding this damage is defined, and the magnitude of the applied load necessary to create failure is determined.

Conclusions

This section was aimed at describing some of the numerous techniques used in the analysis of failed composite structure. Although the techniques described are not all-inclusive by any means, it is hoped that the number and variety of techniques outlined in this section are adequate for an investigator to begin his analyses. Further information regarding composite failure analysis techniques, fractographic data, and case history studies can be found in Ref 4. More detailed information on failure analysis in general can be found in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook.*

Visual Analysis, Nondestructive Testing, and Destructive Testing

Patricia L. Stumpff, Hartzell Propeller, Inc.

Introduction

MECHANICAL AND ENVIRONMENTAL LOADINGS cause a variety of failure modes in composites, including matrix cracking, fiber- matrix debonding, delamination between plies, and fiber breakage. A cumulative state of damage for a composite includes a percentage of each of these loading-related failure modes as well as materials defects originating from processing, which include voids, fiber-rich or matrix-rich regions, fiber misalignment, and laminate stacking errors. The integrated effect of the cumulative damage state of the composite results in the final failure mode. Therefore, to analyze and understand a composite failure, one must recognize the complexity and extent of damage that might have been present before final failure.

Visual analysis, nondestructive testing, and destructive testing are all important techniques in failure analysis of composites. Visual analysis usually is the first and perhaps most important step in failure analysis. In many cases, the diagnosis can be made by visual examination, and testing is performed to confirm or contradict it. Many experimental nondestructive and destructive test techniques have been developed to measure damage levels in composites. Nondestructive testing (NDT) techniques may be categorized as field (bulk) methods or detail (micro) methods, depending on the type of information they yield. Field methods provide test parameters that are a function of the volume of material interrogated by the NDT technique, but do not provide microscopic information on the actual type of damage present. Detail methods provide information on the microscopic damage state. As a general rule, two or more NDT methods should be used to provide complementary information on the state of damage to composites. This article summarizes useful NDT methods for failure analysis; more detail on NDT techniques is provided in the article "Nondestructive Testing" in this Volume. Destructive techniques are quite useful in the laboratory for evaluating materials response, but obviously have limited use for in-service applications.

Visual Analysis, Nondestructive Testing, and Destructive Testing

Patricia L. Stumpff, Hartzell Propeller, Inc.

Visual Analysis

Visual analysis of failed polymer-matrix composites can provide a significant amount of information regarding failure cause. In particular, examination of a composite fracture can be useful in determining the crack initiation site, crack growth direction, fracture sequence, and failure mode.

Crack Initiation, Growth Direction, and Failure Mode. For transverse fractures, initiation site and crack growth direction can often be ascertained by an analysis of the crack pattern. Transverse cracks in a laminate can exhibit the feature known as crack branching, with increases in the number of the branches generally indicative of increasing crack propagation direction. In Fig. 1, the branched crack in the graphite-epoxy wing box is indicative of crack growth in the component from right to left. Other features visually apparent on the fracture surfaces are indicative of failure mode. Figure 2 reveals a transverse fracture of a graphite-epoxy composite wing section, which failed in bending. The upper skin surface exhibits a relatively flat fracture surface with minimal fiber pullout, indicative of a compressive failure, whereas the lower skin surface exhibits a roughened fracture surface with extensive fiber pullout, indicative of tensile failure.

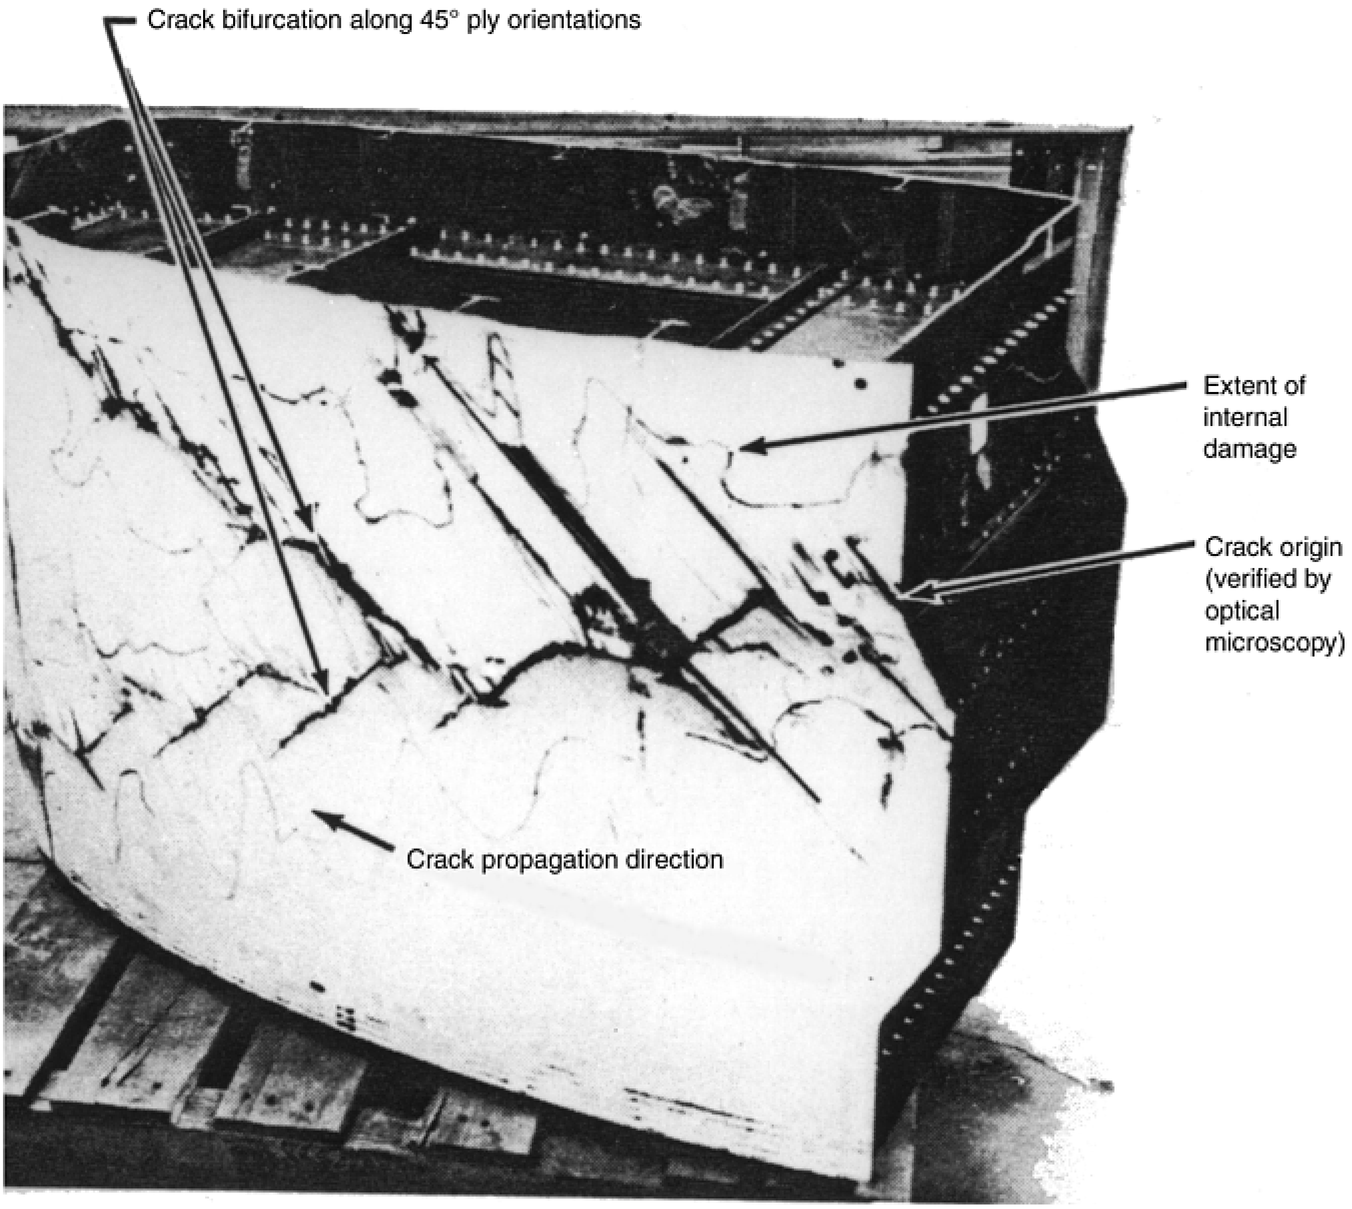

Fig. 1 Crack branching indicative of crack growth direction in transverse fractures. ~0.02×

Fig. 2 Flexural failure of a graphite-epoxy wing box. ~0.03×

For delaminated fracture surfaces, crack initiation and crack growth direction may be ascertained using the fracture feature known as banding. Banding, identified by the white arrows in Fig. 3, often appears on delaminated surfaces formed following a Mode I tensile or mixed- mode failure of the specimen. Banding generally indicates crack growth direction from the convex to the concave side of the bands, with the banding in Fig. 3 depicting crack growth from left to right.

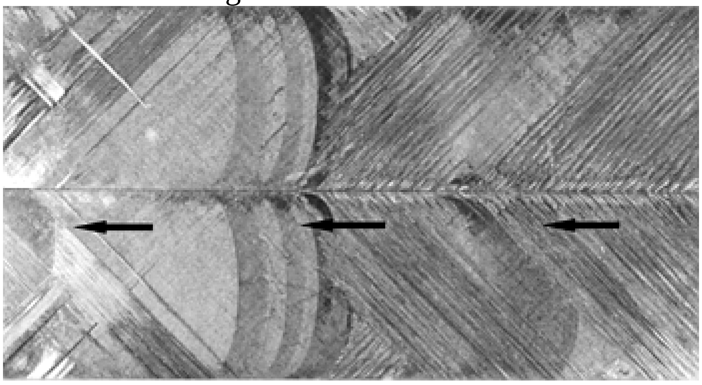

Fig. 3 Delaminated surface revealing beach marks (arrow) indicative of mixed-mode failure in a graphite-epoxy laminate. ~0.7×

Other features on the delaminated surfaces are indicative of failure mode. In graphite-epoxy materials, Mode II shear failures are generally less reflective than Mode I tensile failures. Mode II shear failures generally exhibit a dull, "whitish" appearance, whereas Mode I tensile failures generally exhibit a shiny, black surface appearance. The difference in reflectivity between these two failure modes is thought to be due to the difference in actual fracture features, with hackles formed on surfaces failed in shear, and river patterns formed on the surfaces failed in tension. The differences in reflectivity not only help in the interpretation of Mode I tension versus Mode II shear failure, but can also help in the identification of prior impact damage in a laminate. A graphite-epoxy laminate with internal delaminations due to impact damage was opened at a delaminated surface by Mode I tensile loading. One side of the partially delaminated, and now fully separated, surface is shown in Fig.

4. The internal delamination (area surrounded by arrows in the figure) resulting from the impact damage exhibits a whitish appearance, whereas the newly separated, Mode I tensile failure had a dark, reflective surface appearance. The differences in reflectivity are thought to be the result of the differences in failure modes, with the impact region in this specimen more representative of a combination of compression and Mode II shear failure, and the separated region more indicative of Mode I tensile failure.

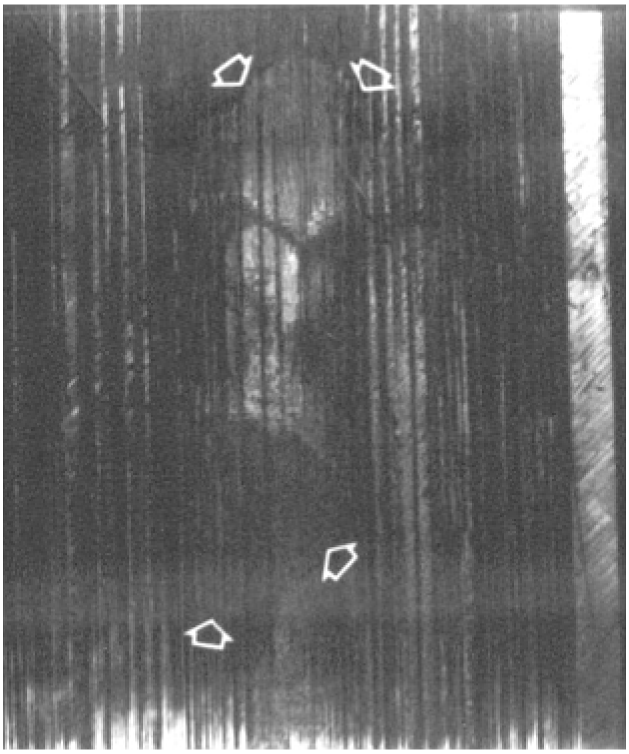

Fig. 4 Reflectivity differences on a delaminated fracture surface indicative of impact damage. ~0.5×

Other fracture features can also be indicative of crack growth direction and failure mode. Figure 5 is a photo depicting numerous small cracks found in the resin of a fractured, graphite-epoxy wing spar. These cracks were visually evident and progressed along the length of the delaminated spar interfaces. Further investigation into the cause of the spar failure revealed that it failed as a result of the wings going into a flutter-failure mode, which then resulted in the extensive, progressive cracking noted along the length of the spar. Further evidence of a dynamic failure such as flutter was found on the transverse fracture surfaces of the spar. The transverse fractures exhibited extensive smearing of the entire fracture surface, a feature not generally found in overload failures of a component.

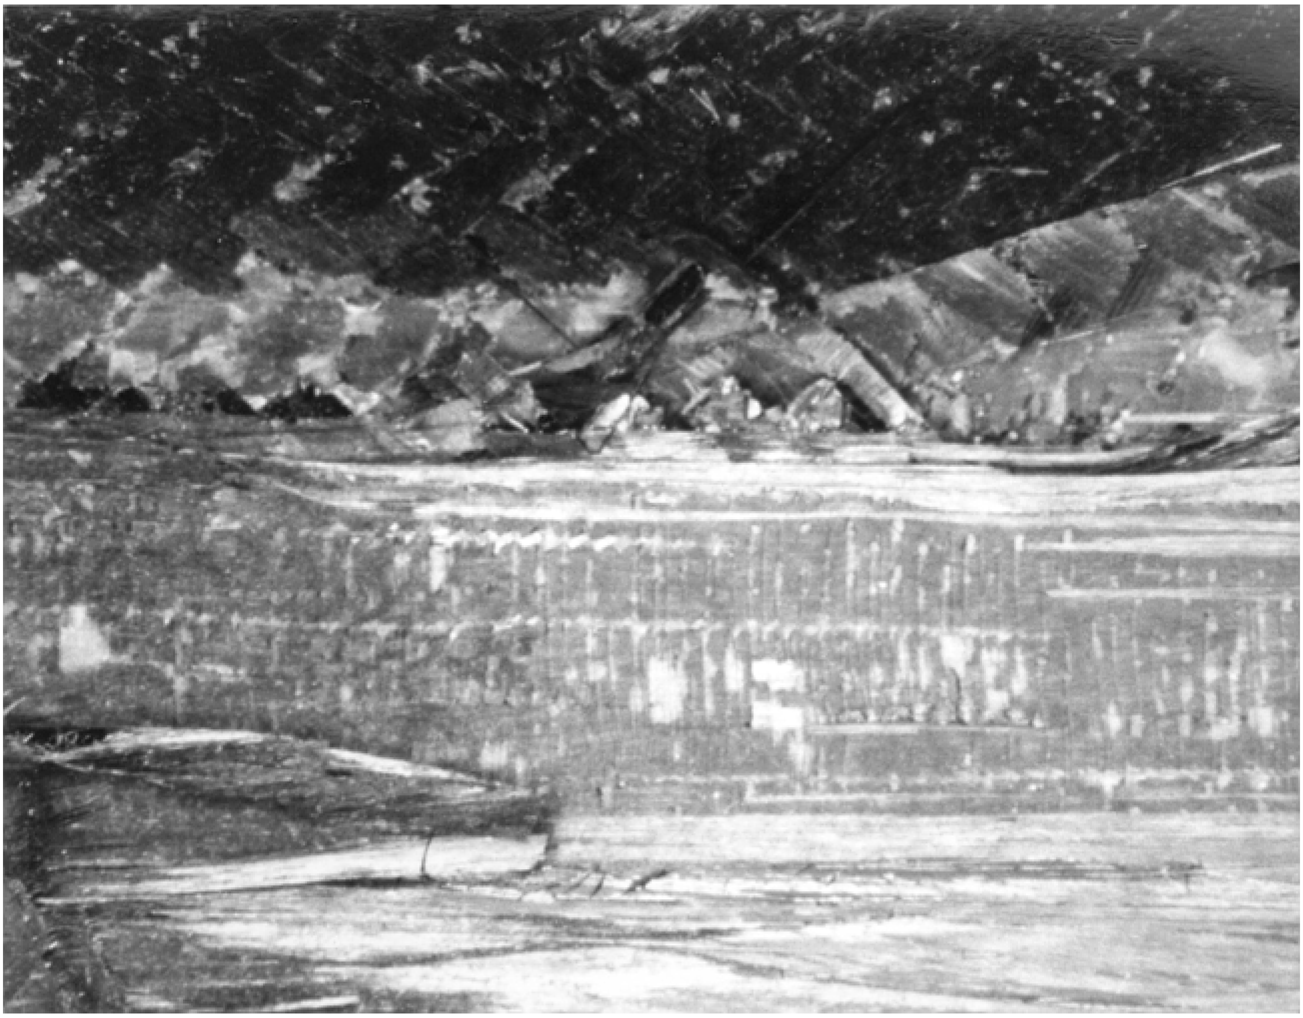

Fig. 5 Longitudinal cracks on a delaminated fracture surface indicative of progressive fracture. ~5×

Fracture Sequence. In addition to crack growth direction and failure mode, however, composite materials often require the determination of fracture sequence in order to identify an initiation site. Fracture initiation and sequence in composite materials can sometimes be difficult to determine, although detailed fractographic analyses of the fracture surfaces can help. Figure 6 depicts a cross section of a composite specimen that was overheated on one side of the sample and then failed in compression. The failed specimen contains both delaminated and transverse fractures. To determine whether the delamination(s) occurred prior to the transverse fracture, the following techniques can be employed. Figure 7 depicts mating fracture surfaces of a delamination obtained from a complex specimen failed in compression. The failed specimen itself exhibited numerous transverse fractures and delaminations, but not all the plies exhibited transverse failure. In this case, only one of the two neighboring plies exhibited a full transverse fracture. Upon examination of the ply without the complete transverse fracture, evidence of the transverse cracking and damage of the opposite ply (reference the damage between the two arrows) can be seen. The fact that the transverse fracture of one ply is evident on the surface of the delaminated ply most probably indicates that the two plies were not delaminated or separated prior to the transverse fracture of the first ply. It is also possible, however, that the two plies were initially delaminated, but not actually separated, when the transverse fracture occurred.

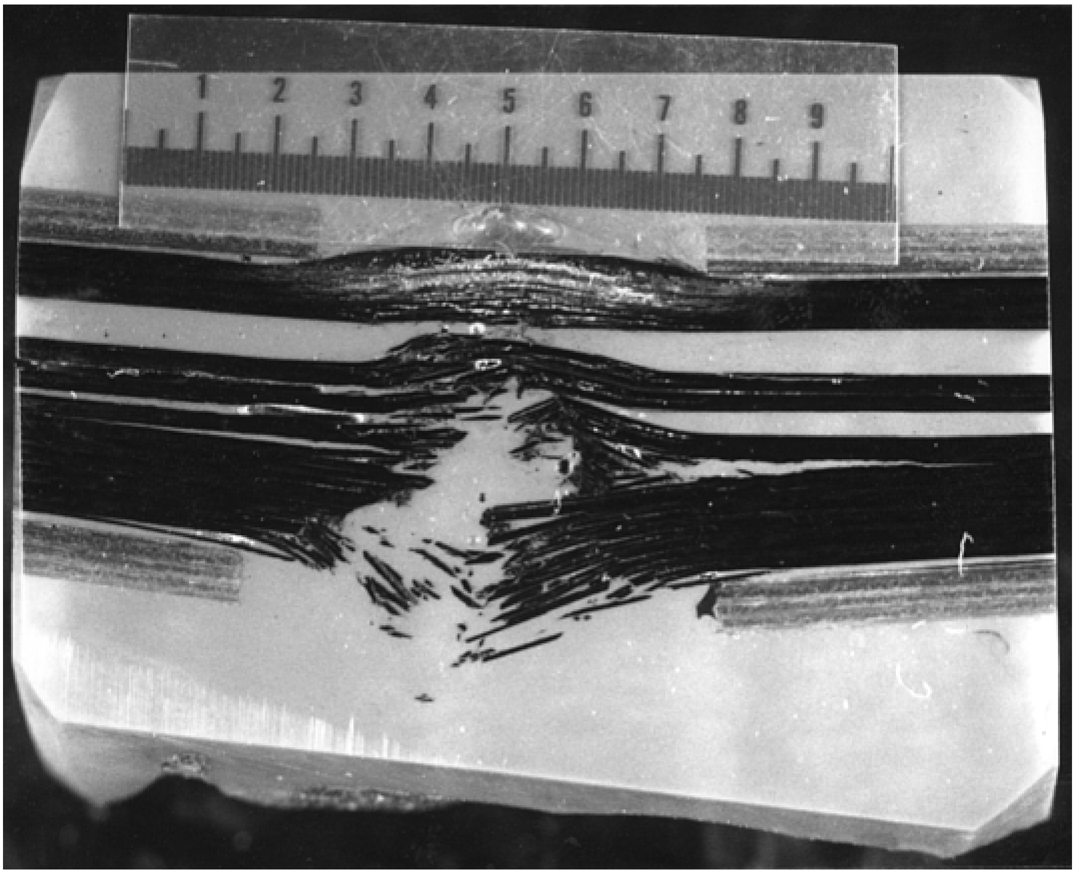

Fig. 6 Cross section of a composite laminate, which failed in compression, containing both delaminations and transverse fractures for examination of fracture sequence. ~2×

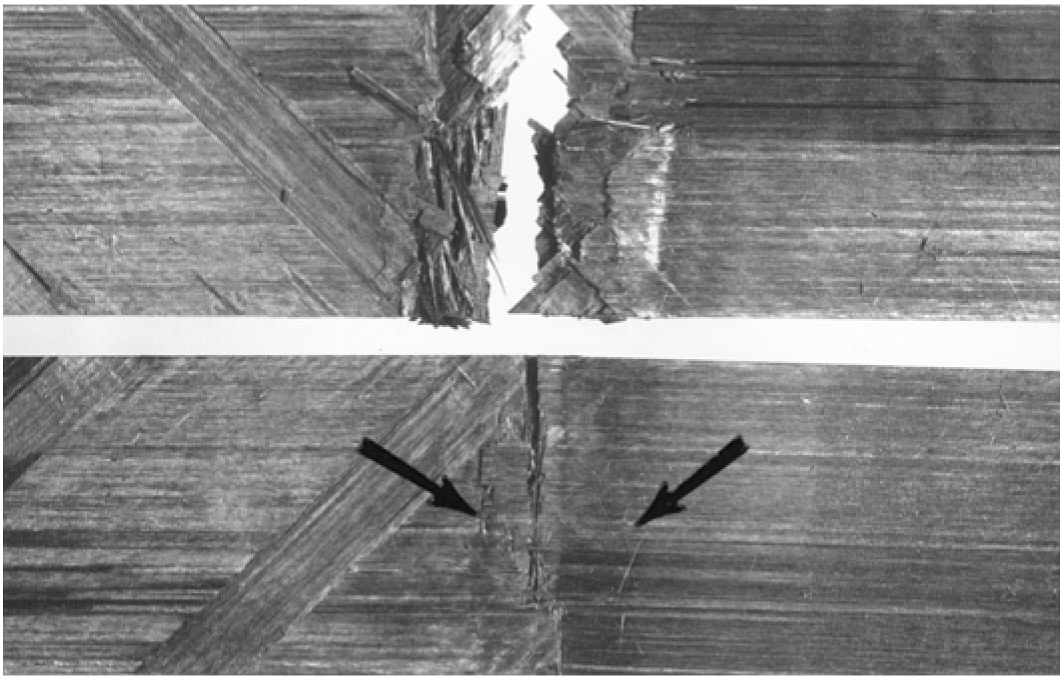

Fig. 7 Examination of separated plies in a graphite-epoxy laminate to determine sequence of fracture. ~0.8×

Figure 8 also depicts how fracture sequence information can be gleaned from visual examination of the fracture surfaces. In this figure, numerous transverse cracks are evident in the thick adhesive layer between the wing skin and its mating spar. The cracks in the adhesive are curved, with the convex surface toward the inboard side of the wing, and the spacing between the cracks increasing as the cracks move outboard. This curvature and increased spacing of the transverse fractures in the adhesive indicate that the fracture initiated at inboard section of the wing and progressed outboard. Additionally, because the transverse cracking in the adhesive is evident

on the surfaces of both the wing spar and the wing skin, it is believed that this transverse cracking in the adhesive is the cause of the skin/spar separations. Had there been any separation of the skin or the spar from the adhesive prior to the transverse cracking, no evidence of adhesive cracking would have been found on the separated surface. Evidence of the transverse cracks in the adhesive, however, was noted on both skin and spar surfaces throughout the failure location.

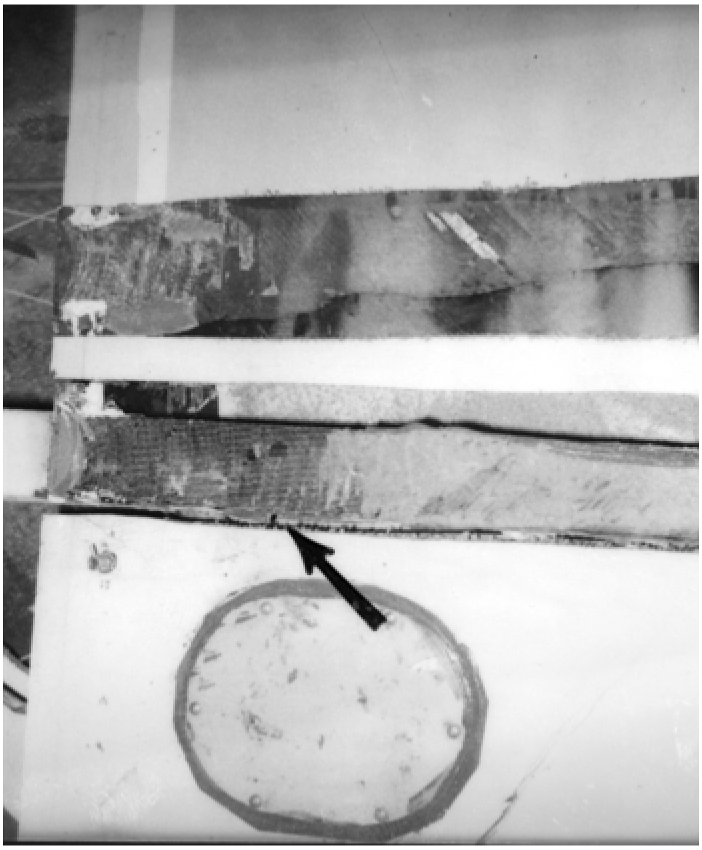

Fig. 8 Mating fracture surfaces of an adhesively bonded wing skin and wing spar. ~0.2×

Other Information from Visual Analysis. Other information about the failure can be obtained from a visual analysis of the variations in the color of the resin and/or the adhesive. Variations from the original resin/adhesive color can be indicative of moisture absorption, undercure, overheat exposure, or the actual amount of resin or adhesive on the surface or within the plies.

Visual Analysis, Nondestructive Testing, and Destructive Testing

Patricia L. Stumpff, Hartzell Propeller, Inc.

Nondestructive Test Techniques

Determining failure modes in a composite is often better performed before final catastrophic failure. Incrementally studying the mechanical state of the composite that is a result of previous loading is useful even though no definitive knowledge exists as to how the final failure event itself would have been related to the damage state prior to failure. Nondestructive tests are performed prior to final failure either in real time—by continuously monitoring the composite during service (or testing in the laboratory)— or at selected service intervals by removing the composite from the load environment to perform the tests. Nondestructive testing is also performed on components after failure, but just prior to destructive analysis.

The lack of definition as to what constitutes “important” damage necessitates searching for all indications of damage. Because NDT methods have different sensitivities to different types of damage, it is usually necessary to apply several NDT techniques to the same specimen to obtain complementary information on the damage

state. In addition to matrix cracking, fiber- matrix debonding, delamination between plies, and fiber breakage, all of which are loading-related damages, other important types of damage resulting from the manufacturing process are voids, foreign objects, misalignment of fibers, and either bunching or lack of fibers.

To monitor damage progression in composites, a number of NDT methods used with homogeneous materials have been modified and adapted. These techniques include edge replication, stiffness measurement, radiography, ultrasonics, acoustic emission, and thermography.

Surface or edge replication is a technique that has found wide application by materials scientists studying surface topography. Because replication tape is typically used to record the surface topography along the edge of a composite laminate, the method is known as edge replication. The technique only requires application of: cellulose-acetate tape (or solution) to the surface, a solvent such as acetone to one side of the tape to soften and partially dissolve it, and a small amount of pressure to the back side of the softened tape so that it will conform to the surface of the material. When the tape hardens, it can be removed from the surface and will carry with it a record of the surface topography at the time the replica was made (Fig. 9).

Fig. 9 Edge replica of graphite-epoxy specimen

This technique was first applied by D.O. Stalnaker and W.W. Stinchcomb (Ref 1) to the study of composites. Since their early work, edge replication has been used by a large number of investigators and is currently recognized as a standard technique for following the development of damage in composites. J.E. Masters and K.L. Reifsnider (Ref 2) applied the technique extensively to composite laminates and found that it provided a very good record of damage progression. Information on damage at the specimen edge provides an accurate record of the transverse cracks occurring in the specimen. Evidence suggests that, at least for laboratory-sized specimens, the cracks observable along the edge run through the entire width of the specimen.

Edge replication can be used to ascertain the degree to which the "characteristic damage state" has been achieved. This concept, developed by K.L. Reifsnider et al. (Ref 3), describes the state at which a saturated number of transverse cracks develop in each off-axis ply of a composite laminate as a result of tensile loading. Attaining the characteristic damage state corresponds to the knee of the bilinear stress-strain curve in a number of laminates (Ref 3).

Stiffness. The elastic modulus of a composite laminate can be predicted using classical laminate theory (Ref 4) based on the concept of ideal laminate behavior; that is, it assumes that each lamina has its respective elastic properties and is bonded to its neighbor without delaminations, and that no damage exists in the laminae to affect their individual elastic properties. As a laminate is quasi-statically loaded to high stress levels or fatigue loaded, damage (such as transverse cracking) develops in the plies. This damage affects laminae stiffnesses and results in as much as 20 to 30% stiffness degradation of the entire laminate, depending on the laminate stacking sequence.

Stiffness degradation in a graphite-epoxy laminate resulting from fatigue loading is shown in Fig. 10. Each of the tensorial stiffness components is affected to some degree (Ref 5). Therefore, stiffness measurement is an acceptable technique for monitoring the degree of damage development in a material. Following the work of T.K. O'Brien and K.L. Reifsnider (Ref 5), stiffness measurements can be made for each of the in-plane tensor elastic moduli. In general, a better correlation between stiffness degradation and damage development is obtained when measurements are made over a relatively large specimen length. For example, when using extensometers, a 5 cm (2 in.) gage length will give better results than a 2.5 cm (1 in.) gage length because the greater the length integrated, the more inhomogeneities in the damage state can be averaged out.

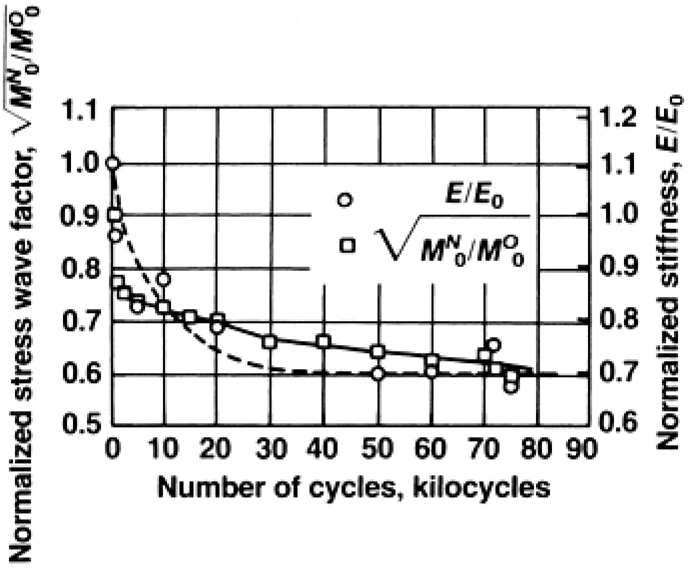

Fig. 10 Change in acousto-ultrasonic stress wave parameter during fatigue test of graphite-epoxy specimen

Radiography is an NDT technique that can provide extensive and detailed information on the state of damage. A variety of penetrating particles and rays, including neutron, gamma, and x-ray, are used to study composites. Detailed information on radiography techniques is provided in the article "Nondestructive Testing" in this Volume.

Ultrasonic techniques are most frequently used for nondestructive inspection of composites. Various materials properties, including stiffness (through the measurement of elastic wave speeds), volume fraction of voids, and attenuation, in addition to various damage modes, including delamination and matrix cracking, are monitored by different ultrasonic methods. Velocity measurement, attenuation measurement, C-scan, and acousto-ultrasonics are ultrasonic techniques that are related, but are distinguished differently, depending on how the data are obtained, analyzed, and presented. Detailed information on ultrasonic testing techniques is provided in the article "Nondestructive Testing" in this Volume.

Acoustic emission **(AE)** is a phenomenon familiar to metallurgists; mechanical twinning in tin and tin alloys is known as "tin cry." Composite materials are equally noisy under load, particularly during quasi-static tension testing; therefore, AE has received significant attention as a technique for monitoring damage development in composites. An article by M.A. Hamstad (Ref 6) reviews use of AE as a tool for composite material studies,

including the following studies, which are pertinent to damage analysis: time- dependent composite properties, impact, relationship of AE-detected damage to other measures of damage, interface, and environmental effects.

Many researchers have attempted to develop AE testing to the point that different failure modes could be distinguished by their respective acoustic emissions. However, no definitive conclusions can be made at present. Several authors have suggested that failure modes might be distinguished by grouping received signals according to energy levels; Ref 7 indicates that there are three distinct energy-level groupings that indicate the differing amounts of energy emitted from fiber breakage, matrix cracking, and delamination. Additional studies of AE in composites need to be performed.

Thermography, or surface mapping of isothermal contour lines, can be performed through a variety of techniques, but use of a video-thermographic camera is the most efficient and offers the highest resolution.

Because matter emits infrared radiation with an intensity dependent upon its absolute temperature and surface emissivity, infrared energy- sensitive sensors can be used indirectly to measure the temperature of the emitting surface. Other materials parameters, specifically surface emissivity, affect the intensity of the emitted radiation and thus the value of the measured temperature. However, as the only concern is relative temperature differences (as in nondestructive inspection for damage), this is of minor concern as long as care is taken to condition the examined surface to ensure that the emissivity is as uniform as possible across the entire surface.

Thermography has been used by a number of investigators to detect and analyze damage in composites (Ref 7, 8, 9, 10, 11, and 12). Thermal gradients are generated using either a passive or active method to delineate defects or damage. In the passive method, an external heat source is applied to the material. Heat may be conducted either into or away from the examined object by an external heat source of either higher or lower temperature. In the active method, energy is applied in a form other than thermal, such as electrical or mechanical energy. Heat is generated by internal mechanisms that transform the applied energy into thermal energy. In either method, differences in the local properties of the material affect heat conduction or heat generation through the region surrounding the damage, thus delineating areas of damage. Both the passive and active methods have been used to examine composites (Ref 11, 12).

Additional information on thermography is provided in the article “Nondestructive Testing” in this Volume.

Destructive Test Techniques

Destructive test techniques are also useful for studying damage in composite materials whether the objective is to develop fundamental knowledge of materials response in the research laboratory, or to analyze a materials failure. Most of these techniques are similar to those used to evaluate homogeneous metal and alloy systems. Therefore, only those two methods peculiar to studying composite failures are described here.

Matrix digestion techniques are used to determine fiber and void-volume fractions in both metallic- and organic-matrix composites. The volume fraction of the fiber present is an important aspect of failure analysis because it is used to determine the apparent strength and modulus of the reinforcing fibers in the composite. Void content is one indication of the quality of the fabrication process and resulting material.

Standard test methods (Ref 13, 14) have been established for both metallic- and organic-matrix composites. The test procedure requires a sample of the material to be weighed and its volume determined by a fluid displacement technique so that the density of the composite can be calculated. The sample is then placed in a hot, liquid medium that can specifically digest the matrix. The mixture is filtered, and the residue is dried and weighed to determine the amount of fiber present. If the density of the fiber is known, the volume fraction of fiber, V_f, present in the composite sample is:

$$V_f = \frac{(W_f / \rho_f)}{(W_c / \rho_c)} \qquad \text{(Eq 1)}$$

where W_f is the fiber weight, W_c is the composite weight, ρ_f is the fiber density, and ρ_c is the composite density. If, in addition, the matrix density, ρ_m, is also known, the same measurements can be used to calculate the volume fraction of void content, V_v, present in the sample:

$$V_v = 1 - \left\{ \frac{\left[W_f/\rho_f + (W_c - W_f)/\rho_m \right]}{(W_c/\rho_c)} \right\} \qquad \text{(Eq 2)}$$

It is sometimes necessary to make corrections for loss of fiber material during the digestion process if the fiber material has some degree of solubility in or reactivity to the digestion mixture.

The deply technique developed by S.M. Freeman (Ref 15) provides information on the discrete nature of fiber fracture in the interior of a layered composite and is presently used with organic-matrix composites. A sample

is heated for a predetermined time period at a temperature sufficient to partially pyrolyze the resin matrix. This process diminishes the interlaminar bond strength to the point that the individual plies can be easily separated by simply applying a piece of adhesive tape to the top lamina, peeling it off, and continuing in the same manner through the laminate, ply by ply. Each lamina can then be examined in an optical or scanning electron microscope (in the latter case, after applying a graphitic or metallic surface coat using a sputtering technique, if fibers are electrically nonconducting). Individual broken fibers can then be easily detected.

Freeman also observed that an image-enhancing agent could be used to delineate in each ply the regions adjacent to delaminations or matrix cracks. This is accomplished by applying a gold chloride solution to the composite before pyrolysis to penetrate cracks and delaminations. During pyrolysis, the solution breaks down and leaves a residue of gold, which demarcates any crack or delamination. When viewed under the microscope, the relationship between broken fibers and cracking/delamination is easily deduced (Ref 16).

Additional information about destructive tests for composites is provided in the Sections “Quality Assurance” and “Testing and Certification” in this Volume.

Introduction

MICROSCOPY is a valuable tool in materials investigations related to problem solving, failure analysis, advanced materials development, and quality control. Microscopy has been used for many decades to provide insight into the microstructure and macrostructure of fiber reinforced composites (FRC). The most widespread use of microscopy for composites is determining void content, ply counts, and fiber orientations. While this makes up the majority of analysis, the investigation of failure mechanisms and microstructural analysis is also common. Furthermore, insight into fiber morphology, matrix modifiers, fillers, and process parameters of composite materials are also elucidated using microscopy techniques.

For most cases, standard reflected light microscopy provides most of the necessary information one would desire. In some cases however, etchants, stains, or dyes may be required for further clarification of the morphology or crack identification. If reflected light techniques do not yield the required information, transmitted-light optical microscopy can provide insights into the microstructures of materials that would otherwise remain hidden when using standard bulk metallographic preparation techniques and reflected illumination. Because most polymeric materials are inert to metallographic etchants, they can be best observed with transmitted polarized light and various contrast media to enhance the differences in refractive index of discrete phases in the composite.

Although an array of different types of composite materials are in use today, the utilization of both thermosetting and thermoplastic (polymer) matrix fiber reinforced composites (PMC) continues to dominate the field in terms of both volume and applications (Ref 1). This is due to easy processing, a wide range of materials and properties, and a much lower cost than that of other composite materials, such as metal matrix (MMC) and ceramic matrix composites (CMC). While not to discount the limited use of other types of composites, all of these heterogeneous and anisotropic materials have unique properties and characteristics lending their use in specific applications.

Throughout this article, the easiest, most cost- effective, and reproducible techniques the authors have found for sample preparation, polishing, and analysis are emphasized. The most common types of composite materials, PMC, are the primary focus, but preparation methods for other composite materials are also discussed.

Sample Preparation

Sectioning. The first question to ask when analyzing a composite material with light microscopy is what type of information is desired. Once this is determined, the part or sample must be systematically and meticulously documented and labeled. After labeling the samples, the composite part typically needs to be sectioned so that it is manageable for polishing. It is important in this stage that no damage is done to the specimen so that artifacts

are not introduced. Therefore, when sectioning the part, never use a band saw with a tooth blade, because it may damage the specimen. Instead, use an abrasive band saw to cut large parts down to a manageable size. Rough cutting may be performed without lubrication or cutting fluids; however, a vacuum apparatus should be used to minimize dust. For final composite specimen cutting, an abrasive cut-off saw with coolant should be used to minimize damage to the specimen. The use of coolant is necessary since increases in temperature during cutting can alter the microstructure of polymer matrices. In general, thin blades reduce damage and material loss; however, thin blades may bend, resulting in a nonplanar surface. Additionally, thin blades are more likely to break during cutting that can be quite costly.

In some cases, if the sample is small enough or after rough cutting, it can be ground down to the required size with the use of 60 or 120 grit silicon carbide (SiC) paper. It is important to realize that the use of 60 grit paper can damage the specimen, so care must be taken when using it for grinding. To use this technique, the ground edge of the sample must be stout enough so that it is not destroyed during the removal process or distorted. For thin materials, the specimen must be mounted first to resist deformation and then ground down to size. This grinding operation should also be done with ample cooling water so that the temperature is not increased.

Before mounting the specimens, thoroughly cleaning the samples to remove any particulates from the cutting or sectioning process is necessary. Also, at this point, any greases or oils (e.g., kerosene from cutting) that may have come in contact with the specimens must be removed. This will enable optimum adhesion of the specimens to the mounting resin during the mounting procedure. Specimen preparation is a key aspect that determines the quality of the microstructural information that can be obtained.

Mounting the Sample. The best mount is no mount, meaning that the specimen is prepared and polished without the use of a permanent mounting resin or material. Automated polishers have holders that allow easy mounting of the specimens by mechanical clamping or grips. The benefit is that after polishing, the specimens may be removed and directly viewed. Likewise, the original sample identifications are easier to discern. A rectangular holder with a 35 by 76 mm (1.4 by 3.0 in.) opening works very well for both laminate and honeycomb composite materials. With this type of mount it is necessary to use scrap backup pieces to protect the edges. After polishing, these scrap pieces can be easily removed. For carbon fiber reinforced polymer (CFRP) samples, CFRP backup pieces are recommended, as the material removal rates will be well matched. The same is true with other composite materials: backup pieces of similar materials and hardness provide superior results. Using this method, void analysis and ply-count specimens may be prepared quickly with excellent results.

Hand-polishing unmounted specimens is possible but often difficult. The long and narrow nature of most composite samples makes it difficult to maintain a high-quality flat surface free of artifacts. Additionally, the edges are prone to tearing the polishing cloth. With special exceptions, this is the least favorable specimen preparation method.

Fragile materials, multiple samples, or samples with surface features require support to ensure a flat planar surface. The use of a mounting medium such as epoxy, polyester, or acrylic resin is necessary. Of these resins, epoxy is preferred, since it has the least shrinkage during cure. Room temperature curing resins are often ideal; however, they frequently need to be cured at least 8 h at 20 °C (68 °F), as oven curing may increase shrinkage. To ensure full impregnation of the specimens, the mold can be placed in a vacuum impregnation chamber while infusing the resin. The use of moderate vacuum to remove entrapped air, followed by applying pressure during cure, is highly effective for sample preparation and creating good adhesion.

The following steps are recommended to achieve a good mounted specimen without voids or specimen pull-out:

1. Select a mold to hold the specimens and rinse with mold release agent. Silicone rubber molds are the most convenient and can be used repeatedly. A convenient size mold for composite specimens is 57 by 25 by 25 mm (2.2 by 1.0 by 1.0 in.). The resulting samples may be used in automated polishers, hand-polishing applications, and thin sections. Circular plastic molds can also be used for these applications but are not as convenient for mounting or for polishing later.
2. Wash and degrease the samples to create a clean interface to bond to the mounting resin.
3. Completely dry all the components of the sample before mounting. A vacuum desiccator or low-temperature, 40 to 50 °C (105 to 120 °F), drying oven should be considered for at least 12 h.
4. Place dry specimens in the mold and position a strip of loosely woven glass cloth between the flat adjacent surfaces of the sample. This will ensure sufficient wetting with the resin (Fig. 1). The glass fabric allows the resin to impregnate (wick) between the specimens, no matter how tightly they are

packed together. This provides the best possible bonding of the specimens so that the mounted sample does not come apart during the grinding and polishing stages.

5. When possible, excess specimens should be used for backup material within the mount to aid in polishing. As a general rule, use materials with the same mechanical properties for the best support.
6. Vacuum impregnate the specimens in the mold with epoxy resin. After the impregnation step, it is recommended that the mount be pressure cured using at least 400 kPa (58 psi) for 12 h at 21 °C (70 °F). The time depends on the epoxy mounting resin selected since curing times may vary.

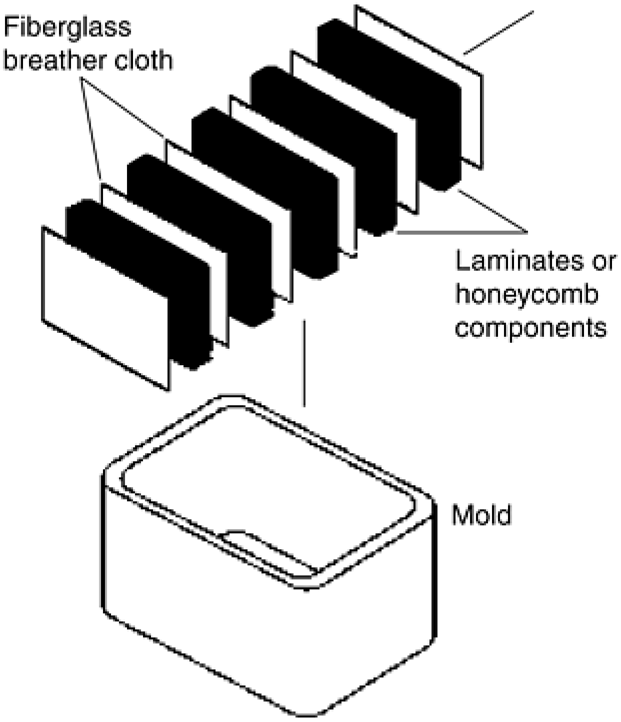

Fig. 1 Schematic showing the mounting of composite specimens in a rubber mold. Note the glass breather cloth used for separation of the samples.

While the previous mounting directions focused on filling specimens in a preset-sized mold, followed by impregnation, another type of mounting is also beneficial for manual or hand polishing. This type mounting is quite fast and economical. Samples can be mounted, polished, and viewed within 20 min. The mount for manual polishing can be prepared as follows (Fig. 2):

1. Cut samples of the laminate or honeycomb specimen into strips that are 25 to 65 mm (1.0 to 2.6 in.) long by 12 to 25 mm (0.5 to 1.0 in.) high (Fig. 2a).
2. Cut sacrificial side panels that are 12 mm (0.5 in.) longer than the subject specimens, using scrap laminates of a similar material to create a custom mold (Fig. 2b).
3. Tightly hold and bind the sample together on five sides with gray vinyl electrical tape or an equivalent product. The open side should be opposite the side to be polished (Fig. 2c).
4. Fill the custom mold with 5 min epoxy. The result is a mount that can be handled easily and maximizes the surface area of the sample. After the specimen is cured, the gray vinyl tape can be easily peeled off, leaving the specimen ready to polish (Fig. 2d).

A photograph of a mounted and polished specimen is shown in Fig. 2e. Notice that the backup pieces are of the same type of material, carbon fiber composite laminates, as the sample to be viewed in the middle of the mount, providing similar sample removal rates.

Rough Grinding and Polishing

Sample Removal (Rough Grinding). The first stage of grinding should be aggressive enough to remove the material quickly and easily, but not so aggressive as to induce damage. Sixty-grit paper, like the band saw, can induce significant damage and may leave the sample in worse condition than it was before grinding. Wet-grinding with silicon carbide (SiC) paper will not introduce damage that cannot be removed easily if 120, 320, and 600 grit papers are used sequentially. However, because of their short useful life, SiC papers are one of the most expensive options for rough and fine sanding (each sheet will not last much beyond three CFRP specimens). Do not use dual papers, the removal rate is decreased and may introduce damage.

Rough and fine grinding using water-lubricated, diamond-impregnated discs remains one of the most efficient means of preparing specimens for final polishing. If used only for composites, a single diamond disc can last for years. A high-quality diamond disc can remove material at a continuous rate with less damage than SiC papers for a given grit size (e.g.,70 μm or 120 grit platen), making it possible to move to the next step (9 μm diamond lapping film, 15 μm or 1200 grit platen). A noncontinuous diamond pattern or a low-density distribution is recommended, as the water and removed material are easily sluiced away, ultimately increasing material removal rate.

The two methods for grinding described previously can be summarized as follows:

- *Method 1:* 120, 320, and 600 grit SiC paper
- *Method 2:* 70 and 15 μm diamond platens or 120 and then 1200 grit diamond platens

Rough Polishing. For automated polishing, a 1200 grit diamond disc or 9 μm diamond lapping film provides excellent results. Likewise, as one sheet is capable of polishing up to 1000 specimens, it is also highly economical. For hand preparation, however, 15 μm aluminum oxide (Al_2O_3 alumina) is recommended.

Polishing (micromachining) with levigated Al_2O_3 is inexpensive and effective if used correctly. Al_2O_3 alumina may be used on most composites with fiber hardness less than that of Al_2O_3. The rough polish Al_2O_3 comes in three sizes: 15.0, 5.0, and 0.3 μm. A fine balance of Al_2O_3 concentration in the lubricant (distilled water) and its proper application is necessary for efficient and quality micromachining as is the cloth type, revolutions per minute of the platen, and applied pressure. Achieving this balance will lock the cutting material into the cloth, resulting in a clean cut across both the soft resin and hard fibers. The Al_2O_3 distribution can be best controlled by adding it to the cloth in a premixed colloidal solution. *Never apply dry aluminum oxide to the cloth.* After the 0.3 μm step, the surface will be nearly free of artifacts that can be seen at 100× magnification. It should be noted that although diamond abrasives can also be used effectively, they are not recommended since the cost is much more significant.

The right concentration of Al_2O_3 is critical. There is a tendency to over concentrate the mixture. In this case, the Al_2O_3 will roll, becoming an ineffective cutting material. In addition, the rolling action will erode the resin from around the fibers leaving the fibers rounded and the surrounding resin undercut. This condition ultimately destroys the surface plane. For this reason, it is better to use a less concentrated Al_2O_3 solution to accomplish the micromachining polishing. A ratio of 5 g of 0.3 μm Al_2O_3 to 1 L of distilled water and 12 g of 15 μm Al_2O_3 to 1 L of distilled water has been found to be optimum.

The purpose of a lubricant is to dissipate the heat from polishing and to act as a carrier for the abrasive material, such as Al_2O_3. The lubricant needs to have a low viscosity to prevent hydroplaning during polishing. Usually, the lubricant consists of distilled water. Any contaminant in the lubricant can cause deep gouges, so avoid using tap water as it often contains abrasive particles.

Although there are many types of cloths promoted for polishing, such as Dacron (E.I. DuPont de Nemours & Co.) and nylon, cloths made from silk are recommended. Silk cloths come in a variety of different types and allow the fastest removal rates.

The speed of the platen is best kept high–typically 300 to 1000 rpm for a 200 to 300 mm (8 to 12 in.) platen. Although this may by limited by the type of equipment, the higher surface speed/pressure helps lock the Al_2O_3 into the cloth without excess buildup of Al_2O_3 on the cloth. Higher sample surface speed, whether increased through wheel speed, wheel diameter, or counter specimen rotation, will increase removal rates.

The pressure needs to be high enough to eliminate hydroplaning, but it is often limited by the capacity of the equipment. A fully loaded automatic head can have as much as 80 cm^2 (12 $in.^2$) of contact area with the platen. It may not be possible to apply sufficient pressure without overloading the equipment. For hand polishing, the pressure is limited by the ability of the operator to hold the specimen under control.

The right application of all the components may be accomplished in several ways. The key is the introduction of the colloidal Al_2O_3 mixture at the right rate: 1 to 2 drops per s will cool the sample and supply an ample amount of abrasive. Since silk cloth has no nap to retain lubricant, caution must be exercised. Damage to the samples may occur in 4 to 10 s if the platen is allowed to run dry.

Final Polishing. The final polish step transitions from micromachining using napless cloths and high pressure to one of lapping with low speed and low pressure. The most efficient process involves using a premixed 0.05 or 0.06 μm colloidal Al_2O_3 suspension diluted with distilled water in conjunction with a napless cloth. The critical parameters of fine polishing are very low vertical force, complementary rotation of the sample relative to the platen rotation, and a low platen speed. If the vertical force is too high, the fiber-resin interface will display cupping. In addition, if the platen speed is too high, the sample will become difficult to control if it is being hand-polished, and the sample will want to stick to the platen. It should be noted that it is hard to control the sample when hand polishing in a counter direction during this step. When hand polishing or automated polishing is done, platen speeds <120 rpm with a complementary sample rotation give $\frac{1}{4}$μm (or better) surfaces in 30 to 180 s. This should be performed using a neoprene cloth (pad). Figure 3 shows how a polished surface of a composite material should look after this final step.

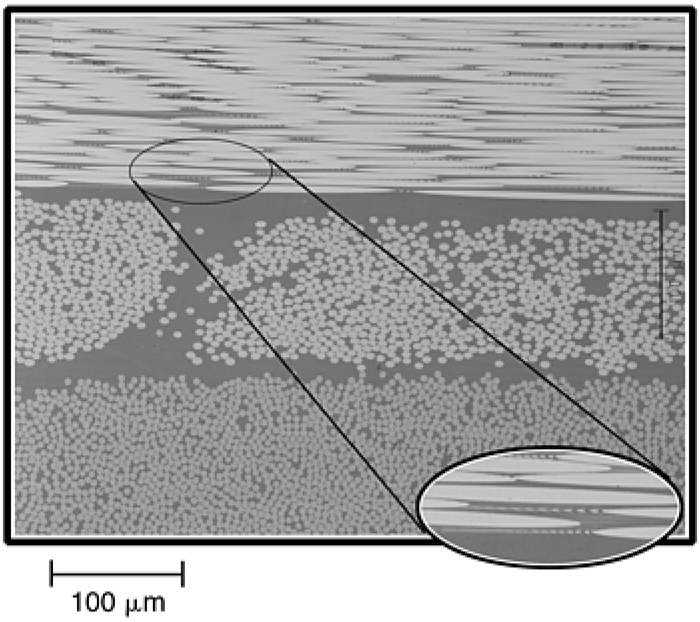

Fig. 3 Bright-field illumination (200×) of a composite specimen after alumina polish. Note the interferometer bands on the longitudinal fibers. This is one way to check the flatness of the polish.

A vibratory polisher can also be used for the final polish. Silk or synthetic silk cloth is recommended, with a diluted premixed 0.05 or 0.06 μm colloidal Al_2O_3 suspension and low applied pressure. There are prestretched synthetic cloths on metallic plates that work very well and are tough. Silk can be used, but it is difficult to stretch over the platen. The vibratory polisher is slower than other automated polishing techniques and is easily contaminated but gives the best possible final surface. This process extends the micromachining with lapping.

The more traditional technique of final polishing with either a high- or low-nap cloth is not recommended. After as little as 20 s, rounding on the fiber-resin interface can be greater than 1 μm. This effect can be seen in Fig. 4 when compared to Fig. 3.

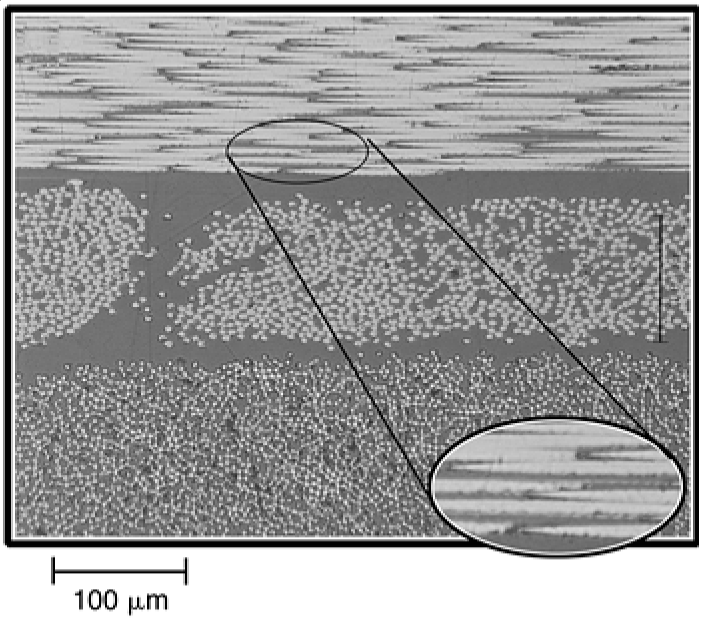

Fig. 4 Same specimen as in Fig. 3, repolished with 6 and 1 μm diamond on a nap cloth. Note the rounded fiber interface and the lack of interferometer bands on the longitudinal fibers.

The following steps summarize the rough and fine polishing steps for both hand and automated techniques:

Method 1. Hand polishing

1. 15 μm levigated alumina slurry (12 g Al_2O_3 to 1 L distilled water), silk cloth, 1000 rpm

2. 0.3 μm levigated alumina slurry (5 g Al_2O_3 to 1 L distilled water), silk cloth, 1000 rpm
3. Finish with a premixed solution of 0.05 or 0.06 μm levigated Al_2O_3 diluted with distilled water, neoprene cloth (pad).

Method 2. Automated polishing

1. 9 μm lapping film or 1200 grit diamond platen (note: use a high-quality diamond platen; not all are the same.)
2. 0.3 μm levigated alumina slurry (5 g Al_2O_3 to 1 L distilled water) with silk cloth
3. Finish with a premixed solution of 0.05 or 0.06 μm levigated Al_2O_3 diluted with distilled water on a neoprene cloth or silk cloth with vibratory polisher.

Preparation and Polishing Boron Fiber Composites. Polishing boron fiber composites is very difficult. The fibers are extremely brittle and the critical crack length is sufficiently short that any stress riser or abrasion may result in the fiber shattering. Given this, trying to cross-section and polish boron fiber composites with conventional techniques can be frustrating, as the boron particles break loose and gouge the polishing surface, frequently inflicting damage faster than it can be removed (Fig. 5). Although diamond is more expensive than Al_2O_3, it is necessary for polishing the harder, brittle fibers such as boron nitride.

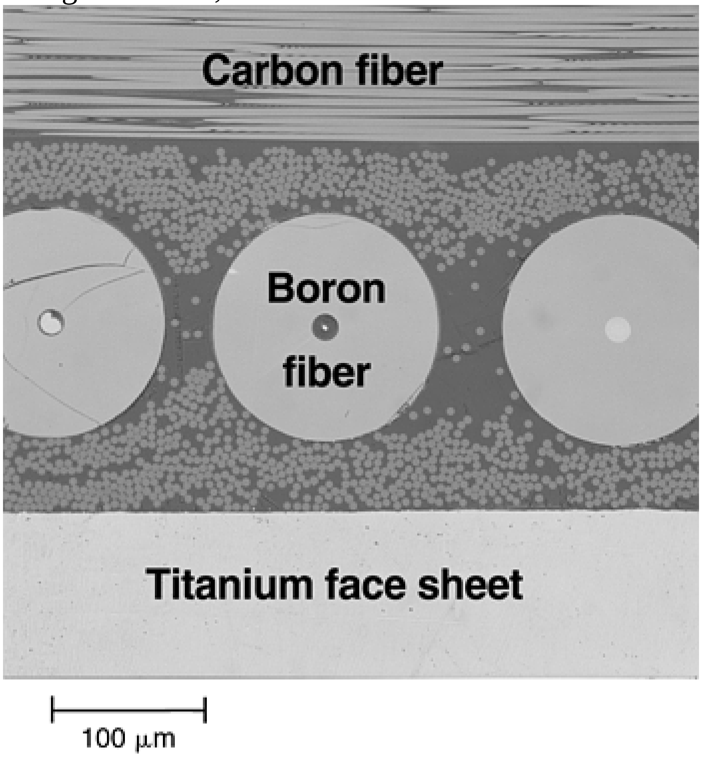

Fig. 5 Results of a diamond saw cut and the effect on the brittle boron fibers. 200×

Most of the problems associated with cutting and polishing boron fiber composites can be averted by combining sawing and polishing into a single step. Using a diamond wafering saw, cut the mounted specimen in half. This will result in a specimen that is ready for final polish. Likewise, this process will bypass the steps that cause the majority of the damage. After being sawed with the wafering saw, the sample is ready for a 1 μm polish (micromachining). Use a 1 μm polydiamond abrasive and a stainless steel mesh cloth or phenolic pad platen. Of these two polishing surfaces, the phenolic pad platen works the best; however, both result in a slow process. The vertical force should be high with a platen speed of 150 rpm and the head rotating counter to the platen. The polishing surface must be kept wet with a diluted solution of the diamond abrasive and ethanol. If the polishing plane is allowed to dry, the fibers can overheat and protrude from the surface of the sample. Destruction of the sample will follow. With its high vapor pressure, ethanol evaporates quickly, helping to cool the specimen-polishing plane. It is therefore imperative that the ethanol be applied at a rate that keeps the wheel wet. A small automatic atomizer works well. This step will take some time, as the hardness of the fiber approaches that of the diamond. Properly performed, this methodology will prepare specimens with no visible

artifacts and with less than one-quarter interface edge rounding. To this point in the preparation procedure using hand polishing is not really recommended, as the brittle fibers will fracture.

Because the fibers do not allow the diamond abrasive to penetrate very deeply into the sample, a final polish is not required. However, a neoprene cloth with a premixed solution of 0.05 or 0.06 µm levigated Al_2O_3 diluted with distilled water and light pressure can clean up the last of the artifacts if so desired (Fig. 6).

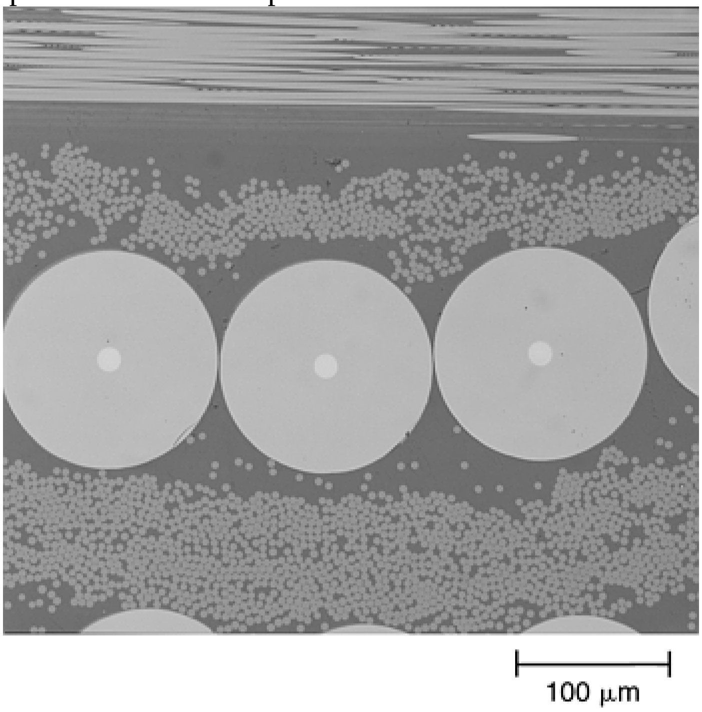

Fig. 6 Boron fiber composite cross section after final polish. 200×

The polishing of other types of composites, such as MMCs is not nearly as difficult as the boron fiber-polymer matrix composite. Most MMCs can be prepared by grinding with 70 µm diamond platen to a 9 µm lapping film, followed by 1 µm diamond abrasive polishing using the same technique as previously discussed for boron fiber composites. An example of a polished metal matrix composite is shown in Fig. 7.

Thin-Section Preparation

Ultrathin sections are typically used as a research tool rather than a production tool. At the ultrathin level, even opaque materials become optically transparent. This preparation is needed in order to resolve and analyze microstructural features at the theoretical limit for optical microscopy. Thin sections allow the use of several types of transmitted-light microscopy on materials normally considered opaque. Transmitted- light methods reveal more details of the morphology of polymers and similar materials than any other microscopy techniques available (Ref 2).

Ultrathin-section transmitted-light microscopy is time and labor intensive, and its use typically can only be justified when required data cannot be obtained by an alternative method. An ideal thin section is one where the only residual stress and strain that should be seen is that from the original specimen rather than due to the preparation (Ref 3, 4). Polymeric materials cannot be microtomed (which induces stress and strain as artifacts) to obtain the high resolution or detail that can be achieved with a polished ultrathin section. The following

sections detail the various aspects relating to the selection and preparation of ultrathin section specimens of polymeric composites and other materials and their examination by transmitted-light microscopy techniques.

Procedure and Selection of Rough Section. The selection of the area of interest for thin-section examination and the procedure for the preparation of the rough section will depend on the nature of the starting bulk material from which the specimen is to be extracted and the type of information sought. When preparing thin sections, the orientation of the section relative to the fiber alignment is a major consideration for fiber- reinforced composites (FRCs). The angle at which the section is taken is important when quantifying anomalies such as voids and microcracks. If extensive microcracking of the resin matrix has occurred, thin sections normal to the fibers would be extremely fragile, and the specimen may tend to fall apart. In this situation, a section parallel to the longitudinal fibers is beneficial because the fibers provide support to hold the cracked matrix together. Here, a section along the longitudinal fibers on a heavily microcracked area can be used to hold the sample together.

Thin-section transmitted light microscopy has been successfully used for the following types of investigations:

- A single small area, such as the fracture origin in a laminate or honeycomb composite part. The feature can be a small zone that requires several sections for broader sampling.
- Finely dispersed particles or chopped fibers imbedded in resin
- Large, complex structures such as honeycomb composites with an array of materials. Frequently, there are zones with intermingled phases between components that need to be documented.
- Surfaces where oxidation or contamination is to be observed and documented.

The mounting of the specimens in a rubber mold can be done as previously described. In all cases, the final mount should be centered to feature the portion of interest. It is easier to control the removal of the material from the center than the edges.

It is better to make an initial slab of the rough cut larger than the final 46 by 27 mm (1.8 by 1.1 in.) petrographic glass slide so that the excess can later be trimmed, thereby eliminating artifacts on the edge of the final product. The "first surface" will become the surface glued to the glass slide. Be careful when preparing the first surface; any artifacts created at this point will affect the optical light path on the final section. Flatness of the surface is also critical, not only on the section plane, but also on the structure interface of different components (e.g., carbon fiber and thermoplastic resin). Polishing this face is performed the same as previously described for the reflected light specimens.

Mounting the First Surface on a Glass Slide. Once the first face is polished, mounting this surface to a glass slide is the next step in the process. The lack of a homogeneous adhesive bond between the sample and the glass slide will decrease the quality of the thin section. Trapped air and contaminants can cause the sample to separate from the slide during final polish, resulting in the self-destruction of the thin section. The following steps should be used to mount the sample onto a glass slide:

1. Clean a standard 46 by 27 mm (1.8 by 1.1 in.) petrographic glass slide with an appropriate solvent.
2. Clean and dry the sample.
3. Vacuum impregnate the polished surface and bond to the glass slide with low-viscosity, highly adhesive epoxy resin to ensure that any cavities opened by the polishing are filled and sealed.
4. Clamp sample to slide and allow to completely cure. The easiest way to bond the sample to the slide is to place a 1 kg (2.2 lb) weight on top of the sample.

Preparing the Second Surface (Top Surface). The second surface is prepared by grinding and polishing down the section from 1 mm (rough cut) to a nominal 1 to 7 μm-thick surface, parallel to the first surface. Like the first surface, this needs to be artifact-free. Any artifact, especially on the top surface, will show up in the microscope optical path. With epi-illumination, scratches can be a problem. When using transmitted light microscopy, the residual stress and strain associated with scratches affect the optical path and interfere with the microscopic analysis. The following sequence of steps is recommended for the preparation of the second surface after mounting the first surface to the glass slide.

Step 1: Trimming the Rough Sample. Trim the flashing from around the slide so it will fit into the vacuum chuck. The excess flashing has to be trimmed to match the slide (Fig. 8).

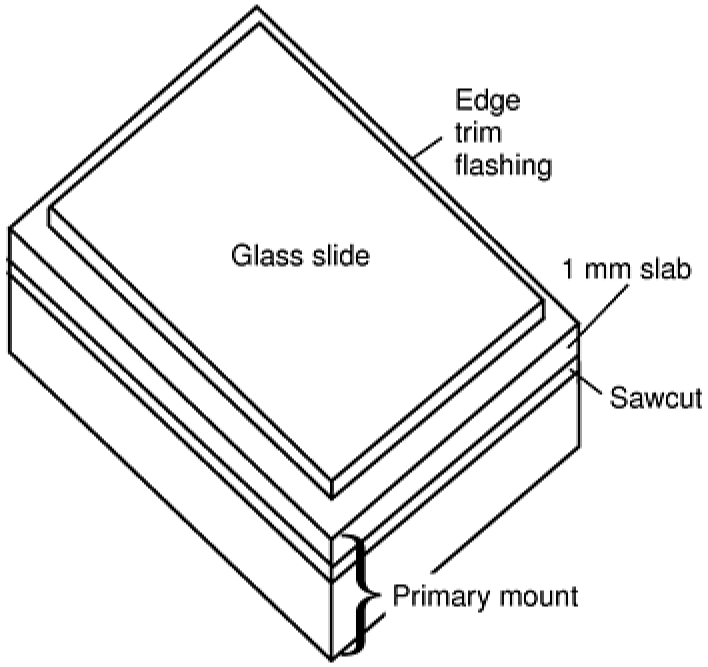

Fig. 8 Schematic of primary mount and area of saw cut

Step 2: Wafering the Sample.

1. Place the primary mount and glass slide in a vacuum chuck.
2. Mount the glass slide, with the primary mount bonded to it, in the wafering saw in preparation for the 1 mm (0.04 in.) cut.
3. Use the wafering saw to cut off a nominal 1 mm (0.04 in.) thick sample bonded to glass. The manufacturer's recommendation for speed and pressure should be followed because these parameters will vary with the resins used and the materials that are cut. The remaining rough-cut specimen may be reprocessed from the primary mount to obtain a series of thin sections.

If a wafering saw is not available, sample removal can also be done by grinding the mounted specimen, using 120 grit SiC paper, to a final thickness of 1 mm (0.04 in.). This is often time- consuming, depending on the original specimen thickness.

Step 3: Mounting the Wafer in the Vice for Grinding the Second Surface. Coarse and fine grinding are performed with the aid of a sacrificial hand vice:

1. Mount the sample in a sacrificial hand vice using glycerin (Fig. 9). The purpose of this type of vice is to increase the surface area of the specimen and provide a holder. The sacrificial hand vice is an aluminum cylinder with a 46 by 27 mm (1.8 by 1.1 in.) removable rectangular piston.
2. The surface of the piston and the surface of the hand vice must be synchronized on the same plane for each use, which is accomplished by grinding them to a common plane. After the piston and the hand vice have been “planed,” the piston should be reset to 375 μm, plus the thickness of the glass slide, into the cylinder. The easiest way to set the standoff distance is to use a blank slide and 375 μm of shim material.
3. At this point, a few drops of glycerin are placed on the recessed piston, and the glass- bonded 1 mm wafer is inserted into the cylinder. The sacrificial hand vice with the glass- bonded 1 mm wafer is now ready for the grinding process (Fig. 10).

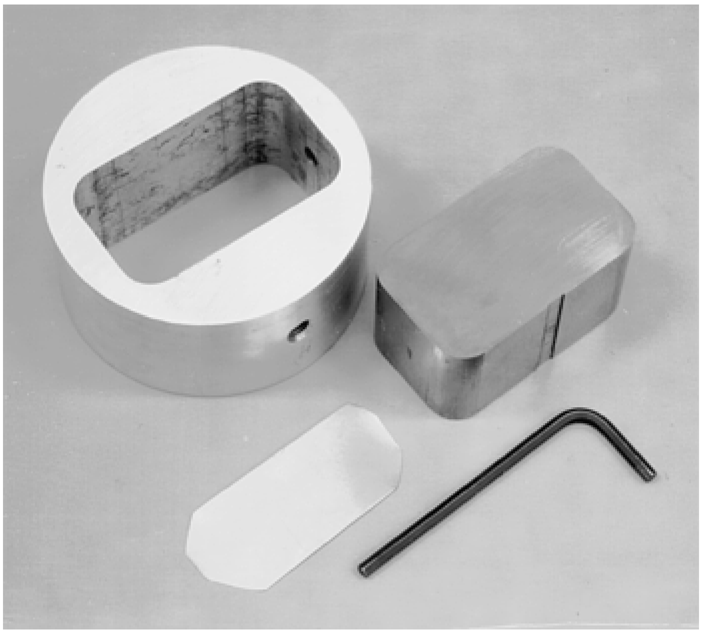

Fig. 9 Sacrificial hand vice with 375 µm shim material

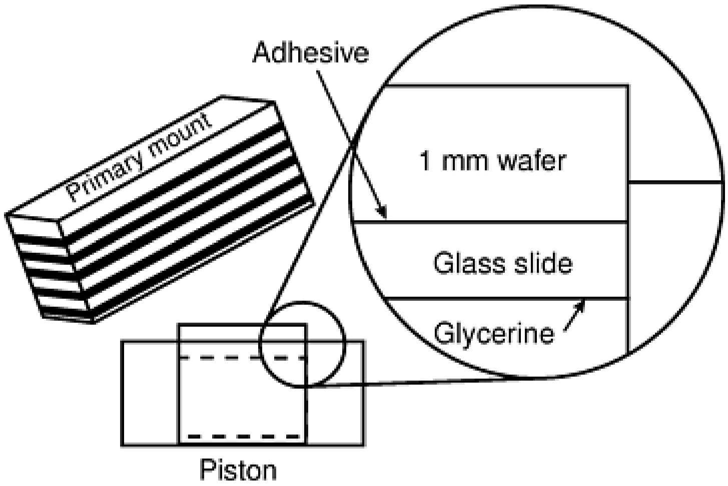

Fig. 10 Sacrificial hand vice with wafer assembly

Step 4: Grinding the Second Surface:

1. Grind the excess material with 120 grit SiC paper until the excess sample is removed so that it is flush to the aluminum vice surface. Do not use coarse paper because damage and deep scratches may result. Use reflection off surface to identify high spots where additional grinding is required.
2. Continue the grinding process in the vice with 320 grit SiC paper down to a level of roughly 50 µm above the first surface.
3. Finish the grinding process in a vice with 600 grit SiC paper down to approximately 25 µm. This completes the grinding process, and now the polishing process can begin. The sacrificial hand vice is no longer needed.

Step 5: Polishing the Second Surface. Mount the specimen in a hand vice. The purpose of the hand vice is to serve as a handle to hold the slide while polishing. A few drops of glycerin should be applied to the well to hold the specimen. The specimen can be removed at any time for a microscopic evaluation and reinstalled in this vice holder for further preparation. The polish action is hand pressure on a polish wheel. The direction of rotation is critical to follow. As previously described, the polishing can be done by hand. However, the 15 µm polishing step should be stopped when the thin section is within 1 to 3 µm of the final thickness. Shaping is done by center-weighting or off-center-weighting to control the final plane of the thin section so that it is parallel to the first surface or is a wedge to a very thin edge (Fig. 11). This is the last opportunity to do any major shaping of this plane.

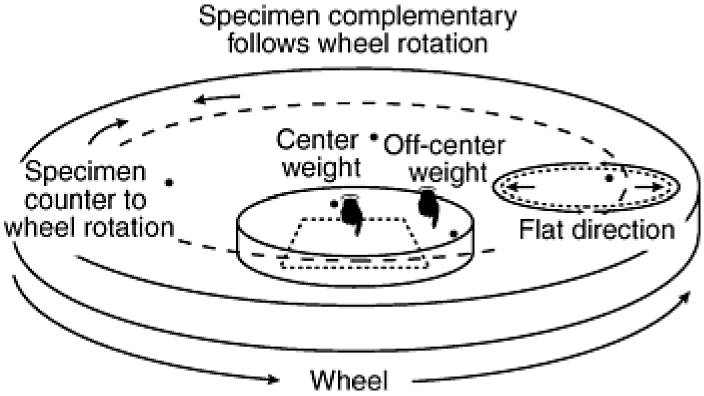

Fig. 11 Polishing wheel and specimen movement

The second polishing step uses a 0.3 μm alumina slurry on a silk cloth. This step removes the last 1 to 2 μm and will achieve the final plane, leaving the surface at a point where it can be examined. It is important to maintain center- weighting. Overpolishing can cause the sample to disbond. This step will test the effectiveness of the adhesive. The last polishing step can be accomplished as previously mentioned using a diluted 0.05 or 0.06 μm levigated alumina suspension either by hand or with automated vibratory polishing.

General Considerations for Thin-Section Sample Preparation. It is important to pay attention to all aspects of polishing (e.g., center- weighting, hand pressure, and cutting rate). Even the sounds of the sandpaper and the polishing cloth as the specimen is prepared can help guide the microscopist to maintain the desired plane. Going through the steps involved in preparing a specimen, a good microscopist continuously checks the specimen by viewing the light refracting off the surface. This technique saves time and is an excellent tool. Knowing when to stop and when to continue to the next step is critical and usually done by feel and experience. Each step leaves damage of decreasing magnitude. When too much material is removed at any given step, the sample in most cases is either lost or distorted. If not enough of the sample is ground down at any given step, it becomes difficult and sometimes impossible to reach ultrathin dimensions.

Feathering out is defined as the process of creating a slight wedge that is spread across the entire sample thickness varying from 0 to 5 μm. The advantage of feathering is that it allows the entire thickness range to be scanned utilizing the thickness effect on the optical contrast, refractive indices, and resolution. This allows the microscopist to obtain the maximum information and photographic detail. The biggest advantage of this is that the different optical contrast modes can be utilized for different portions or thicknesses of the sample. By carefully controlling the weighting of the sample during polishing, the specimen can be tuned to any shape or thickness needed. It is possible to obtain a near parallel surface; however, most polymeric composite materials have an optimal thickness that corresponds to differences in contrast. Therefore, tapering the surface of the specimens may offer more information while also providing easier identification of sample removal.

Viewing the Specimen

Reflected Light Microscopy. There are many factors to consider when viewing a specimen. The first is what type of specimen: what are the fibers and what is the matrix? What are the capabilities of the microscope? Viewing samples with the light microscope is the preferred start. In most cases, relevant detail may be resolved from 5 to 100× magnification. An understanding of the microscope is helpful in order to fully use its capabilities (Ref 5, 6, 7, 8, 9, 10, 11, and 12).

Epi-bright-field illumination (reflected bright field) is used in most cases. Bright field is used >90% of the time and on all types of composites. This method is particularly useful for imaging samples for void studies, fiber-orientation verification, resin-to-fiber ratio determination, and most microcrack studies. In general, it is advisable to observe all polished specimens with bright field before continuing with other illumination methods. Macro bright field (<30× magnification) can be difficult to achieve. The 6 to 10× range is where a large portion of documenting porosity in composites falls. Most microscopes are not set up for this range, and those that are have difficulty achieving the quality of a dedicated macroscope.

Void analysis of composite specimens can be performed using low-magnification bright-field illumination of the cross section (6 to 50×). An example of a unidirectional-fiber polymer composite material containing a significant number of voids is shown (Fig. 12). The voids show up as dark holes on the surface.

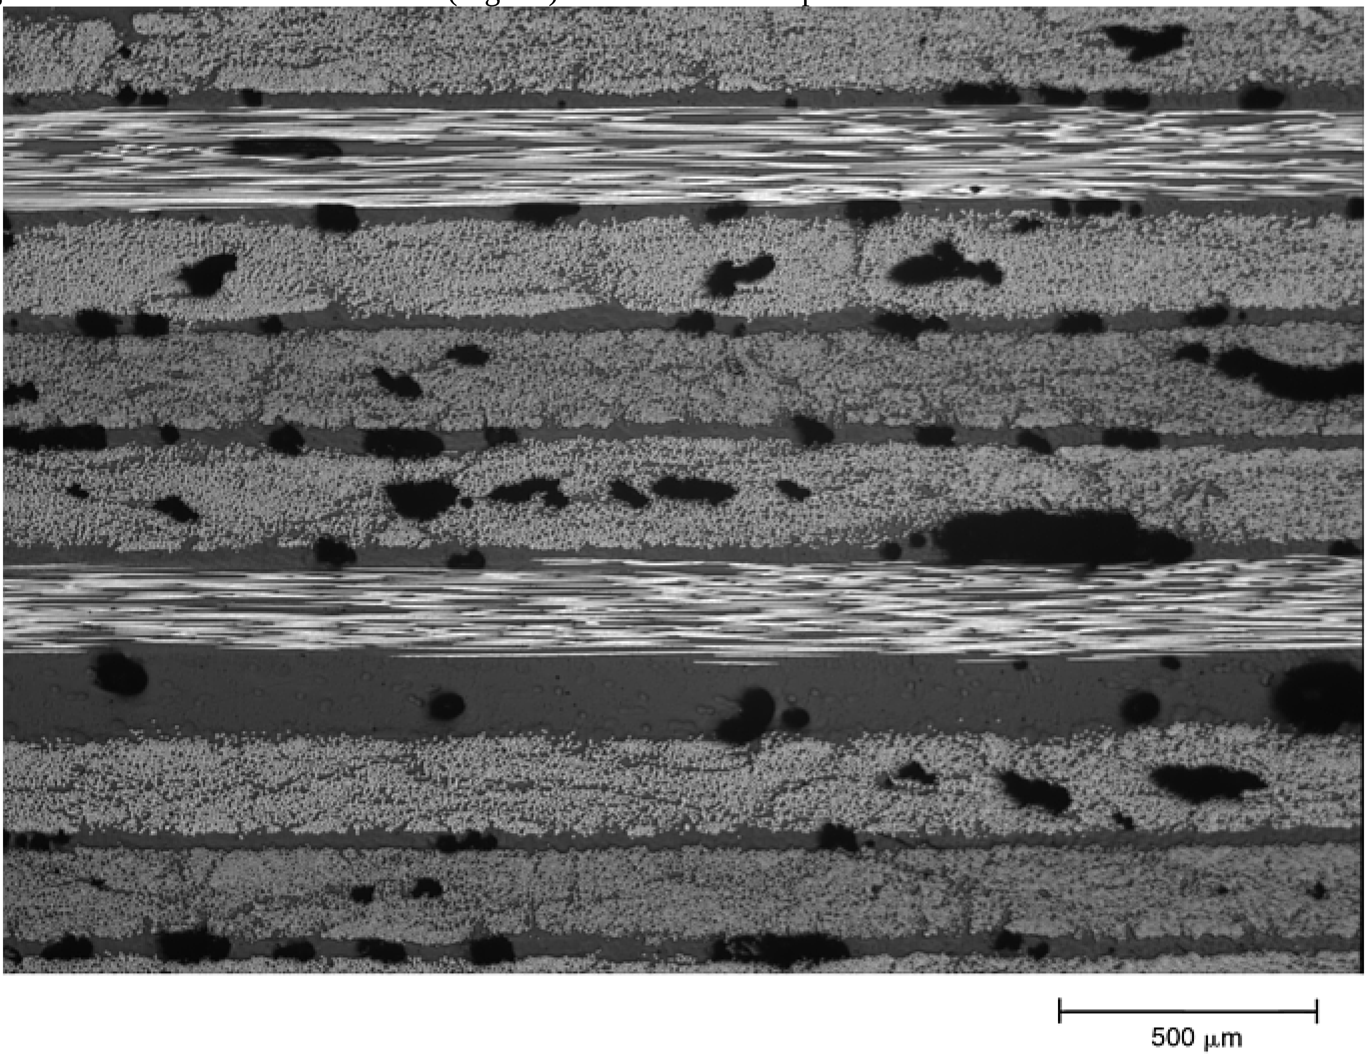

Fig. 12 Unidirectional composite specimen showing voids in the cured structure. 50×

Ply counts on unidirectional carbon fiber composite laminates can be accomplished by mounting and polishing the specimen at 45° to the plane view. This is the easiest way to sort the ply angles with only bright field (Fig. 13). Likewise, ply counts can best be performed on carbon fiber fabric composites using low magnification bright-field illumination of the cross section (30 to 80×). 90° tows can hide in the node zone. It is important to use a large field of view because of the structure of the weave. Figure 14 shows a montage of a chamfer area of a honeycomb composite structure where the 3K-70 plain-weave carbon-fabric plies are easily observed, as are voids in the structure.

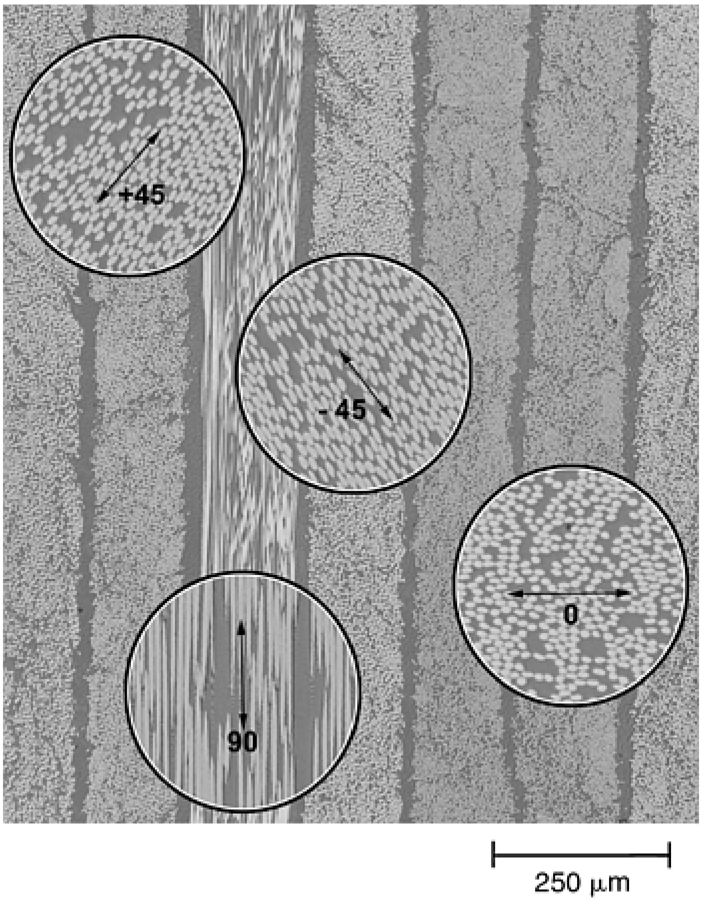

Fig. 13 Bright-field illumination of a unidirectional carbon fiber composite specimen showing the ply angles. 80 to 200×

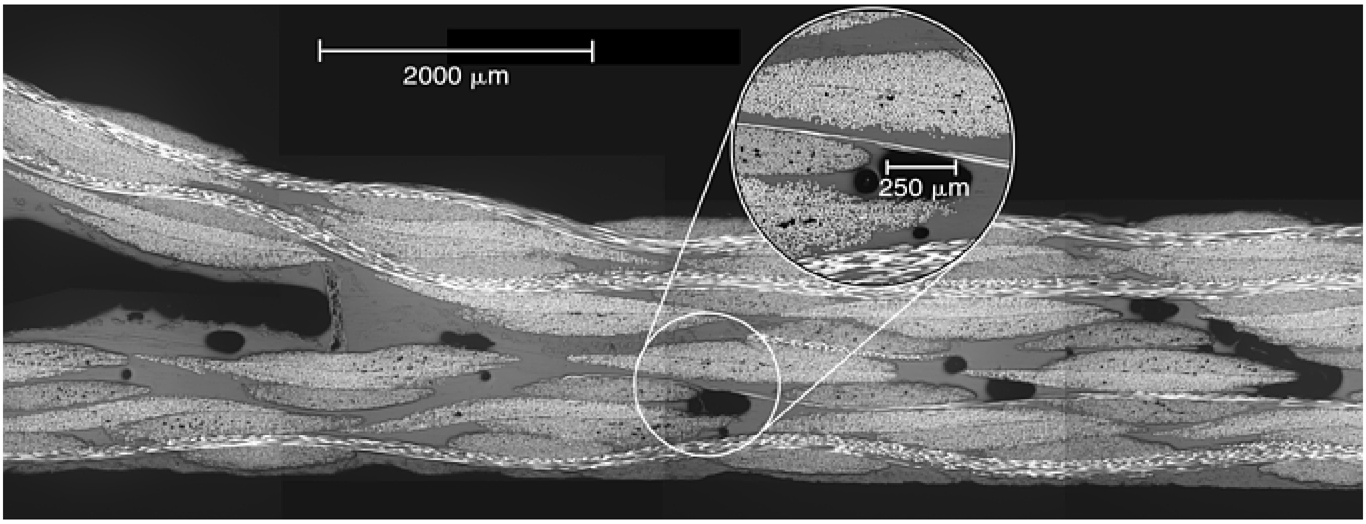

Fig. 14 A montage of a chamfer area of a honeycomb composite part made with carbon fabric skins. A highlighted area of a void in the structure is also shown.

Different composites present different types of resoluble features, depending on the reflectivity of the individual components present. The carbon fibers tend to be very reflective (or to show a high degree of contrast) and are easily resolved in thermoset resins. By comparison, glass fiber composites tend to absorb light equally across the spectrum, making it difficult to resolve the individual components (Fig. 15). Note the bright-field image of the glass fabric on the edge (top) and the carbon fiber plies.

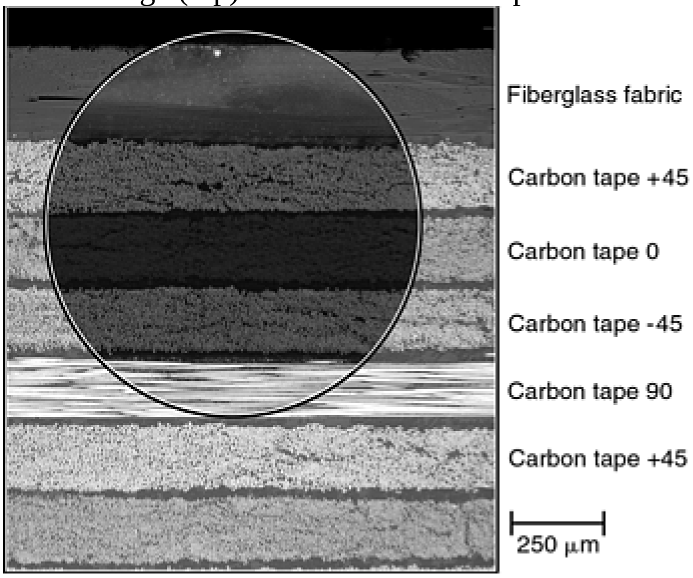

Fig. 15 Ply-count image showing bright-field background and polarized light center. A cross section of a glass fabric/unidirectional carbon fiber composite (80×). Note the lack of contrast of the glass fabric when compared to the carbon fibers.

Epi-dark-field illumination (dark field) is used to bring out subsurface features such as microcracks. With dark field, the light path is blocked from the objective center and is directed to the specimen at an oblique angle. This eliminates the reflected image in favor of the image formed as light passes through the sample subsurface. Using bright field, microcracks in CFRP composites are easily resolved. Similarly, samples with low surface contrast, such as glass fiber composites, are often visualized using dark field. However, there may be cases where subsurface features remain indistinct. The use of penetrant dyes or a red permanent ink felt-tip pen is often effective in highlighting these features (Fig. 16).

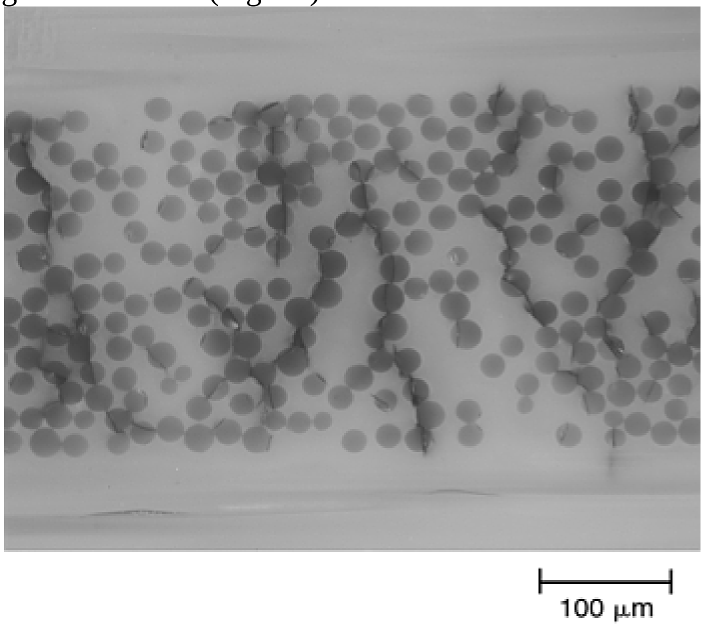

Fig. 16 Dark-field image (200×) of a nylon fiber composite with Magnaflux Spotcheck Penetrant SKL-H (Magnaflux, Glenview, IL). The transverse fibers and microcracks appear red. This technique works well for most translucent fibers.

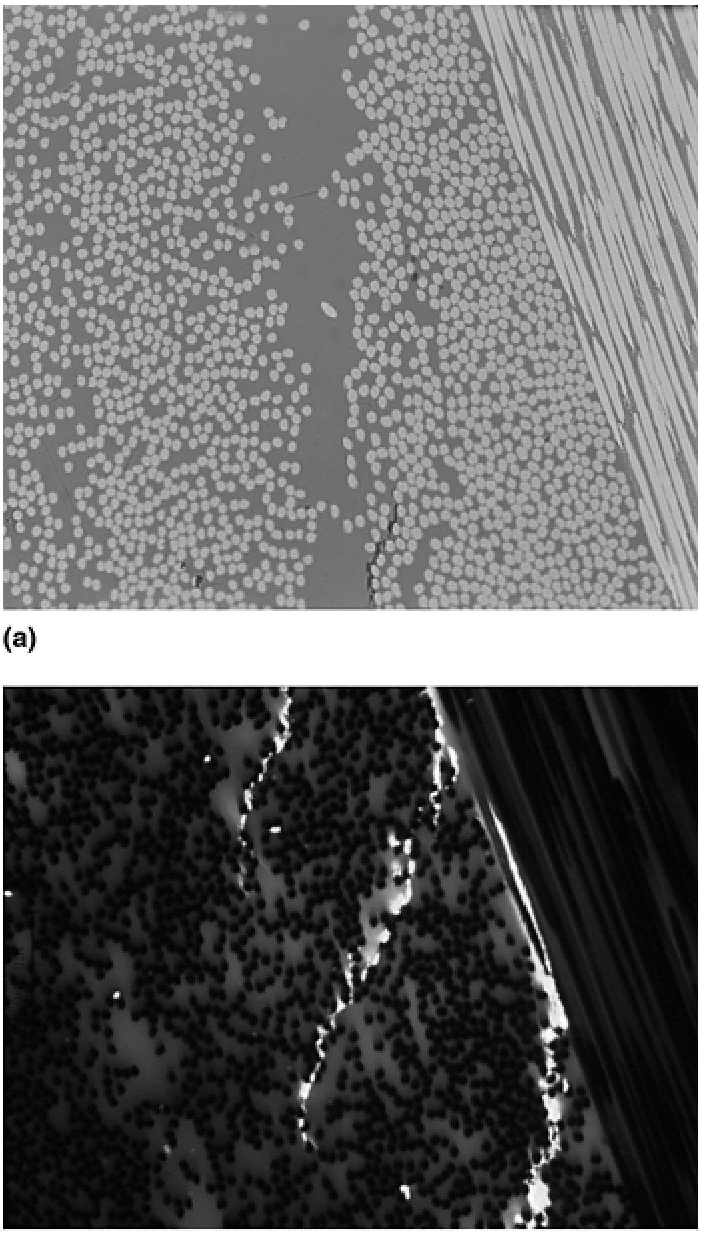
Epi-polarized light (polarized light) is similar to dark field, except that there is a polarizing element at the light source and an analyzer-polarizer between the sample and the eye. These additional elements allow the visualization of contrast created as light to be both reflected and polarized by the sample surface. An advantage of polarized light is best exemplified with fiber- orientation studies of CFRP composites (Fig. 15). The carbon fibers on the transverse (0°) axis are “blacked out” using polarized light, while the longitudinal (90°) fibers depolarize the light and, as a result, are seen as bright features. With a 540 nm wave shift, the transverse fibers appear as first-order magenta; the longitudinal fibers appear white. While these two orientations appear in this manner with any type of illumination, the real advantage of polarized light is the ability to discern other orientations (e.g., ±45). Using polarized light, the ±45 fibers appear pink. Those closer to 0° will turn progressively more first- order magenta, while those that are closer to 90° will fade, eventually becoming white (Fig. 15).

Epi-fluorescence uses an ultraviolet light source (mercury or xenon) for illumination. Light is transmitted though an excitation filter that blocks all but a narrow bandwidth of the light spectrum. The narrow bandwidth of light strikes the sample surface, which is mostly reflected. However, some of the light is absorbed and reemitted, causing a lengthening of selected light bands. The image is passed through a dichroic mirror that filters some of the spectrum that then passes through a barrier filter. The filter removes all light except that which was emitted (fluoresced) from the sample.

It is important to note that with fluorescence microscopy, one does not see detail but sees only the fluorescing illumination. The selection of appropriate light source and filters is critical. All microscope manufacturers offer a wide range of filter combinations for this purpose. One of the most useful combinations is the following: 390 to 440 nm light, a 460 nm dichroic mirror, and a 475 nm barrier filter. Although some polymeric resins naturally fluoresce, most do not. In some multiphase resins, it is possible to selectively dye certain phases with laser dye for increased contrast. Dyeing the specimen is accomplished by first dissolving the laser dye in methanol and then adding it to three parts methylene chloride and a few drops of a wetting agent (Tergitol 15 S-7 surfactant, Union Carbide Corp., Danbury, CT). The specimen can then be immersed in the solution. The dyes can be absorbed through the skin and are extremely toxic. The most common application of fluorescence is observing microcracks that remain obscure with any other type of microscopy. Some carbon fiber composites and thermoplastics can have microcracks that will be invisible with bright field, dark field, and circularly polarized light (Fig. 17a). These microcracks can be easily observed with MagnaFlux Zyglo Penetrant ZKL-H (Magnaflux, Glenview, IL), a commercially available laser dye solution, wicked into the microcracks (Fig. 17b).



(a)

(b)

Fig. 17 A composite specimen containing a crack. (a) Bright-field illumination. (b) Same location with the use of fluorescence 390 to 440 nm and Zyglo Penetrant (Magnaflux, Glenview, IL). Both 200×

Use of Dyes and Etchants. For the majority of specimens, the microstructure is readily visible after polishing, though some features may need to be etched or dyed to be fully visible (Ref 13). The features of a multiphase polymer matrix, such as a thermoset containing a second phase thermoplastic or elastomer, are usually not resolved using bright-field microscopy. Although some phases may be observable with dark-field techniques, most multiphase polymer matrices require additional sample preparation after polishing. One option is the ultrathin section, but other methods such as etching and staining (dyeing) are less time consuming and work well for elastomers and thermoplastics. Some recommended etchants include: tetrahydrofuran (THF), etch time 16 to 48 h; formic acid, etch time 20 to 120 s; a solution of CrO_3 12.5 g, HNO_3 50 mL, and 50 mL water, etch time 10 to 120 s. If the second phase material is known, it can be etched from within the thermosetting matrix with a suitable solvent for that material (e.g., a second phase consisting of polyetherimide in a thermosetting matrix can be etched with methylene chloride). An example of a carbon-fiber composite with a dyed multiphase epoxy matrix that contains a second phase thermoplastic and elastomer is shown in Fig. 18. This specimen was dyed with rhodamine B and viewed at 390 to 440 nm using fluorescence microscopy (1 g of rhodamine/25 ml of methanol/75 g methylene chloride; soak for 30 s).

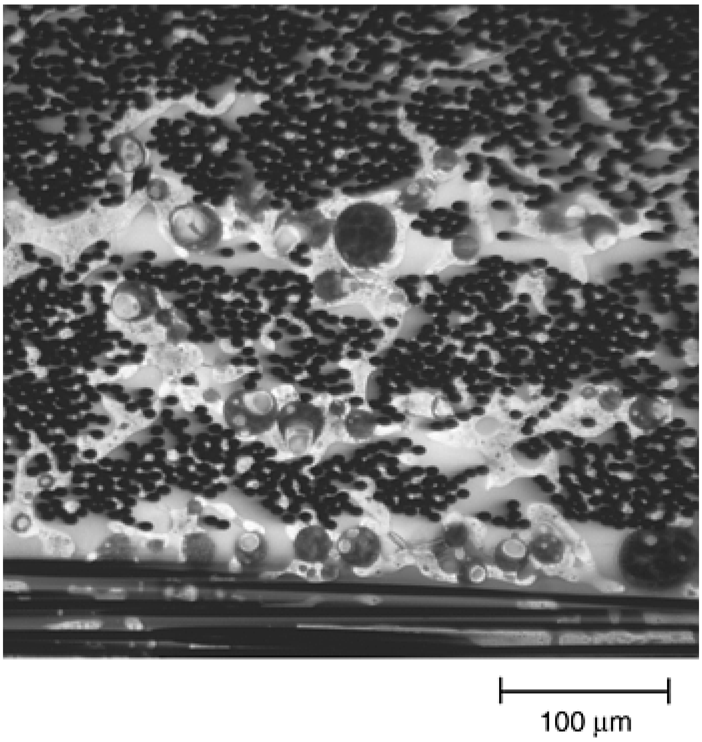


Fig. 18 Image of a composite cross section dyed with rhodamine-B and viewed at 390 to 440 nm. The use of dye was necessary to distinguish the dispersed second phase in the matrix.

Transmitted light microscopy methods use several contrast-enhancement methods that are not commonly used in metallurgical reflective microscopy. These methods include bright field; polarized light; phase contrast; differential interference contrast (DIC), also known as Nomarski; modulation contrast, also known as Hoffman contrast; epi-illumination; and optical staining. The methods of transmitted optical microscopy are to enhance or selectively detect changes in light intensity or color. The human eye and photodetectors are sensitive to differences in light intensity or wave amplitude and changes in color indicating changes in frequency of light. An example of several contrast methods applied to one material is shown in Fig. 19. At low magnification, bright-field microscopy shows the composite with good contrast. Modulation contrast at 100× and DIC at 200× are used to bring out the features at higher magnification.

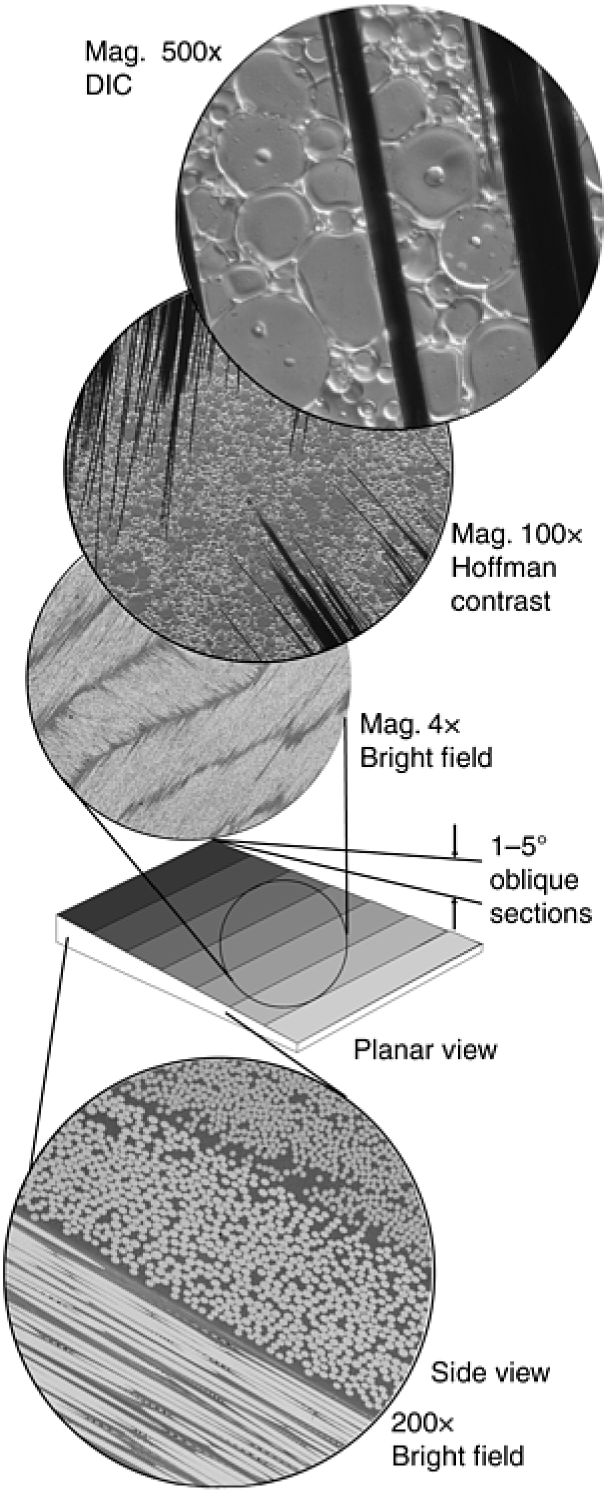

Fig. 19 Examples of laminate micrographs showing a side view and planar views of a thin section using different contrast modes and magnifications.

Color and/or light intensity effects shown in the image are related to the rate of changes in refractive index (RI) and the thickness of the specimen or both. Use RI oils with a cover slide to increase relief and contrast of the specimen (Ref 5, 6). This requires a basic knowledge of the RI of the composite or polymer components in order to select appropriate oils. Optical path differences are sometimes referred to as optical thickness or optical color staining (Ref 5).

Thermal Analysis

George Dallas, TA Instruments

Introduction

FAILURE OF A COMPOSITE STRUCTURE can be caused by several factors, such as tensile failure (dominated by fiber properties) and fiber/resin interface or interphase problems (e.g., failures in 90° plies). Thermal analysis is of limited use for such failures. However, in failure modes sensitive to the properties of the matrix resin, thermal analysis can help determine whether the matrix resin of a failed composite has the appropriate glass transition temperature (T_g). Some thermal analysis techniques, especially dynamic mechanical analysis (DMA), can also be used to "fingerprint" resins by determining properties over a wide temperature range.

Composite Failure Modes Affected by Matrix Resin

If failure occurs under high-temperature conditions, then the T_g of the resin should be checked using a thermal analysis technique. Even if failure occurs at low temperatures, T_g should be checked for indications of overcure, because an excessively high T_g can lead to microcracking. In addition, for a multiphase resin (for example, elastomeric or thermoplastic modified), thermal analysis can determine the T_g of the modifying second phase. If such a fingerprint differs to a significant degree from a control sample, there may be a problem with the composition of the modifier, the resin preparation (for example, improper prereaction), the formulation (too little or too much modifier), or the cure cycle. For example, such changes in fingerprint could indicate that the modifiers are not acting to toughen the resin effectively, which could lead to low interlaminar toughness.

Testing Approach

Usually, it is neither possible nor informative to compare the T_g of a laminate to a literature or brochure value. It is therefore necessary to run a control specimen with a test specimen from the failed laminate. Ideally, the control laminate should be made from a batch of prepreg that is within composition specifications for which quality control data are available from both the manufacturer and the end user. The control laminate lay-up should be of the same configuration as the failed laminate and should be done under controlled, or at least monitored, humidity. Also, it should then be cured under the same cycle as was the test specimen. Then a thermal analysis can be performed, and the T_g and other transitions for both specimens can be compared.

Reasons for Variations in T_g. There are several reasons that T_g may be lower in the test laminate than in the control laminate. The test laminate may have been undercured because an incorrect cure cycle was used. This sometimes occurs if the cure cycle is controlled using tool temperature rather than part temperature when the specified cycle is based on part temperature. The T_g also can be lower if the prepreg were cut and laid up under high relative humidity (RH). For example, T_g can be lowered by as much as 20 °C (36 °F) if it is exposed to 80% RH at 30 °C (85 °F) for 4 h (compared with dry prepreg). Incorrect formulation can also lead to a low T_g.

The T_g of the failed laminate could be higher than the control laminate if an incorrect cure or postcure were used. In addition, if temperatures higher than cure or postcure were experienced in service, T_g could be increased. Incorrect formulation can also raise T_g.

Thermal Analysis

George Dallas, TA Instruments

Thermal Analysis Techniques

Several thermal analysis techniques can be used to verify the cure of a polymer composite and to determine if the polymer had other associated thermal history that might have resulted from aging or faulty processing.

Thermal analysis is a family of techniques used for studying the thermophysical and kinetic properties of materials. Uses for polymers include monitoring the cure of thermosetting resins, measuring the degree of cure of the final product, studying crystallinity in thermoplastics, studying the compatibility of multiphase systems (Ref 1, 2), and identifying transitions imposed upon the polymer by faulty processing or aging (Ref 1). The techniques include differential scanning calorimetry (DSC); its advanced analog, modulated DSC (MDSC) (TA Instruments, New Castle, DE); thermomechanical analysis (TMA); DMA; and dielectric analysis (DEA). Differential scanning calorimetry and TMA are simpler, lower-cost methods compared with the others.

These techniques monitor the resin-curing process or determine the degree of cure of the finished product either by measuring the increase in T_g as cure advances, or by a technique-specific measurement of the curing reaction itself (e.g., increase in modulus by DMA). However, the low-energy T_g signal that is easily observed by DSC or TMA in a polymer-matrix, laminate, or a lightly filled composite may be difficult or impossible to detect in conditions of high humidity or in a highly filled composite of the same polymer due to the damping effect of the fillers. Dynamic mechanical analysis, however, should easily detect the same T_g, since it offers nearly two orders of magnitude of additional sensitivity over DSC to this measurement.

Differential scanning calorimetry is the most popular thermal technique for polymer characterization. It is easy to use, requires small samples (~20 mg), operates from–180 to 725 °C (–290 to 1335 °F) and measures heat flow associated with sample transitions as a function of temperature (or time) under controlled-atmospheric conditions. Differential scanning calorimetry has been used to study thermodynamic processes (glass transition, heat capacity) and kinetic events such as cure and enthalpic relaxations associated with physical aging or stress (Ref 1).

Differential scanning calorimetry is commonly used to measure the T_g of uncured prepregs and cured laminates, advancement in cured laminates, and also the degree of cure of the final product, the heat of reaction during prepreg processing, and relative resin reactivity. The degree of cure is determined either by the increase in the T_g with cure, or by measurement of the heat evolved from the curing reaction. Figure 1 shows an example of both techniques in a comparison of an undercured and an optimally cured epoxy resin system for a given end use. The T_g shift with advance in cure is evident, while the residual cure is directly quantified. If the heat of

reaction of a 100% unreacted resin is known, the degree of cure of each sample can be computed. If not, relative degrees of cure can also be assessed. If the material was 100% cured, upon reanalysis the exothermic heat of reaction peak would be absent.

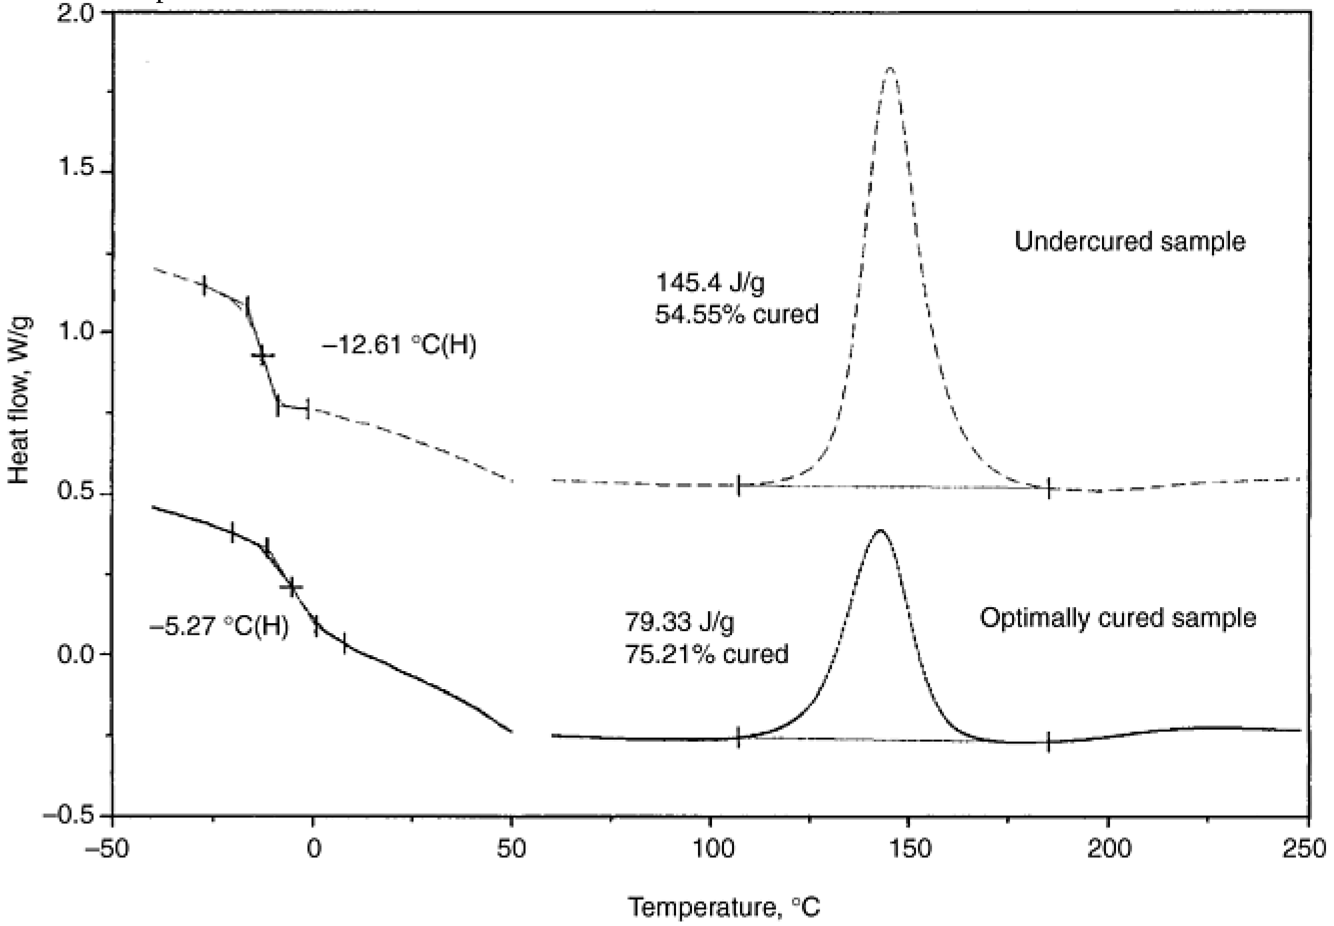

Fig. 1 Degree of cure determined using DSC. Graph shows advancement in T_g and measurement of heat of reaction. Heating rate: 10 °C/min; nitrogen gas purge (50 mL/min). Curves rescaled and shifted for readability

As mentioned previously, detection of the T_g by DSC may prove difficult or impossible in highly filled composites or where moisture is present. In filled composites with reactive resin matrices (epoxy), the heat of reaction is usually sufficient for comparisons to be made of degree of cure. However, quantitative accuracy can be affected by variability of fiber (and filler) content in the small samples used.

Modulated DSC, a high-performance version of DSC, improves the possibility for T_g detection because it can offer a fivefold increase in sensitivity over DSC and with no loss in signal resolution (Ref 3). Figure 2 shows MDSC detection of a broad T_g in a complex glass fiber reinforced epoxy-Kevlar/polyimide composite that was unobservable using DSC even at highest sensitivity. Modulated DSC can also resolve the total heat flow signal into its thermodynamic (heat capacity related) and kinetic (temperature/time related) components. This allows direct analysis of the effects of aging or process-induced stresses, which appear as an enthalpic relaxation that can mask the T_g, with the net result being a signal that looks like an endothermic melt. The total heat flow signal is shown in Fig. 3. Modulated DSC can resolve these overlapping events; the actual T_g of the epoxy composite appears in the upper curve in Fig. 3, while the relaxation is resolved into a second kinetic-related signal (nonreversing).

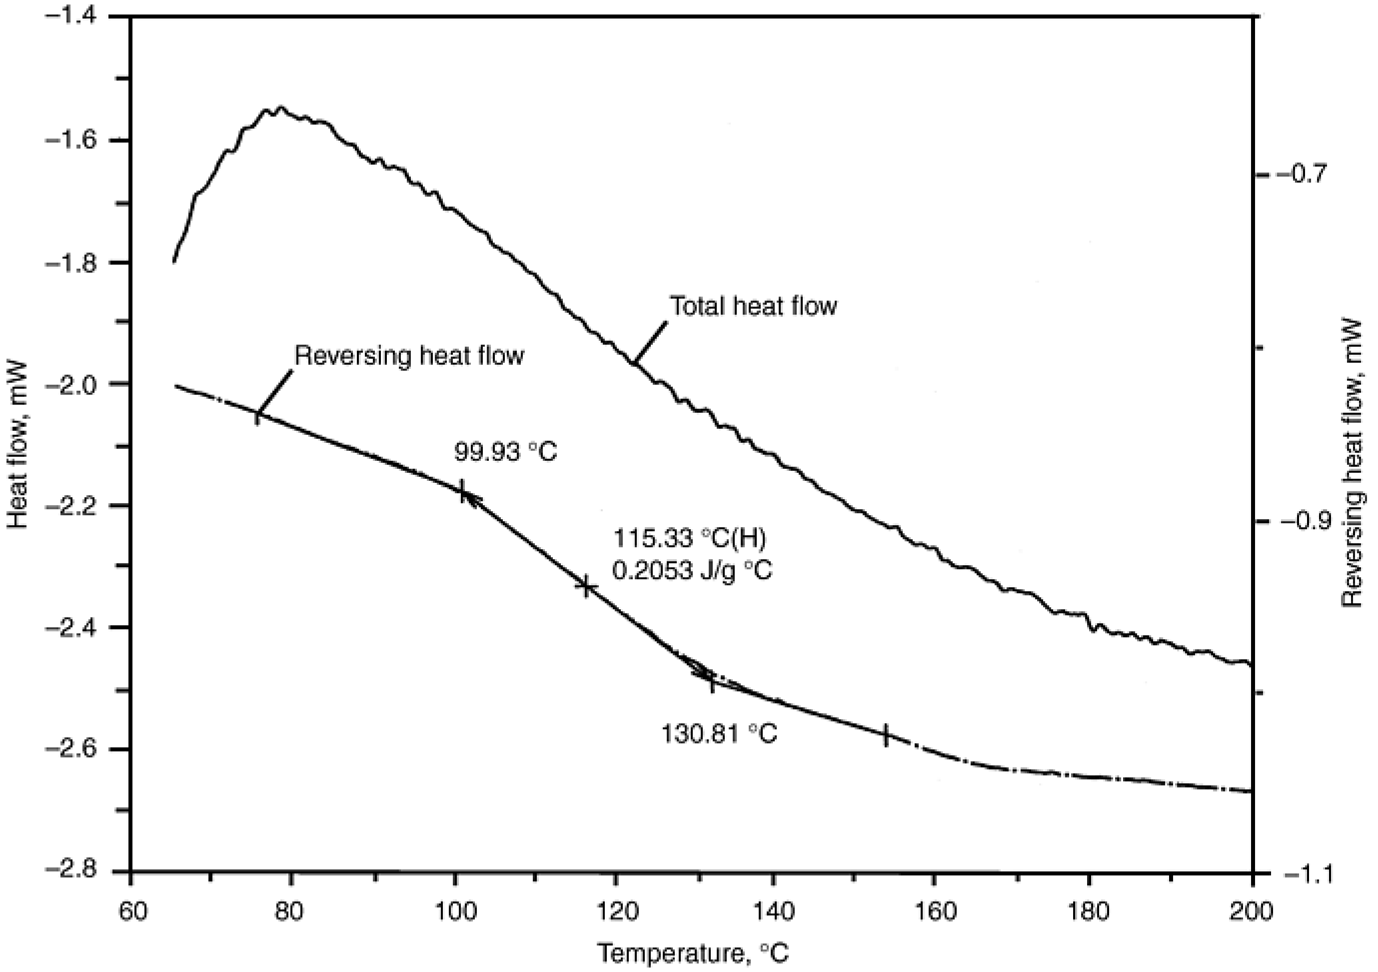

Fig. 2 High-sensitivity T_g detection using MDSC. Sample: glass fiber reinforced epoxy-Kevlar/polyimide; sample size: 32.9 mg; method: MDSC 2.5/60 at 1 °C/min; crimped pan; nitrogen gas purge

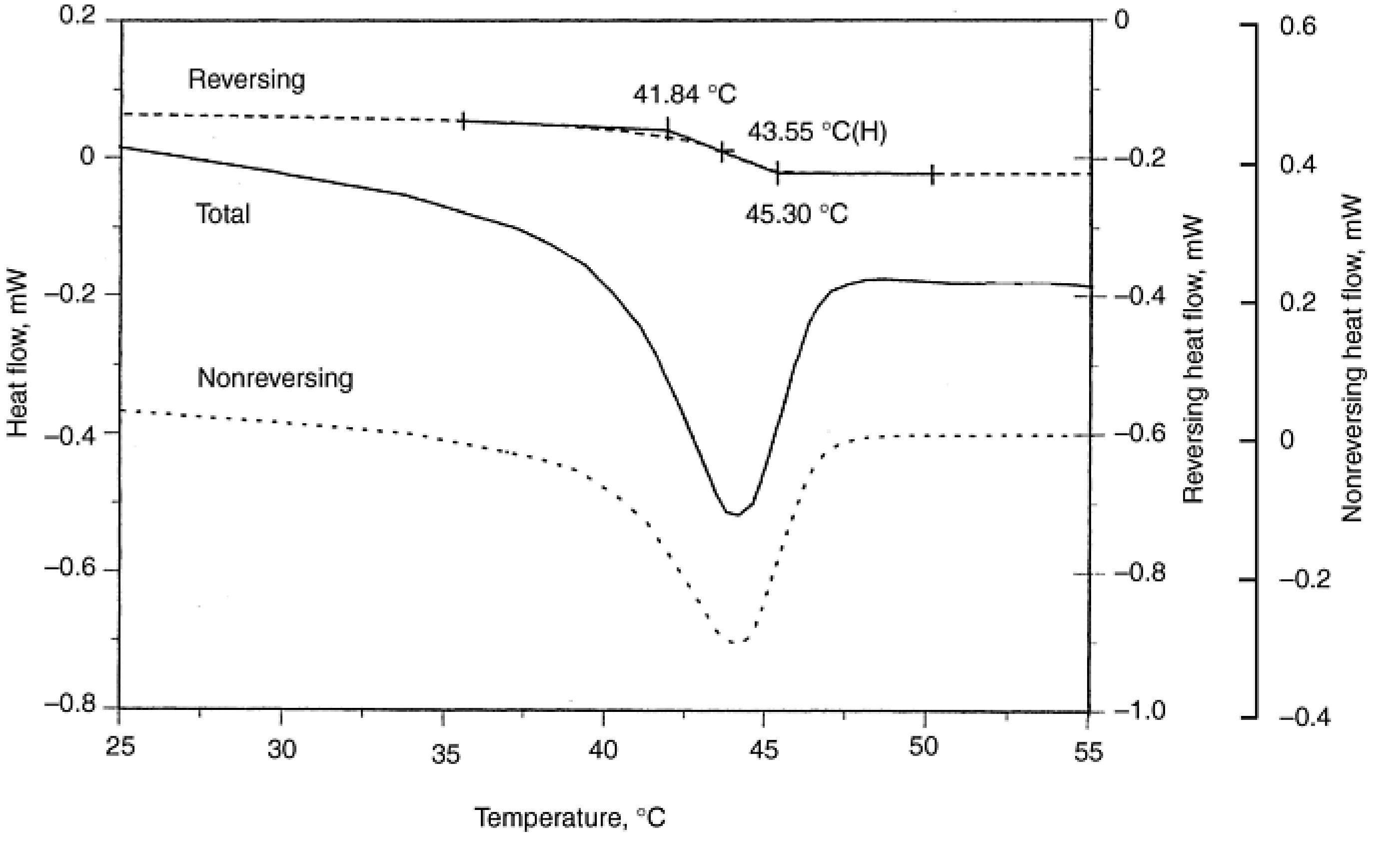

Fig. 3 MDSC separation of T_g from enthalpic relaxation. Upper curve: T_g; lower curve: enthalpic relaxation

Thermomechanical analysis determines dimensional changes in a material as a function of temperature (or time) under a controlled atmosphere. It is easy to use, has a wide temperature range (–150 to 1000 °C, or–240 to 1830 °F), and its multiple measurement modes (penetration, expansion, flexure, compression, tension, stress relaxation) permit analyses of a wide variety of materials. The primary applications of TMA to thermosets are the measurement of both T_g and the changes in its coefficient of linear thermal expansion (CTE) with cure.

In TMA, the T_g is measured as the intersection of the expansion curves in the glassy and rubbery states of the polymer matrix, possible for most polymers because there is a threefold difference in CTE at this point in the TMA curve (Ref 1). Figure 4 shows measurement of the expansion coefficient and the T_g in a printed circuit board (PCB) laminate, where the signal is affected by an enthalpic relaxation effect due to stress induced by processing (lower curve). Annealing the sample removes the relaxation and allows clear detection of the glass transition upon reanalysis (upper curve).

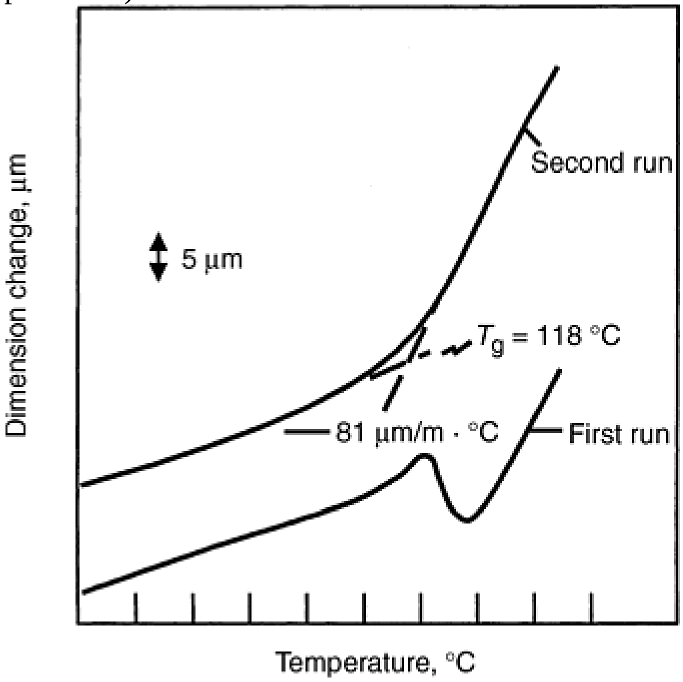

Fig. 4 TMA analysis of a PCB laminate

As with DSC, the success of a glass transition measurement using TMA may be compromised by effects of moisture, fiber orientation with respect to the probe, and the presence of filling materials.

Dynamic mechanical analysis measures the stiffness (modulus) and damping of a material as a function of temperature, time, and frequency under a controlled atmosphere. Operational from–150 to 600 °C (–240 to 1110 °F) and over a wide frequency range, DMA is used to probe material structure by measuring mechanical, flow, and viscoelastic properties (E', E'', G', G'', tan δ, η*). Multiple clamping systems allow operation in a variety of measurement modes (single and dual cantilever, three-point bending, shear, compression, and tension) on a range of samples. Its high sensitivity makes DMA an ideal tool for following the course and kinetics of the cure process and for analyzing the viscoelastic properties of the final product. Dynamic mechanical analysis can detect some or all of the events in a thermoset curing cycle, including initial T_g of the uncured resin, the temperature of minimum viscosity, the onset of gelation, the cross-linking reaction, the cure completion, and the modulus of the fully cured material. The sharp increase in the shear modulus with cure in Fig. 5 shows the high sensitivity of DMA to the cross-linking reaction even with complex materials such as a highly filled sheet molding composite.

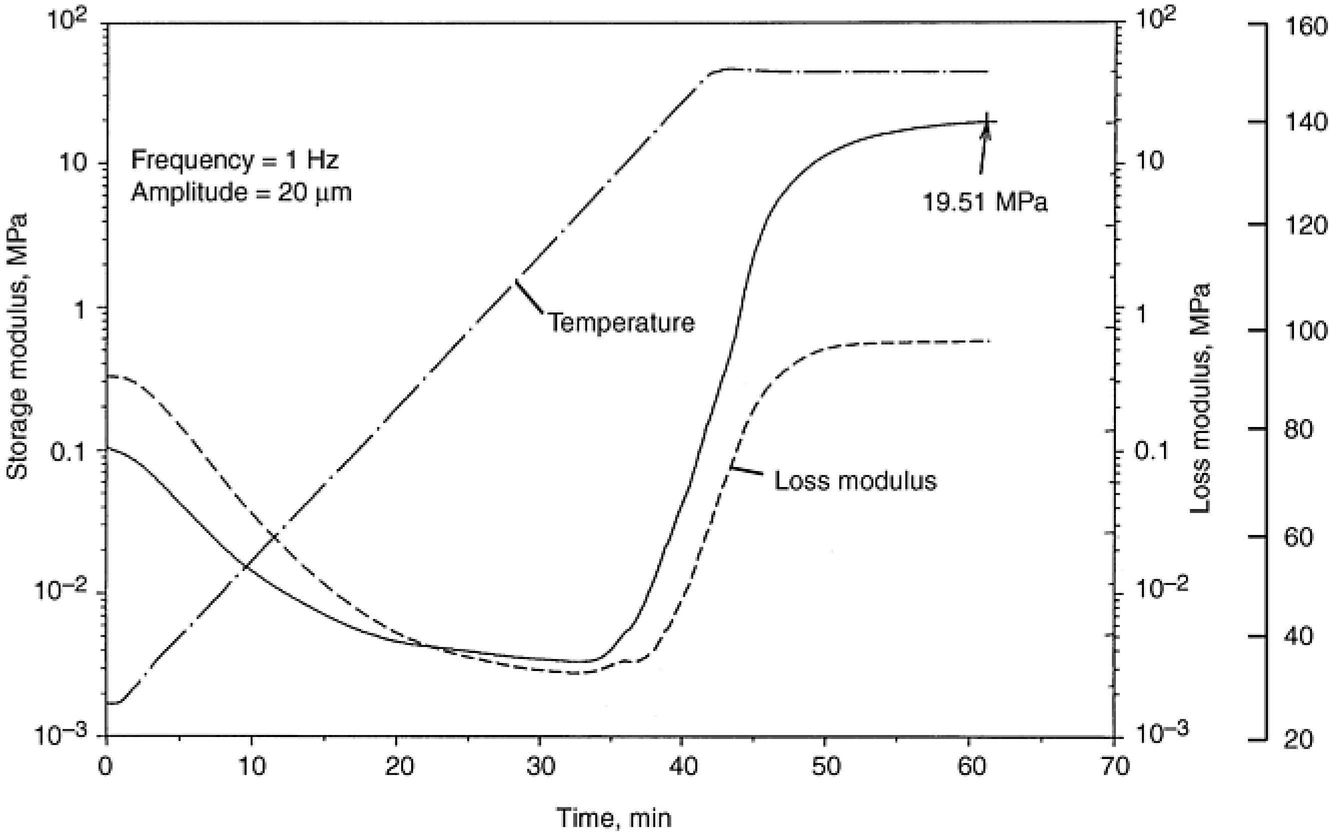

Fig. 5 Cure of sheet molding compound in shear sandwich mode. Cross-linking reaction indicated by sharp increase in shear modulus. Frequency: 1 Hz; amplitude: 20 µm

Dynamic mechanical analysis is also used to measure the T_g of a cured material versus a target value and in relative-cure comparisons. Its very high sensitivity to T_g detection is valuable in samples where the T_g is inherently weak or reduced by the presence of moisture or fillers. Absolute modulus numbers both below and above the T_g can easily be obtained. The higher the modulus above the T_g, the higher is the degree of cure, while in comparative situations, the higher the T_g, the greater is the degree of cure. In analyzing composites by DMA, the sample should be loaded in a resin-dominated direction. In fiber-dominated orientations, the superior fiber stiffness controls the composite stiffness and masks the effect of the resin.

Dielectric analysis measures dielectric properties of a material as a function of temperature, time, and frequency under a controlled atmosphere. Ceramic parallel plate and ceramic single-surface sensors permit analysis of powders, liquids, pastes, and films from–150 to 500 °C (–240 to 930 °F) and over a wide frequency range (0.003 to >100 kHz). Measured properties are dielectric permittivity (ϵ') and loss factor (ϵ''), from which other useful parameters (tan δ, ionic conductivity, complex permittivity) can be automatically computed. Permittivity (dielectric constant) is related to the ability of a material to store energy, while loss factor describes its conductive nature and is composed of two factors: energy loss associated with time-dependent polarization and bulk conduction. The former dominates below the T_g, and the latter above it, due to ionic mobility (Ref 4). Dielectric analysis is useful in resin-curing studies because it readily detects the T_g, minimum viscosity (seen as maximum ionic mobility), resin cure, and vitrification. It is very sensitive to the last stages of the curing reaction (Ref 5). Dielectric analysis is at least an order of magnitude better than DSC or TMA in detection of the T_g and can also measure lower energy β and γ transitions.

Figure 6 shows a DEA curing study on an Epon 828/DDS system, where the T_g, flow, minimum viscosity, and cure portions of the curve are readily apparent. Dielectric analysis is also useful for evaluating cure in solvent-based urethane/isocyanate systems, which pose problems for DSC and DMA due to the low viscosity of the initial resin, the small heat of reaction, and solvent volatilization.

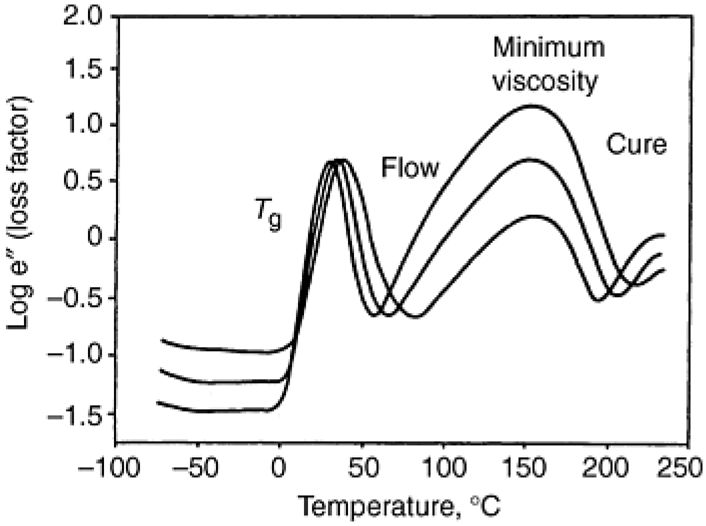

Fig. 6 Epoxy resin cure determined using DEA with a single-surface sensor. Sample: Epon 828/DDS; heating rate: 3 °C/min; frequency: 10, 30, 100 kHz

Dielectric analysis may have limited utility in analysis of highly filled composites, since the filler material can reduce signal sensitivity by restricting dipolar alignment with the electric field (permittivity) and also impede ionic mobility. Dielectric analysis is impractical if electrically conductive fillers or supporting fibers are present, because these would short the electrodes.

Fractography

Patricia L. Stumpff, Hartzell Propeller, Inc.

Introduction

FRACTURE SURFACES are examined during most investigations of failed structural components because these surfaces provide an actual physical record of the events at the time of failure. Fractographic analyses of the surfaces of metallic components reveal useful information about the cause and sequence of failure. Those surfaces reveal features that identify the crack origin, crack propagation direction, failure mode, load, and environmental conditions at the time of failure. This information is extremely useful in the determination of failure cause. Hence, as composites developed into structural materials, a similar need arose to understand the fractographic evidence that these materials can provide.

The best method of developing an understanding of the fractographic evidence provided by those failures is to obtain pedigreed, fractographic data. These data are obtained by documenting the fractographic characteristics of specimens manufactured from different composite materials under different processes and exposed to different environmental and load conditions. The fracture surfaces of the pedigreed test specimens are examined, documented, and analyzed to determine which features are specific to a particular material, process, load, and/or environmental condition. The fractographs can then be used in the analysis of component failures.

This article depicts typical fractographic features for a number of different composite materials. Although not all-inclusive by any means, the fractographs depict a range of different, yet typical, fractographic features obtained from various composite materials that were manufactured and tested under different load and environmental conditions. It is hoped the fractographic data provided are useful for comparison with actual fractured surfaces to help determine the cause of component failures.

Material systems examined include epoxy resins with different fibers, such as carbon/epoxy (AS4/3501-6), fiberglass/epoxy (Hexcel E-glass/ F155) and aramid/epoxy (Kevlar 49/3501-6), as well as fibers with different thermosetting resins, including carbon/bismaleimide (AS4/5250-3) and glass/polyimide (Celion 3K/PMR-15). Carbon fiber and thermoplastic resin composite systems are also highlighted, mainly for comparison purposes, and include carbon/thermoplastic (AS4/APC-2) and (AS4/KIII).

The specimens used for the fractographs depicted in this section were generally manufactured according to material supplier recommendations. Those specimens that were not manufactured according to manufacturer recommendations were processed with changes made solely to examine the effect of different material processing conditions. Material processing variations included changes in cure cycle, such as overcure or undercure conditions, surface contamination, and reduced resin content.

Environmental conditioning of the test specimens was conducted as noted in the fractographs provided. Environmental conditions examined included the effect of moisture in the laminate, moisture saturation followed by elevated temperature exposure (i.e., hot/wet conditions), and elevated temperature exposure without prior moisture conditioning.

Loading on the specimens was conducted using a variety of test specimens and load conditions. Mode I tension and tension fatigue failures were obtained using double cantilever beam (DCB) specimens; mode II shear and shear fatigue failures were obtained using end-notched flexural (ENF) specimens. Translaminar tension and compression specimens used either the notched bend bar specimens with four-point loading or the specimen configurations defined in ASTM D 3039, “Tensile Properties of Fiber- Resin Composites” and ASTM D 3410, “Compressive Properties of Unidirectional or Cross- Ply Fiber Resin Composites.”

Following manufacture, environmental conditioning, and testing to failure, the fracture surfaces of the test specimens were examined in the scanning electron microscope (SEM). Typical fractographic features of each test specimen were then identified and documented. Further examination and analysis of the fractographs were then conducted in order to define the specific fractographic features that were indicative of a specific material, processing, environmental, or load condition at failure.

Patricia L. Stumpff, Hartzell Propeller, Inc.

Interlaminar Fracture Features

An interlaminar fracture occurs when the load is applied perpendicular to the composite laminate and failure occurs in the plane of the reinforcement. Interlaminar fractures occur following mode I tension or fatigue loading, mode II shear or fatigue loading, flexural loading, and impact loading on the surface of the laminate.

Interlaminar Fracture of Composites with Brittle, Thermoset Matrices. Most of the fractographic evidence in interlaminar fractures that would be indicative of the material, processing, load, and/or environmental conditions at failure are found in the matrix materials, rather than the fibers, of the composite. Analysis has shown that the fractographic features associated with these brittle thermoset matrices, including the epoxies, bismaleimides, and polyimides, are similar in nature. Because of this, most of the fractographic data presented in this section were obtained from epoxy matrix materials; minimal fractographic data from the other brittle thermoset resin systems are presented.

Differences in Fracture Characteristics Due to Different Loading Conditions. In general, brittle matrix composite materials tested under interlaminar, mode I tension loads fail in the plane of the reinforcement. Visually, these surfaces exhibit a glossy appearance, with some banding and resin covering most of the fibers on the fracture surfaces. On a microscopic level, the fractographic features evident in this failure mode consist mainly of river patterns on the surface of the matrix, as shown in Fig. 1 and 2, and matrix feathering, as shown in Fig. 3. River patterns are basically created by cleavage of the matrix on different levels, resulting in what appear to be branches or small tributaries of a river. They can be found emanating from the resin at the surface of the fibers or fiber imprints, as shown in Fig. 2(b), or in the matrix between fibers. Matrix feathering, on the other hand, consists of small flow lines in the matrix that emanate from an imaginary centerline as the crack moves forward. Feathering is particularly evident in large, flat, resin-rich regions, where river patterns are not usually noted. Both river patterns and matrix feathering are not only indicative of mode I tension loading in brittle composite materials, but have also been noted to be indicative of crack growth direction. Crack growth direction can be ascertained by noting the direction in which the smaller rivers combine into the one large river, as shown in Fig. 1. In this figure, the crack-growth direction is from left to right. It has also been noted during fractographic examination that larger river patterns tend to give a better indication of the overall direction of crack growth in the specimen, as the larger river patterns are less influenced by the fibers themselves. In general, however, river patterns are indicative of mode I tensile loading and must be vectorially added across the majority of the fracture surface in order to obtain a definitive crack initiation site and crack-growth direction. Flow lines are also indicative of crack growth direction, as shown in Fig. 3, where they are indicative of crack-growth direction from right to left.

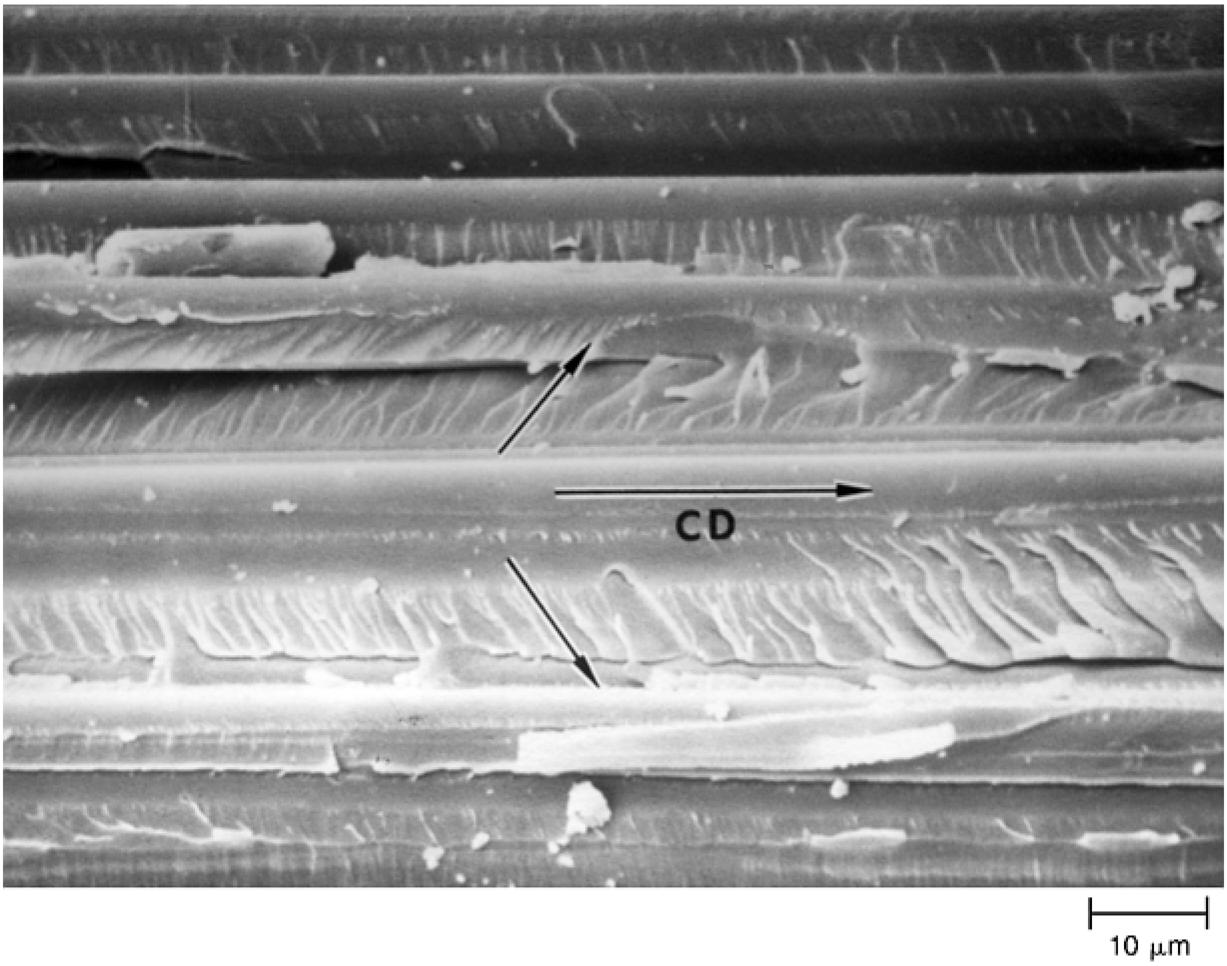

Fig. 1 River patterns on the surface of a mode I tensile failure in a carbon/epoxy (AS4/3501-6) composite laminate. Overall crack growth direction is from left to right. 1000×

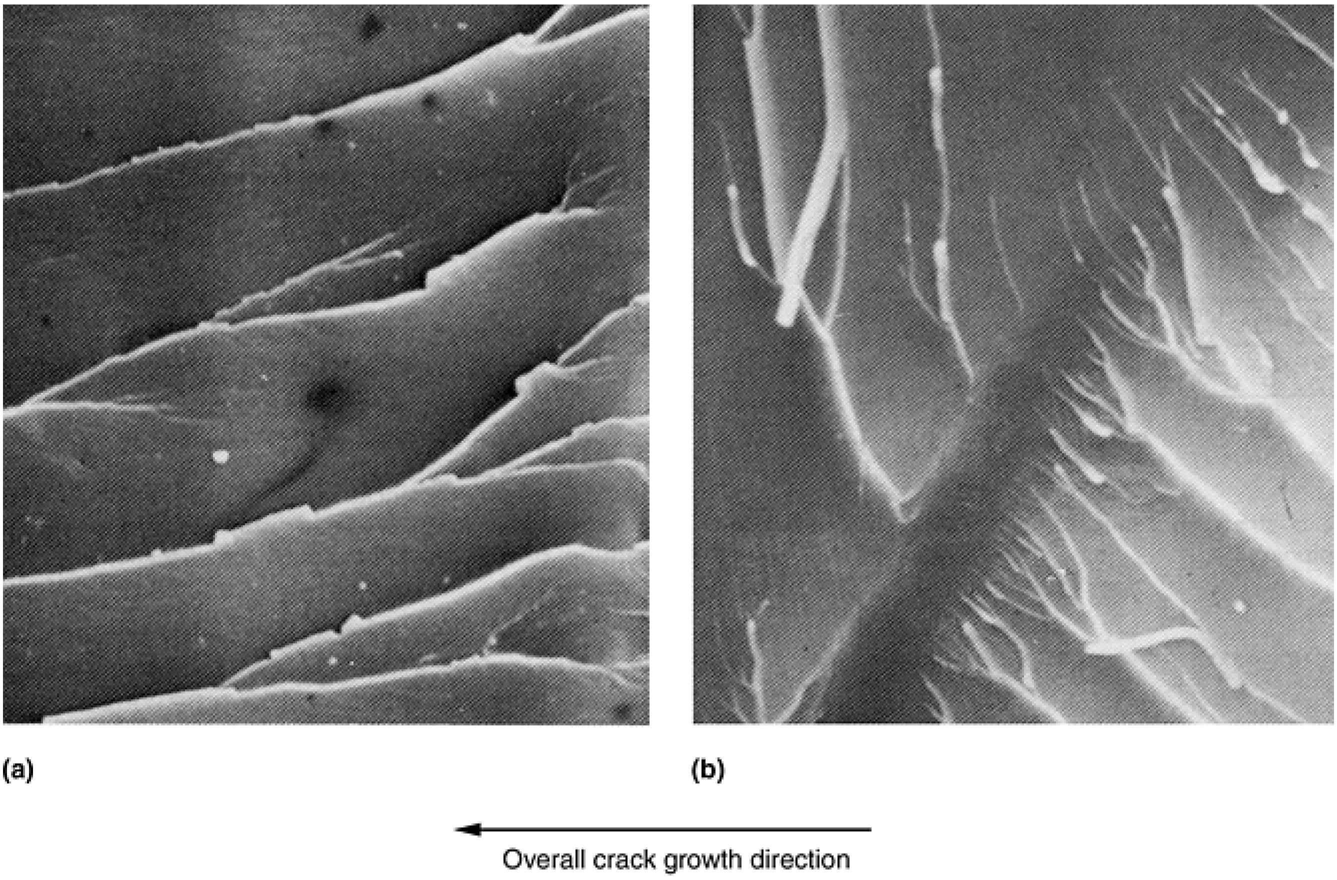

Fig. 2 Mode I tension interlaminar fractures that propagated at various angles to the direction of fiber reinforcement. (a) Fracture between adjacent 0° and 90° plies. (b) Fracture between 45° and–45° plies. 2000×. Source: Ref 1

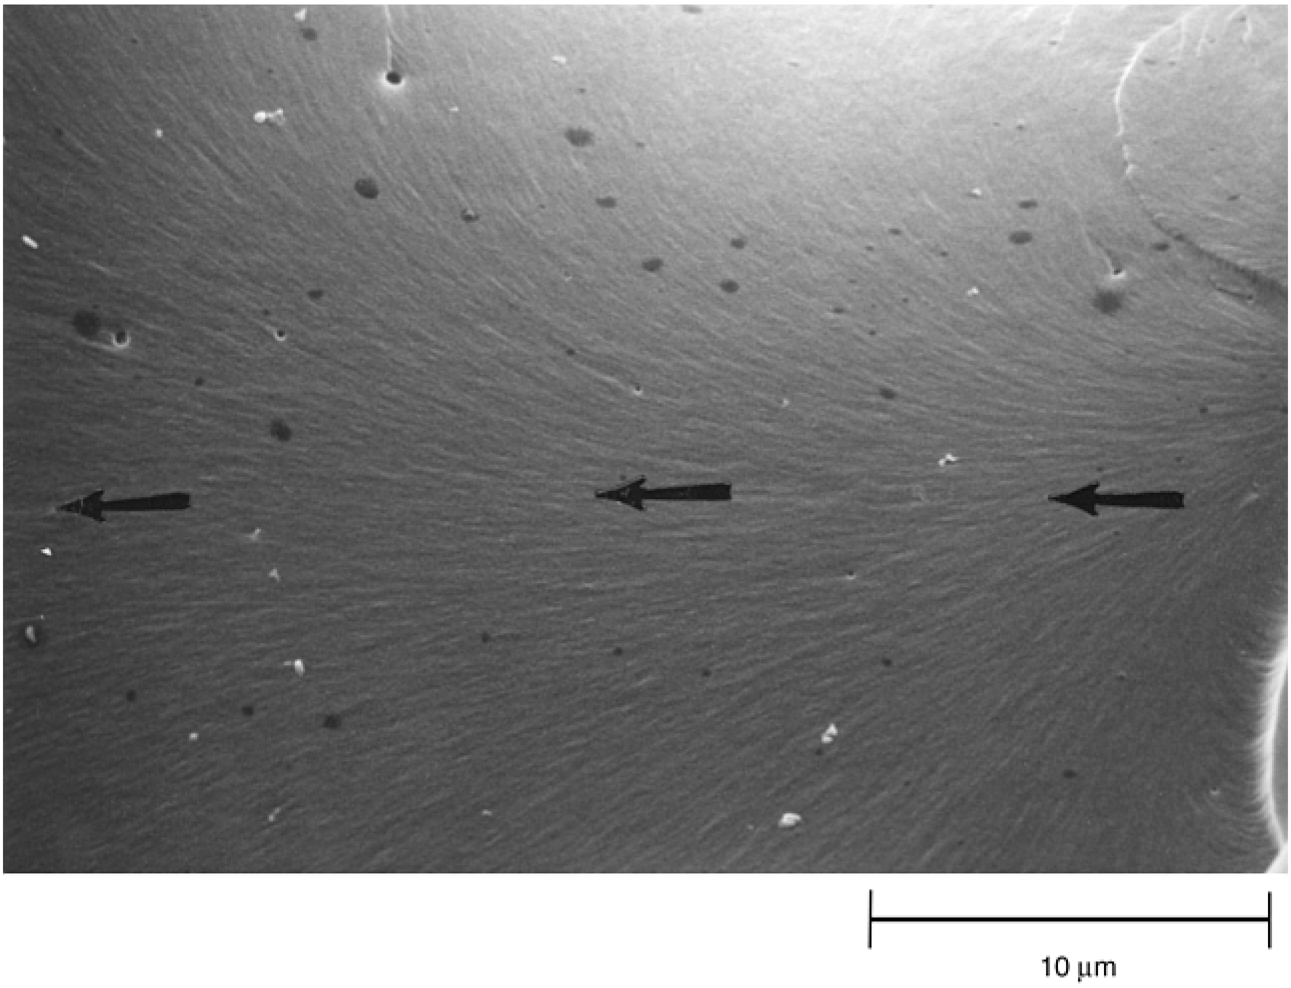

Fig. 3 Matrix feathering produced under interlaminar mode I tension. 3600×. Source: Ref 1

Composites with brittle matrices tested under interlaminar mode II shear loading exhibit different fractographic features than those tested under interlaminar mode I tension loading. Visually, these surfaces exhibit milky white, dull fracture surfaces. Again, failure of the laminate generally occurs in the plane of the reinforcement, and SEM analysis reveals distinctive fractographic features. On these fracture surfaces, the appearance of the feature known as *hackles* becomes evident, as shown in Fig. 4 and 5. Hackles appear to form by the coalescence of numerous, small, 45°, tensile micro cracks that form between the fibers under shear loading, as illustrated in Fig. 6 and 7. The size, shape, and form of the hackles are quite varied over the fracture surface, and the variation appears to be related to the actual percentage of mode I versus mode II loading, the amount of resin between the fibers, and the orientation of the fibers to the applied load. Under some mode II shear or mixed mode load conditions, small river patterns are sometimes evident at the base of the hackle or on the surface of the hackle as depicted in Fig. 5. These river marks can sometimes be used to help in determining the crack-growth direction.

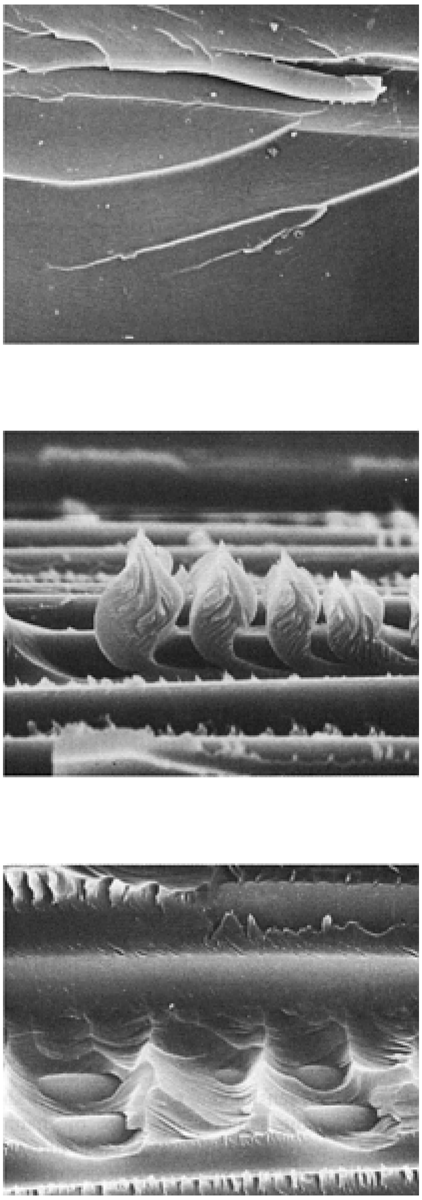

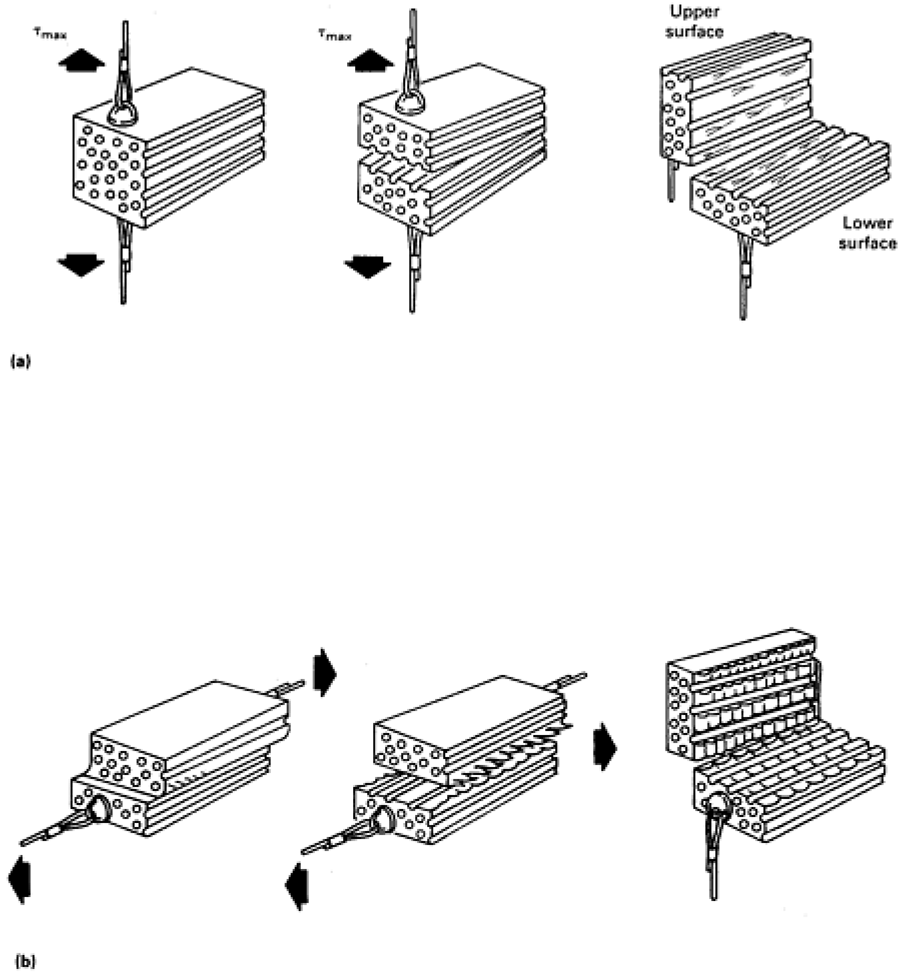

Fig. 6 Schematic of mode II interlaminar shear failure

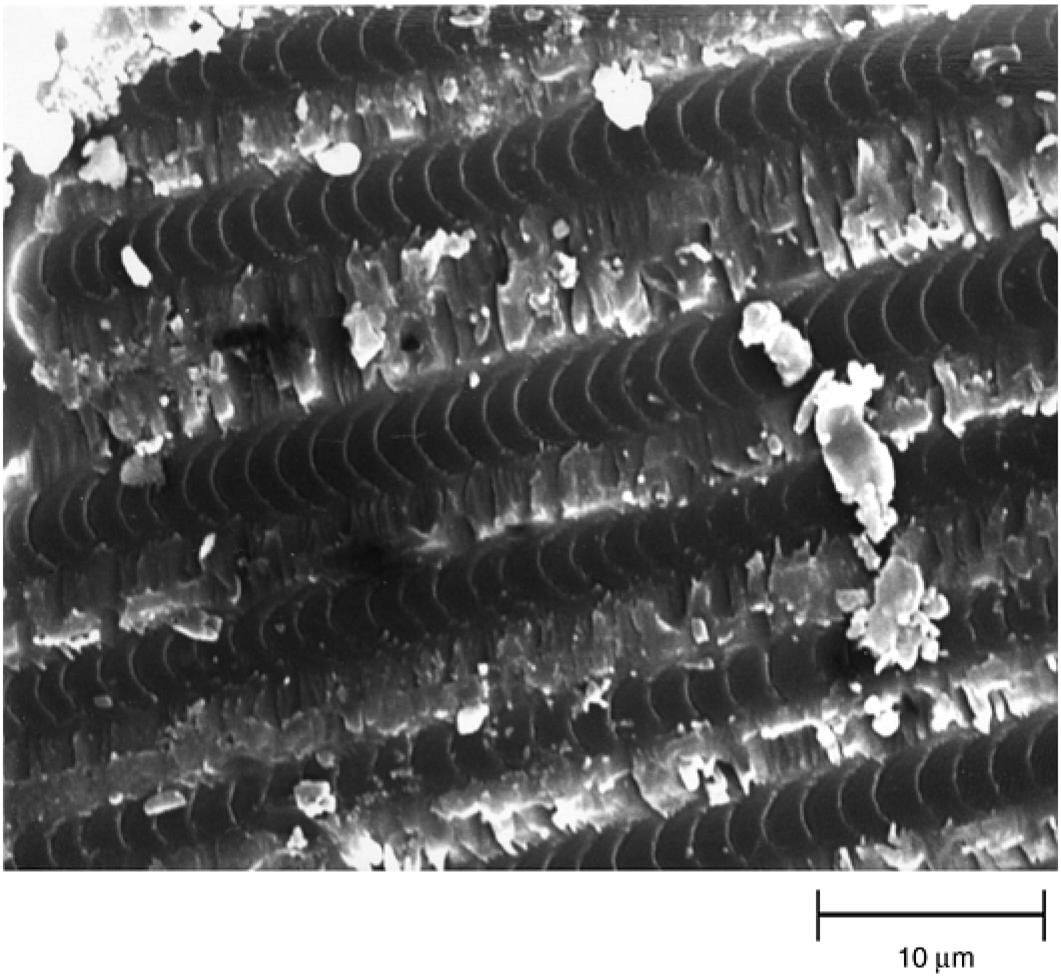

Fig. 7 Fatigue striations in a carbon fiber composite. 2000×

Specimens tested under mode I tension and mode II shear fatigue loading generally result in fracture surfaces that contain fatigue striations. Fatigue striations, however, are not easily found in composite materials. This is partly because there may be little difference macroscopically between specimens that failed in fatigue and those that failed in overload by tension or shear. Unlike metallic materials, in which beach marks can often be found radiating outward from a visual fatigue initiation site, composite materials lack an apparent visual fatigue initiation site, which makes the diagnosis of fatigue failures at the macroscopic level somewhat more difficult. Additionally, fatigue failures can also be difficult to diagnose on the microscopic level. There are usually relatively few areas on the fracture surface that contain the fatigue striations. This lack of a significant number of striations on a fatigue fracture surface and the large separation between areas containing fatigue striations make locating them somewhat difficult and more time-consuming than in metals. The difficulty in finding these features is also enhanced by the fact that a certain amount of specimen tilt is often required in order to make them visible in the SEM. The amount of specimen tilt is of utmost importance in detecting the striations; higher tilt angles (>30°) often are required to find them. However, when fatigue striations are found, they can be found either in the matrix between two fibers, as shown in Fig. 7 and 8, or in the matrix itself, as shown in Fig. 9.

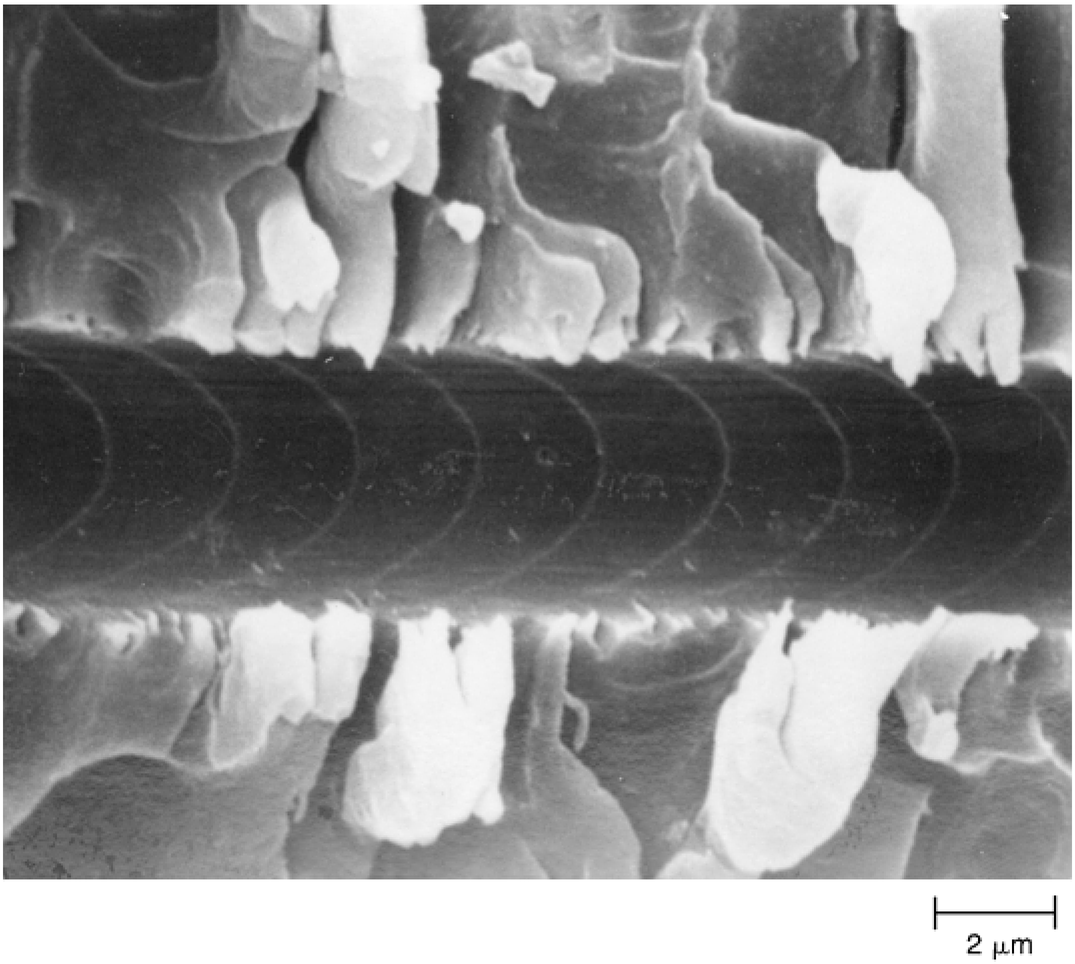

Fig. 8 Fatigue striations in the resin beneath a carbon fiber that was pulled out of a carbon/epoxy (AS4/3501-6) laminate following mode I fatigue loading. 5000×

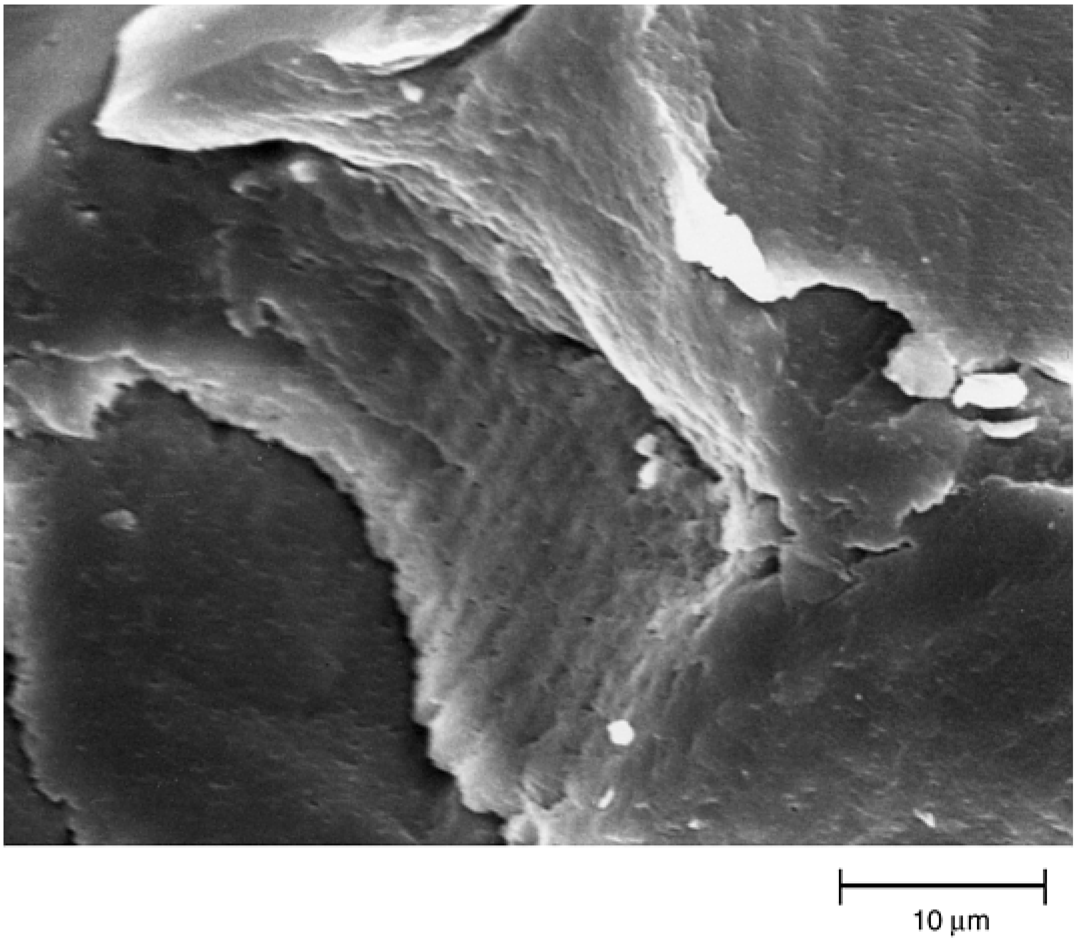

Fig. 9 Fatigue striations in the resin of a carbon/fiber composite laminate that failed in mode I fatigue loading. Striations cover the surfaces of several fibers. 1000×

Impact damage is another form of loading that can result in specific interlaminar fracture characteristics in composite materials. In general, a delamination resulting from an impact load can often be ascertained by opening up the laminate in the plane of the delamination under mode I tension or mixed-mode loading. Visually, the delamination will generally exhibit a whitish, damaged surface, as compared to the darker, smoother, reflective surface of the manually fractured region. The delamination due to impact will also exhibit more evidence of shear (i.e., hackle formation in the damaged region) as compared to the surrounding area, which will generally have more river patterns indicative of the manually applied, mixed mode, or mode I tensile loading. The impact damaged region will also exhibit considerable matrix debris on the surface of the laminate, as compared to the surrounding area. For woven Kevlar/epoxy laminates, the fractographic evidence of impact damage can be found in both the matrix and in the fibers. Figures 10 and 11 depict the difference between an interlaminar fracture due to impact damage and an interlaminar fracture due to mode I tension loading for this particular material system. In addition to the visual differences noted above, the microscopic features in the impact damaged region (Fig. 10) include hackles, matrix debris, and significant fiber fibrillation and damage. The microscopic features in the mode I tensile region (Fig. 11) include the formation of river patterns, minimal matrix debris, and significantly less fiber fibrillation than in the impact-damaged zone.

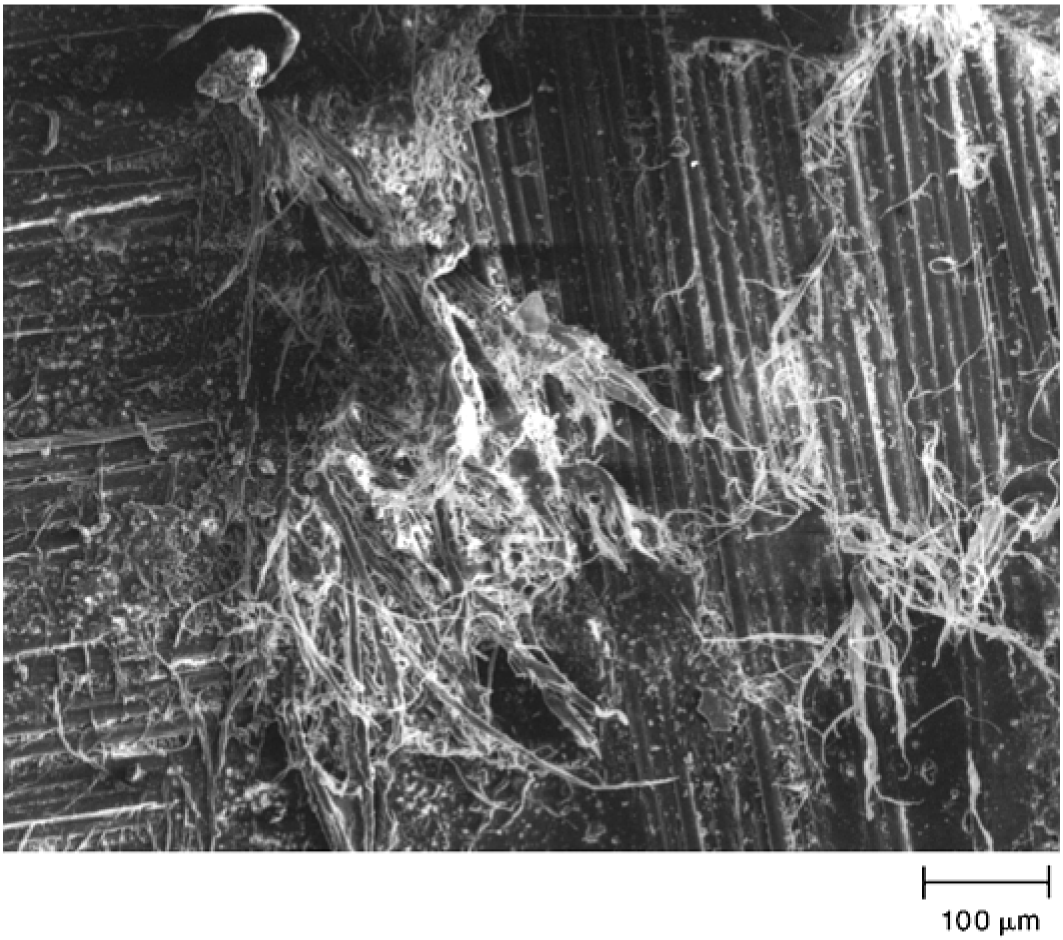

Fig. 10 Impact damage in a Kevlar/epoxy composite laminate depicting hackle formation indicative of shear loading; resin debris indicative of impact loading and fiber fibrillation. 120×

Fig. 11 River patterns and fiber fibrillation in a Kevlar/epoxy laminate in the region surrounding the impact damage, following peel failure of the laminate. 120×

Differences in Fracture Characteristics Due to Different Material Processing Conditions. Composite materials were then manufactured using material processing conditions other than those recommended by the manufacturer. The purpose of manufacturing and testing these specimens was to determine if material processing defects could be identified in the fracture characteristics of the laminates. Brittle thermoset-matrix composite test specimens were either overcured or undercured during the processing of the laminates and then tested to failure under mode I tension loading. The fracture surfaces of these specimens exhibit variations in the fractographic features that appeared to coincide with the variations in processing conditions. In specimens that were undercured and then tested to failure under mode I tension, the river patterns generally exhibited a more feathery appearance than the specimens that had received a normal cure cycle. Specimens that were overcured and then tested to failure under mode I tension generally exhibited more brittle-looking and distinct river patterns in the matrix. Other material processing variations, including the use of materials with inadequate resin content, generally resulted in interlaminar fracture surfaces with fewer matrix-rich regions and, hence, fewer fracture features, such as river marks, matrix feathering, hackles, and fatigue striations. Inadequate resin content in laminates also generally reveals the fracture characteristic known as fiber splinters. Fiber splinters are fibers that separate readily from the fracture surface because insufficient adherent-matrix cannot keep them attached to the rest of the specimen under mode I tension loading. These splinters are shown in Fig. 12 for a woven, glass/polyimide composite laminate. Other processing defects, such as contamination of an internal ply of the composite laminate with a release agent such as Frekote (Dexter Adhesive & Coating Systems) can also be found on the delaminated fracture surface during routine examination, as shown in Fig. 13.

Fig. 12 Exposure of fiber splinters in a glass/polyimide laminate having inadequate resin content, following mode I tension loading of the specimen. 40×

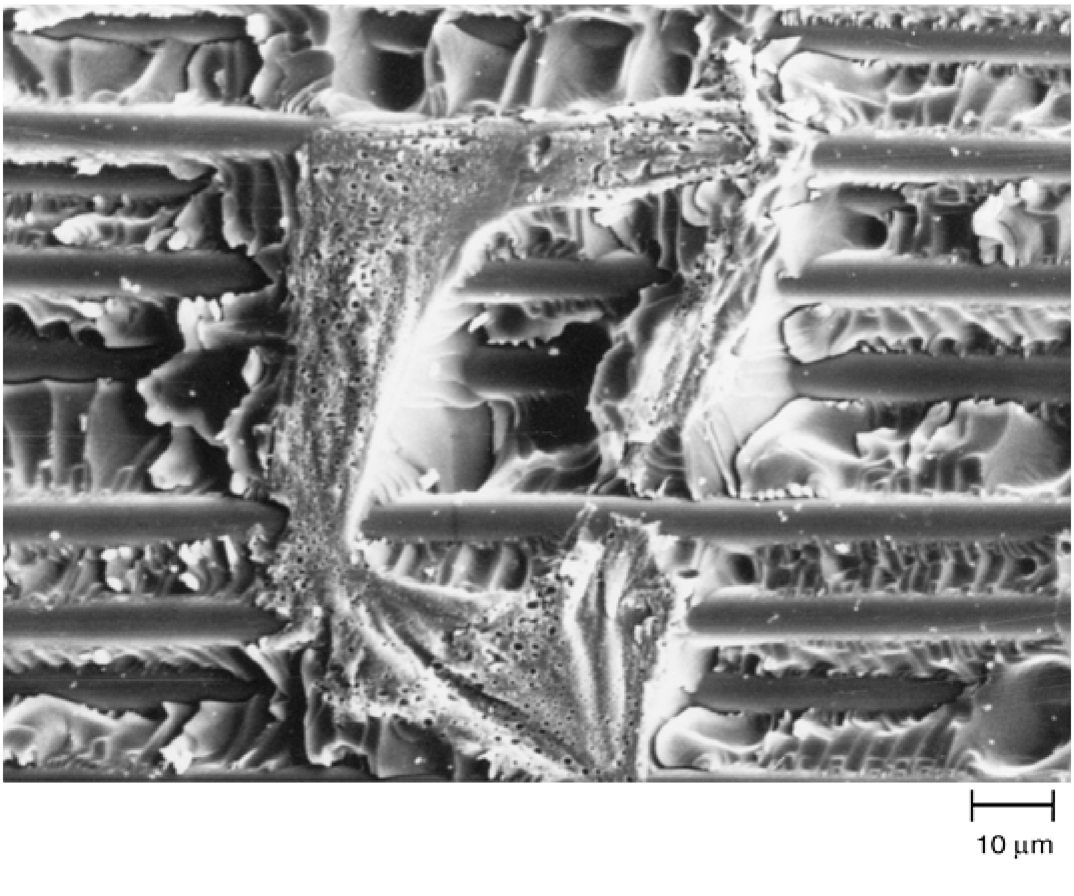

Fig. 13 Frekote contamination on the center portion of the fracture surface of a carbon/epoxy specimen, following mode II shear loading. 780×

Differences in Fracture Characteristics Due to Different Environmental Conditions. Environmental exposure of the test specimens either before, during, or after loading also influences the fractographic features of brittle matrix composite materials. Specimens first exposed to moisture and then tested at room temperature or specimens exposed to moisture and then tested at elevated temperature revealed specific, identifiable fracture characteristics. Composites that were moisture-saturated and then tested at room temperature generally revealed more plasticity in their fracture characteristics than those specimens that were not moisture-conditioned. This effect, however, is very subtle and may or may not be evident, unless a similarly manufactured and tested dry specimen is available for comparison. For specimens that were moisture-conditioned and then exposed to elevated temperature, however, the fracture characteristics include not only an increase in matrix plasticity, but also an increase in the amount of fiber/matrix interfacial failure in the composite, as shown in Fig. 14. Although an increase in the amount of fiber/ matrix interfacial failure may also be somewhat subjective in nature and difficult to discern, this effect is usually more significant, particularly at high moisture contents and temperatures near the wet, glass transition temperature of the resin. Environmental exposure of an organic, composite laminate to high heat or fire, without prior moisture exposure, may also be determined from the fractographic evidence. Following exposure to elevated temperatures, the resin itself is often degraded or pyrolized. The carbon fibers themselves tend to become thinner and more distorted; they have a loss of fiber end fracture features and decomposition products appear on the surface, as shown in Fig. 15. The amount of degradation will depend upon the glass transition and oxidation temperatures of the particular resin system used in the composite, as well as the time and temperature of the exposure. The result can be a partial or total loss of matrix fracture features, including river patterns, hackles and striations, which makes analysis of composites exposed to high temperatures or fire significantly more difficult.

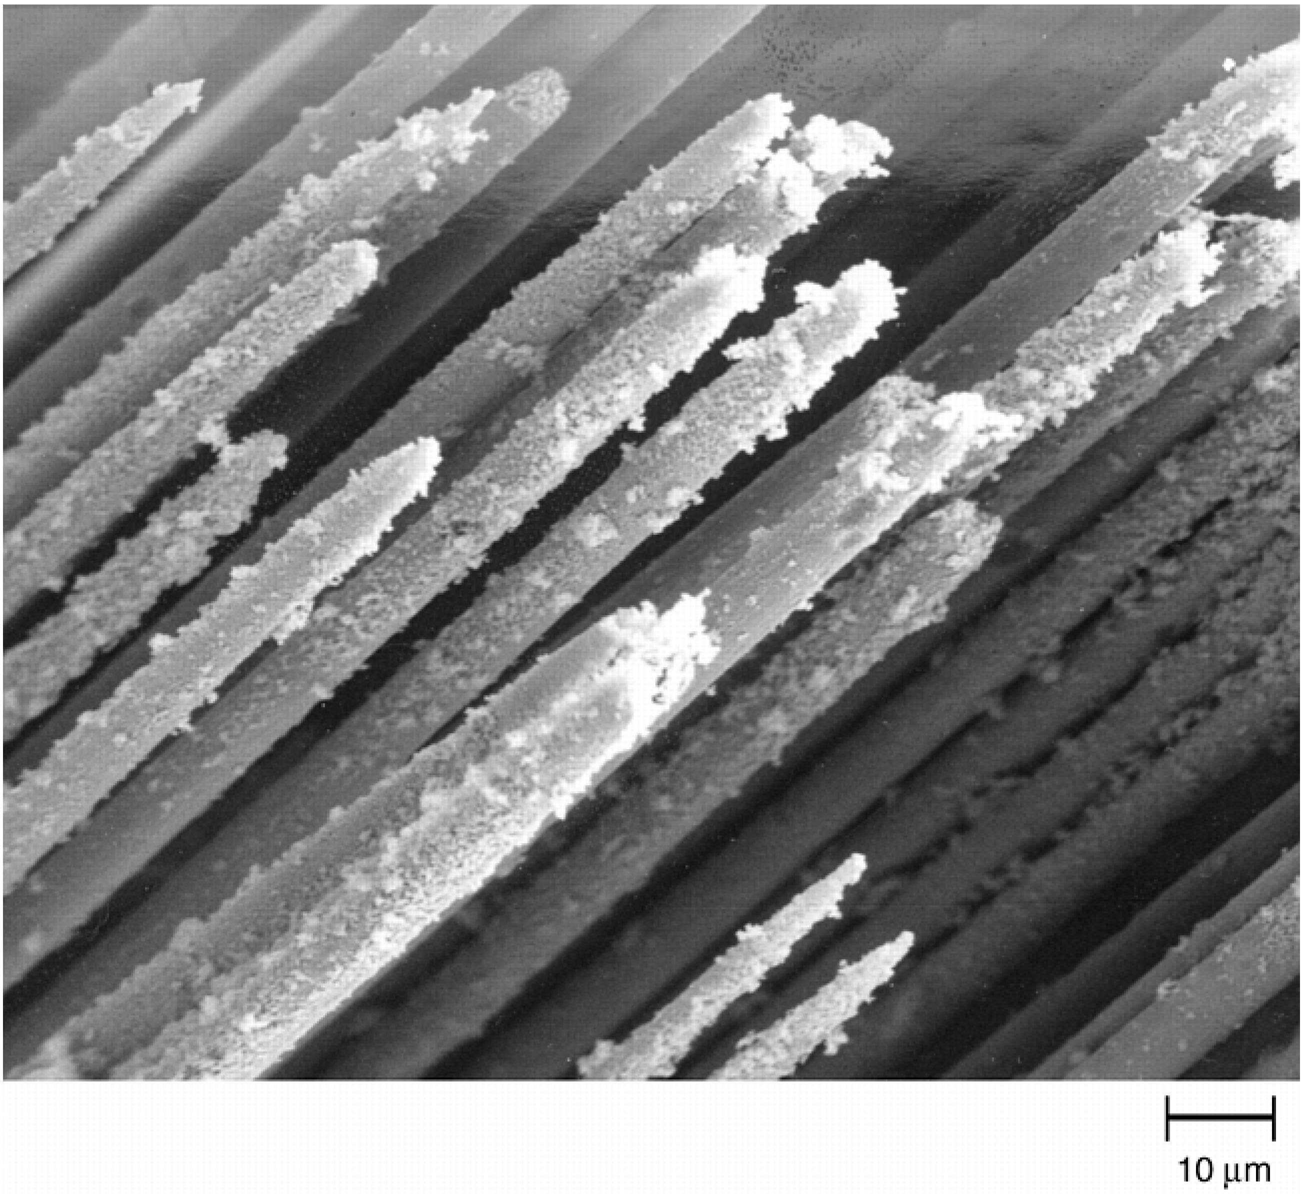

Fig. 15 Carbon fibers in a carbon/epoxy (AS4/3501-6) laminate, following exposure to fire for an unknown time period. 780×

Interlaminar Fracture of Composites with Ductile Thermoplastic Matrices. In ductile thermoplastic resin systems, the interlaminar mode I and mode II fracture characteristics of composite materials are significantly different than for the brittle, thermoset resin systems. In the case of carbon/thermoplastic (AS4/APC-2), the mode I tension fracture surfaces do not exhibit river patterns. These surfaces exhibit small matrix peaks, as shown in Fig. 16, or small flat, radiating, crystallite formations on the fiber surfaces, as shown in Fig. 17. Both of these formations are indicative of the semicrystalline nature of the polyetheretherketone (PEEK) resin system.

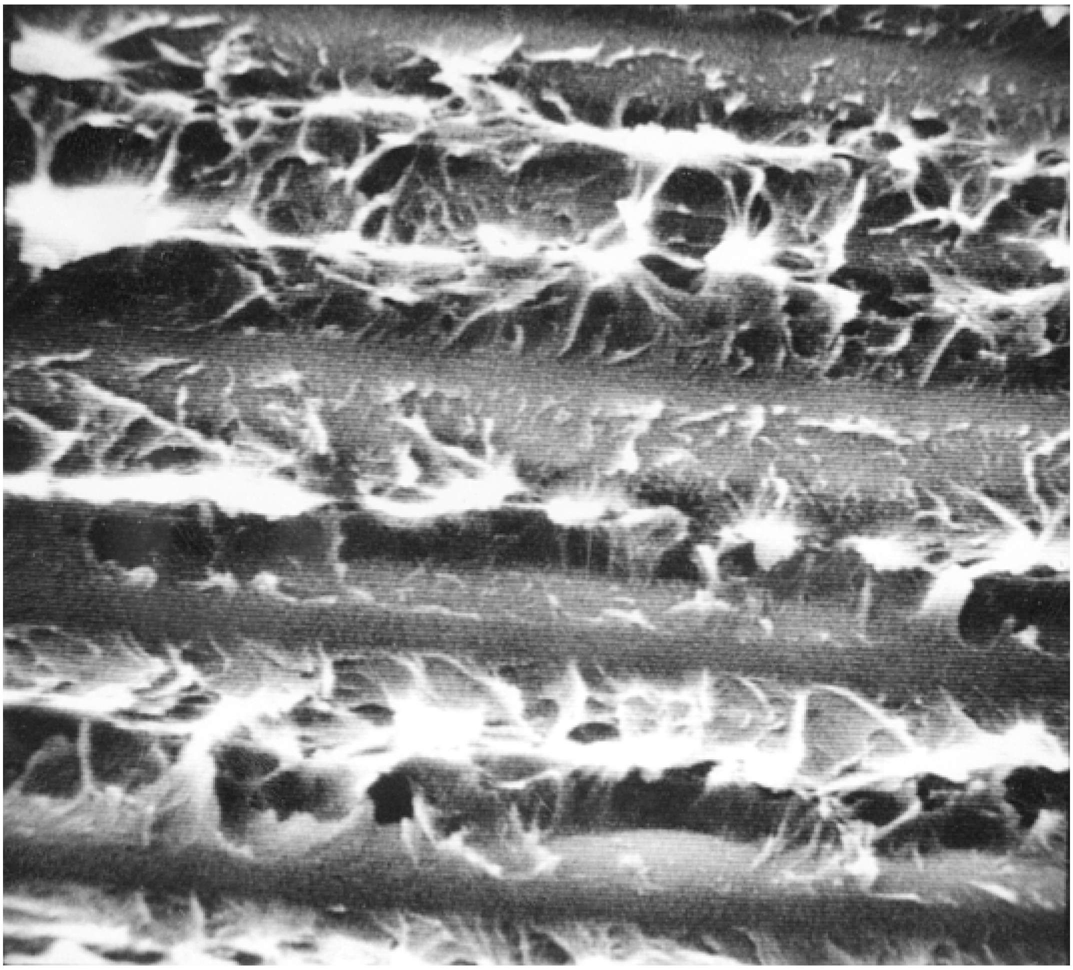

Fig. 16 Surface features of carbon/polyetheretherketone (AS4/APC-2), following mode I tensile fracture. 1500×

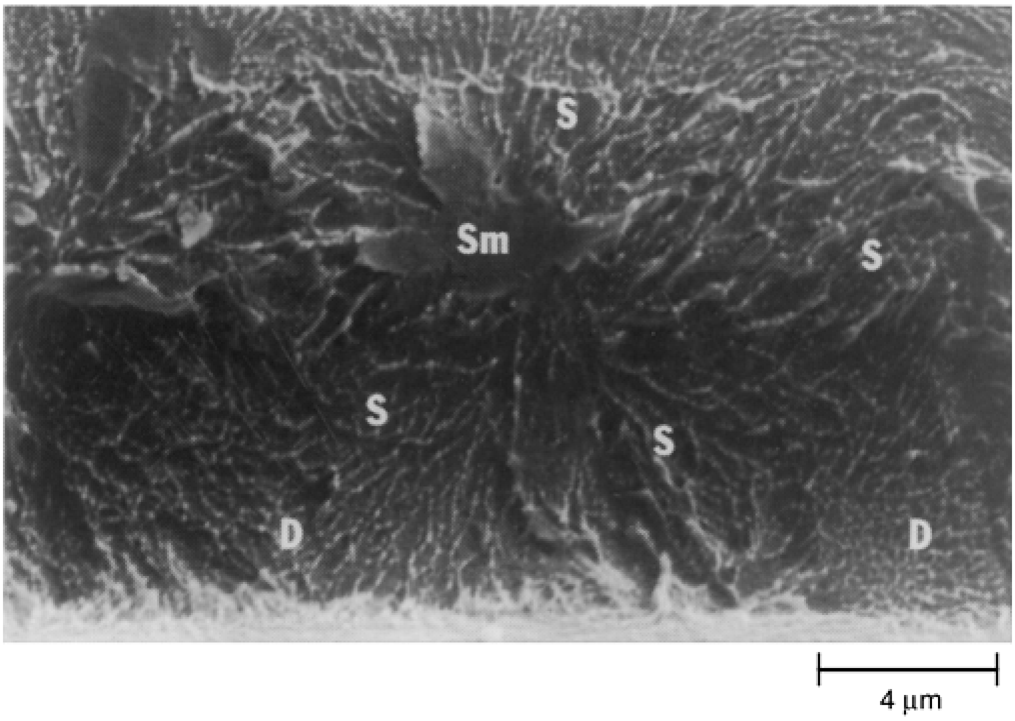

Fig. 17 Radial features thought to be crystallites in the matrix of the APC-2 material, indicative of the crystalline nature of the carbon/thermoplastic (AS4/APC2) resin system, following failure due to mode I tension loading. 5000×

For thermoplastic composite laminates such as AS4/APC-2, tested under mode II shear, the fracture features are again unique and unlike the brittle thermoset matrices in which hackles are formed. However, in this case, a similar, repetitive formation of the resin occurs on the surface of the fibers, as shown in Fig. 18. These formations have been termed “spikes.” The tilt of the spikes and the flow of the material from the base to the tip can again be used as an indication of crack-growth direction.

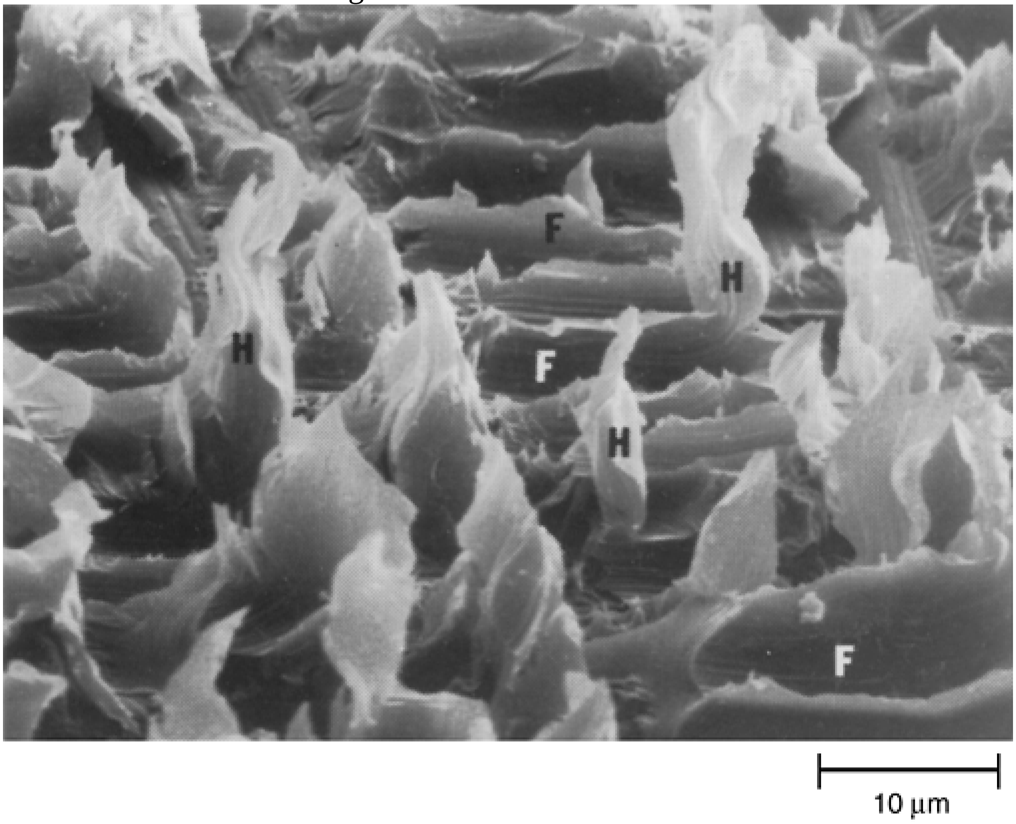

Fig. 18 The formation of the feature known as *spikes* in a mode II shear fracture surface of a carbon/PEEK composite laminate. 1700×

Thermoplastic composite specimens, tested under mode I tension and mode II shear fatigue loading conditions, were also examined and fractographically documented. The fracture surfaces of these specimens also exhibit fatigue striations. These striations are similar to those formed in brittle thermoset-matrix composite systems but seemed to exhibit considerably more matrix plasticity, as shown in Fig. 19. The striations in these thermoplastic materials also tend to take on a somewhat irregular shape, often following the ductile matrix material; in brittle thermoset composites, the striations are generally sharp and regular and follow a relatively flat fracture path. Additionally, another feature indicative of fatigue has been noted on the fracture surface of other thermoplastic composite materials, including the carbon/KIII thermoplastic system; when tested under mode II shear fatigue loading conditions, the fracture surfaces of this material exhibit the feature known as *matrix rollers*. This feature consists of resin that tends to roll up upon itself, as shown in Fig. 20. The appearance of these rollers, either between two fibers and/or on the top of the fracture surface, also indicates fatigue failure of the part.

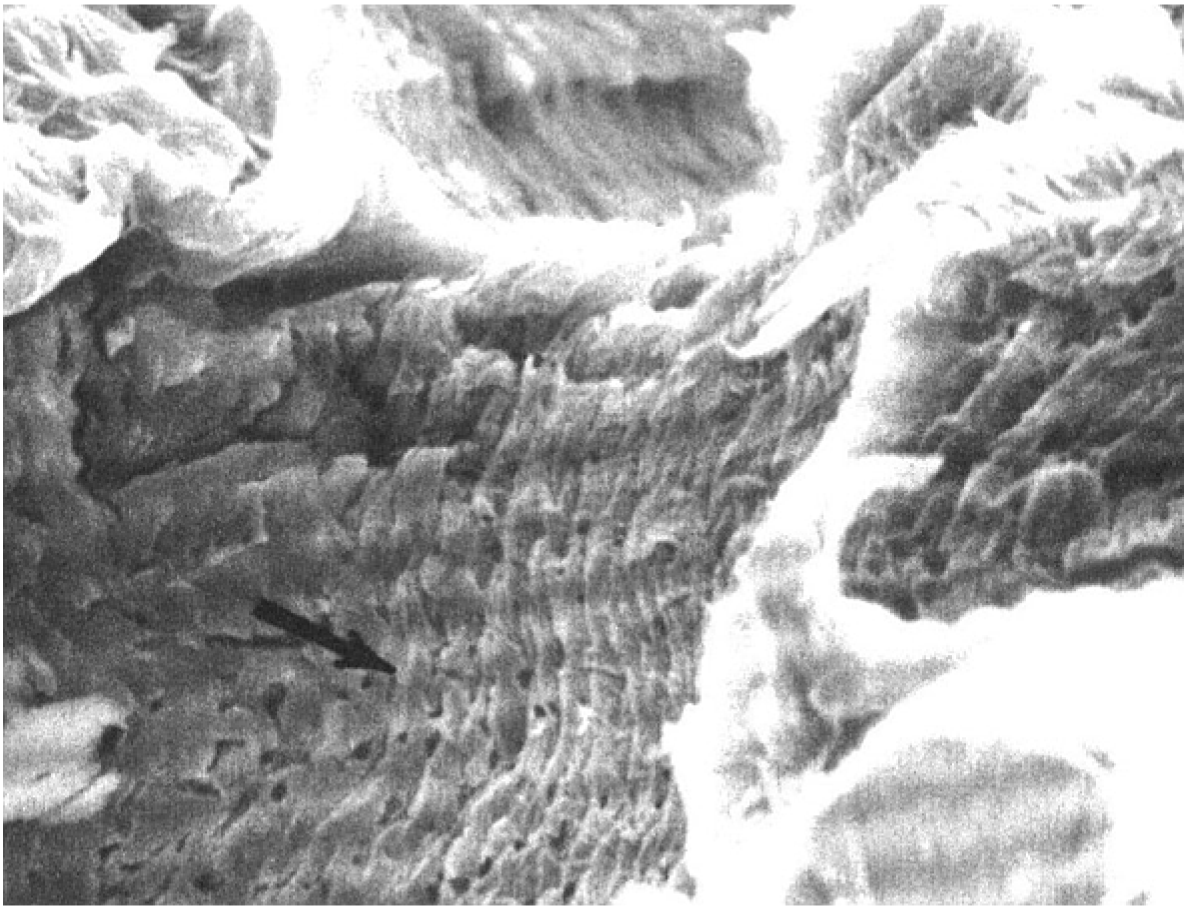

Fig. 19 Fatigue striations in the resin of an interlaminar failure, following mode I loading of a carbon/PEEK composite laminate. 900×

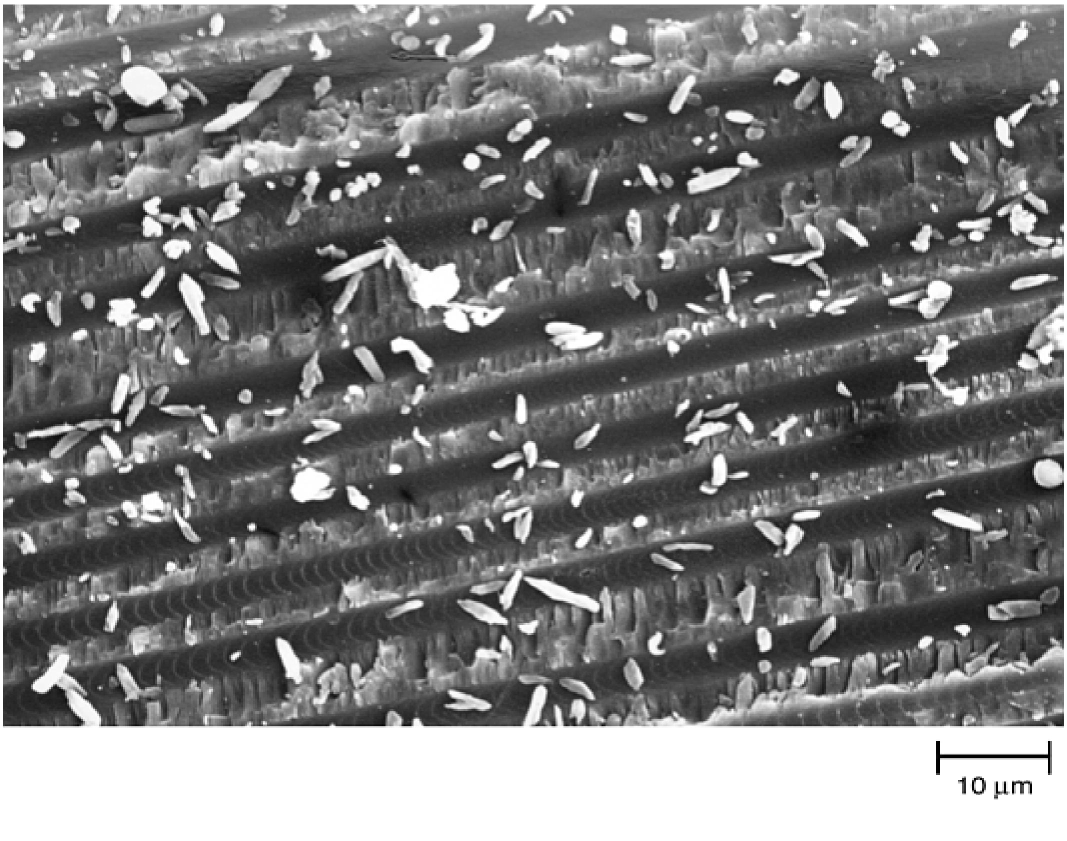

Fig. 20 Fracture feature known as *matrix rollers* on the surface of a carbon/KIII thermoplastic composite, following failure under mode II shear loading conditions. 1000×

Minimal changes in the manufacturing processes were explored and minimal environmental exposure was conducted for the thermoplastic composite systems. Moisture conditioning of the thermoplastic composite with room temperature testing, however, did not appear to significantly alter fracture features of the carbon/PEEK material.

Translaminar Fracture Features

Translaminar fractures occur when loading of the composite specimen causes fracture perpendicular to the plane of fiber reinforcement. Unlike interlaminar failures, where most of the fractographic information is in the matrix material, translaminar fractures have the majority of the fractographic information in the fiber ends. Visually, translaminar fractures that fail under tensile loads, particularly those with some zero-degree or other off-axis plies, will exhibit considerable fiber pullout and have very irregular fracture surfaces. Scanning electron microscopic examination of the fiber end fractures of carbon and glass fibers will often depict the feature known as *fiber radials*, as shown in Fig. 21 and 22. These fiber radial patterns can often be found in groups, particularly if failure occurred directionally across the laminate, as in the four- point, notched-bend specimens. In these directionally failed test specimens, the fiber radials can be used to determine the direction of the crack propagation. To do this, the direction of each fiber fracture must first be determined. The direction of fiber fracture is determined by creating a vector from the initiation point of the fiber, where the lines on the fiber ends radiate outward, to a point 180° across the fiber surface. Crack growth direction in the laminate can then be determined from addition of these vectors on each fiber across the entire fracture surface.

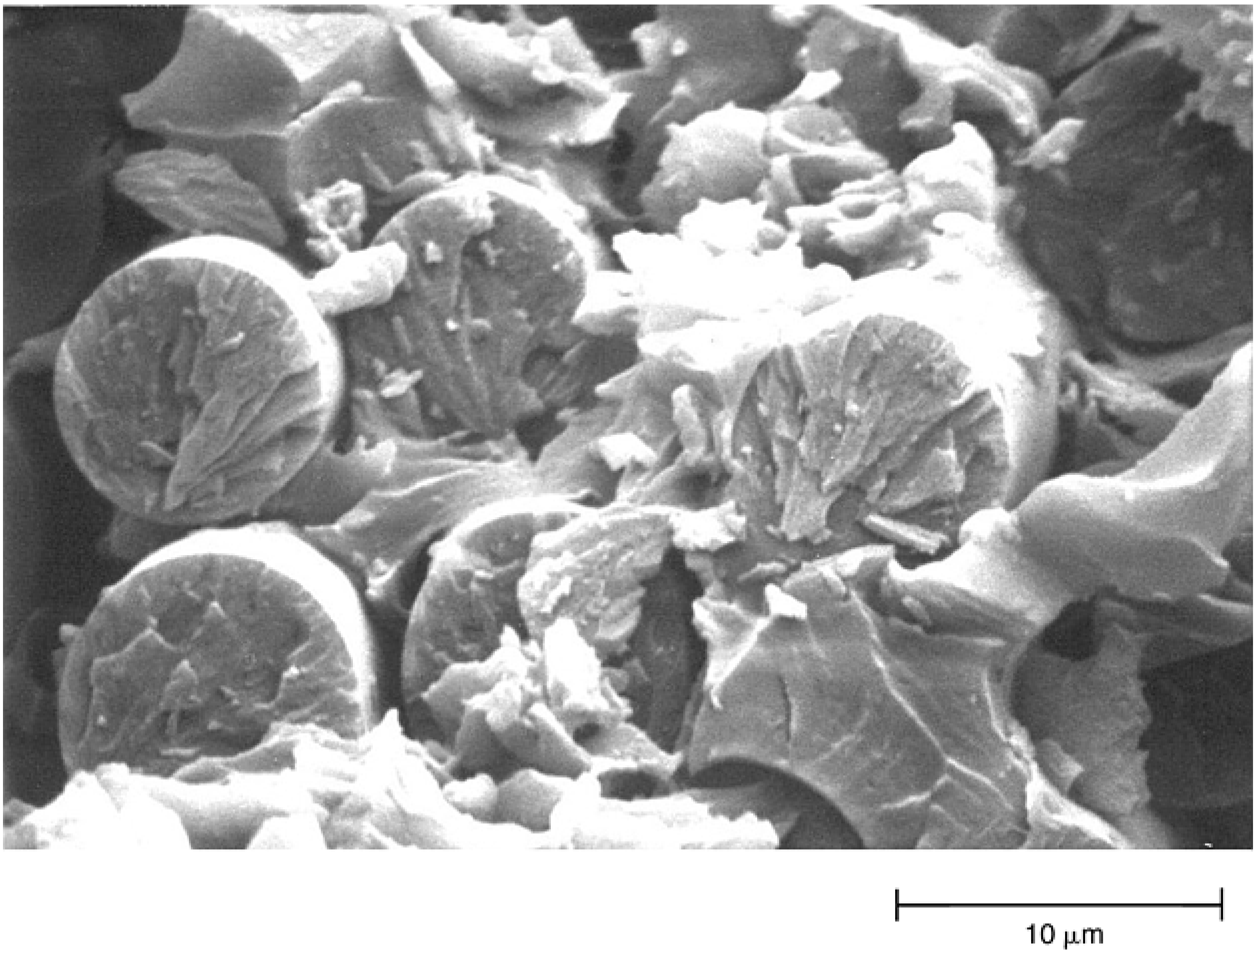

Fig. 22 Radial marks on the surfaces of glass fibers indicative of tensile failure in a glass/polyimide composite following failure of a notched four-point bend specimen. 3000×

For composites loaded under translaminar compression, the fracture surfaces are straighter and less jagged than those that failed under translaminar tension. The fracture surface of a composite failed in compression exhibits several different fracture layers, secondary cracking and minimal fiber pullout. They often exhibit shear crippling due to microbuckling of the fibers, which occurs when the fibers kink under compressive loads (Fig. 23a, b). This shear crippling then results in the fracture feature known as *chop marks,* along with pieces of matrix debris on the surface, as shown for carbon fibers in Fig. 23(c) and (d) and for glass fibers in Fig. 24. Chop marks generally have three specific regions on the fiber ends: a tensile region, indicated by fiber radials, a compressive region, indicated by a flat, often angled, fracture surface, and a neutral axis or line separating the two regions.

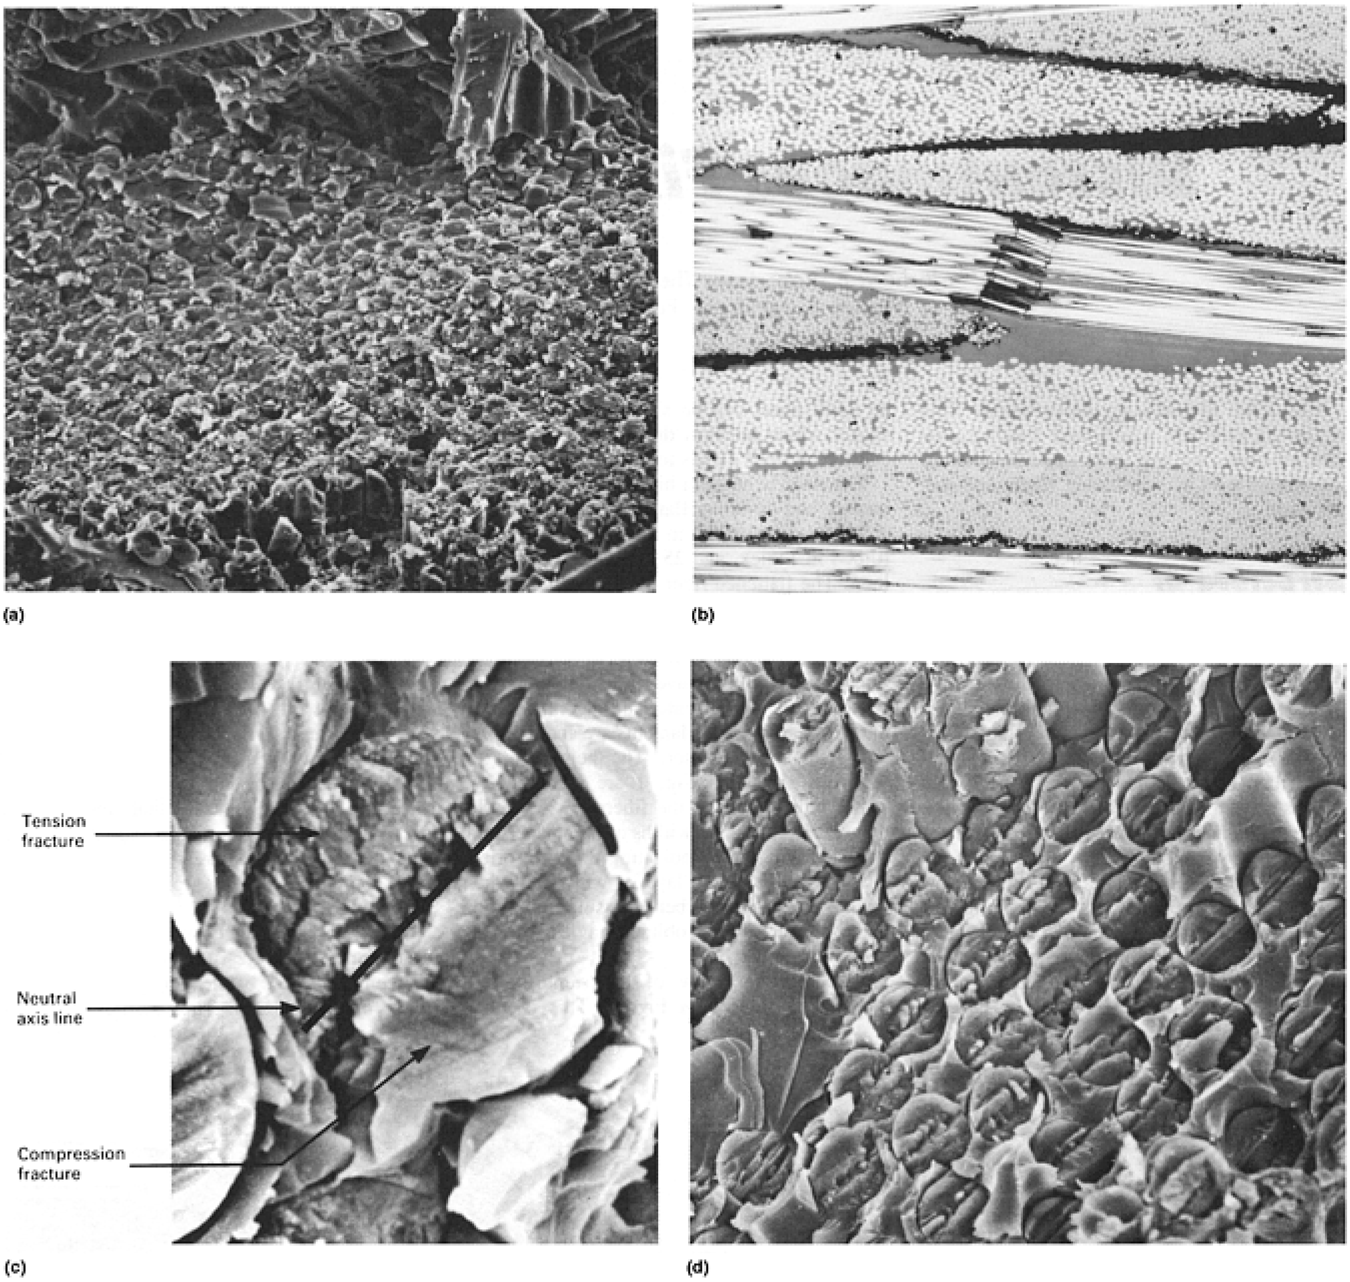

Fig. 23 **Examples of translaminar compression fractures. (a) Translaminar compression fracture with extensive post-failure damage to fiber ends. 750×. (b) Translaminar compression- generated fiber kink in graphite/epoxy fabric. 100×. (c) Flexural fracture characteristics on fiber ends of a compression specimen. 10,000×. (d) Translaminar compression fracture illustrating parallel neutral axis lines representative of unified crack growth. 2000×**

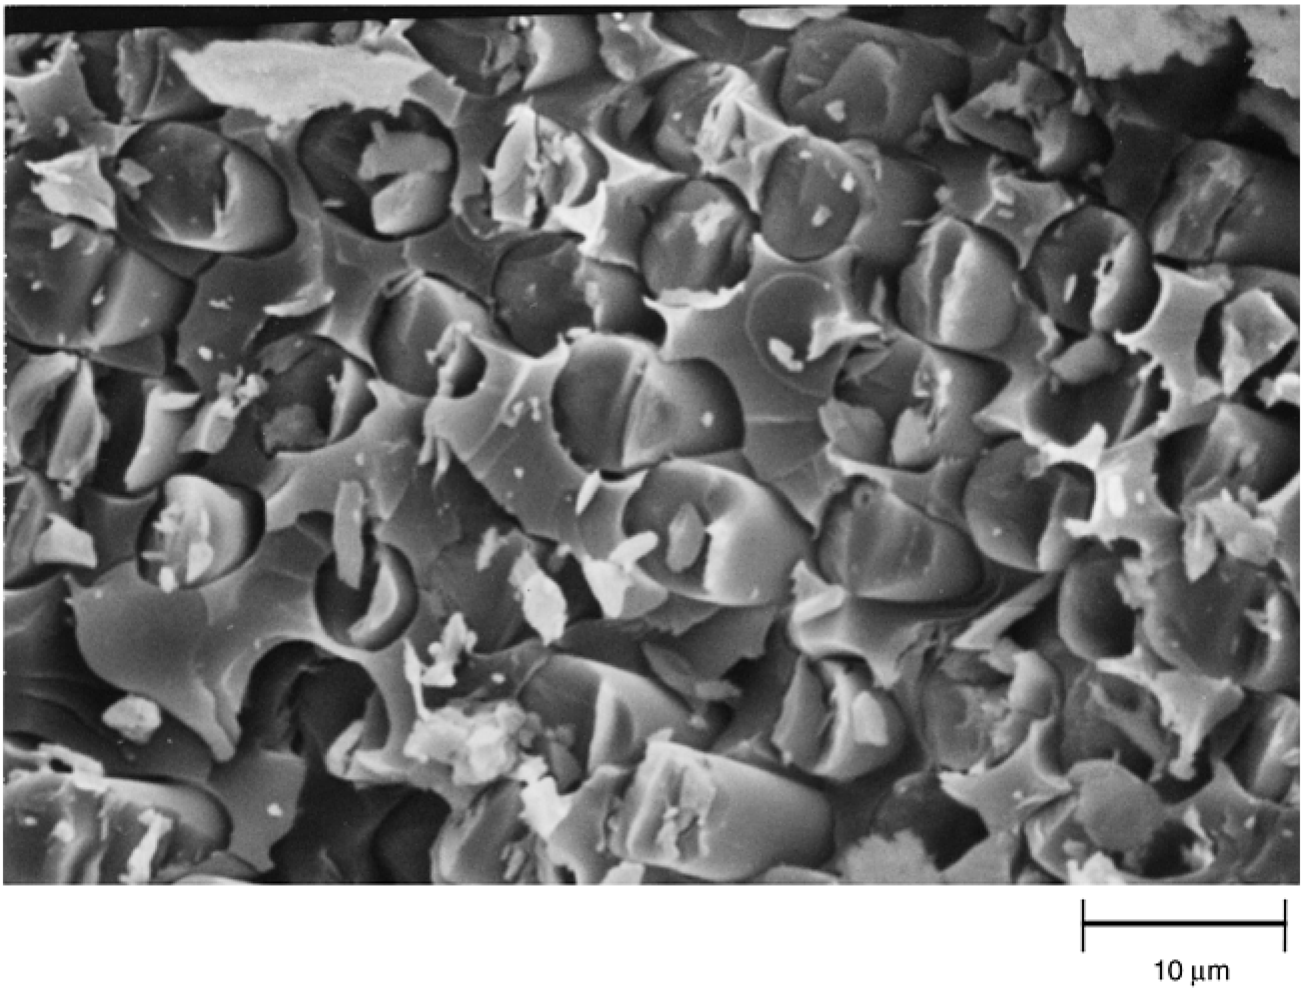

Fig. 24 "Chop marks" on the fracture surface of the glass fibers in a glass/polyimide composite tested as a notched four-point bend specimen that failed in compression. 1800×

Translaminar flexural failure of composite laminates generally exhibits both tensile and compressive failure regions on the fracture surface. The amount of each depends upon the loading conditions and the differences between the tensile and compressive strengths of the fibers. The differences between the two regions are generally quite visible, and the location of the neutral axis line can be easily identified from the differences in the fiber end fractures.

Fractography

Patricia L. Stumpff, Hartzell Propeller, Inc.

Conclusion

In conclusion, the fracture surfaces of a number of composite test specimens have been examined and fractographically documented. It appears that, similar to metallic materials, composite materials have unique fractographic features that can be related to specific materials, processing methods, environmental exposures, and load conditions. These features have been catalogued by a number of researchers over the years and have been evaluated, based on the type of information they are able to provide about the fracture. The features can be used for determining information about component failures, particularly, information regarding crack initiation site, crack-growth direction, environmental conditioning, and failure mode. It should be noted, however, that even with the large amount of fractographic data that have become available in recent years, it still may not be possible to always determine the failure cause. This is because some of the fractographic information may have been obliterated, lost, or destroyed by some postfailure condition. Additionally, there are limitations as to the amount and type of information that can be obtained from a fractographic analysis, and additional techniques, such as mechanical testing and stress analysis, may be required to determine failure cause in some instances.

Case Histories

Patricia L. Stumpff, Hartzell Propeller Inc.

Introduction

THIS ARTICLE describes the results of several case history studies of the failure of polymer-matrix composite (PMC) components to provide not only some representative types of failures one can encounter, but also to provide some insight into the investigative process. These case histories deal mainly with structures that exhibit an initial material and/or manufacturing defect or anomaly—failures that are most prevalent and most easily solved. Component failures traced to some initial material- and/or manufacturing-related defects seem to have fewer fracture surfaces compared with those that do not have any initial defects. In addition, more complex failures (those without defects and those having transverse fractures) often require the use of stress analysis in addition to fractographic analysis.

In the investigations presented here, final analysis often was considerably more involved than is possible to describe in a brief summary. However, the results of these investigations hopefully will enable the reader to understand the need not only for careful technical analyses, but also the need for insight, patience, persistence, and experience to solve the myriad types of problems related to the failure analysis of composite structures.

Helicopter Rotor Blade Failure

Circumstances Leading to Failure. A helicopter rotor blade failed after a minimal number of flight hours. The blade failure consisted of a complete separation of the outer carbon/epoxy sleeve from the internal Kevlar/epoxy paddle, as well as complete transverse failure of the paddle and the sleeve (Fig. 1). The outer sleeve and the paddle are manufactured separately and then adhesively bonded together during final assembly of the blade. The Kevlar/epoxy paddles are machine sanded after molding to remove any traces of silicon that may have adhered to the surface of the paddle during the molding process. The paddle itself has a convex curvature across its width, with foam inserts bonded to the underside of the paddle to fill in the concave area. The woven carbon/epoxy plies of the outer sleeve, the Kevlar/epoxy paddle, and the foam inserts are bonded together during final assembly of the blade.

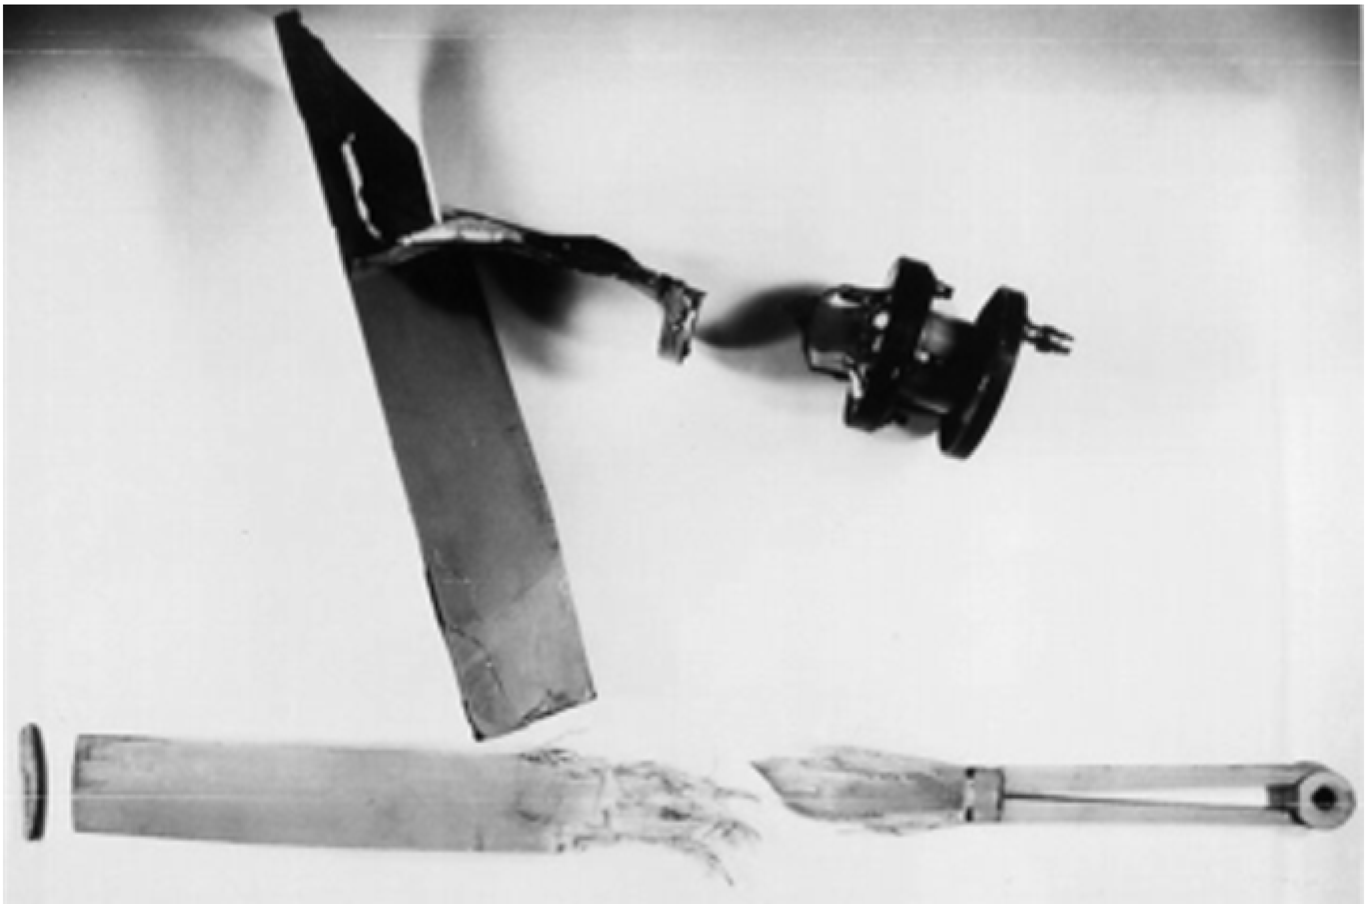

Fig. 1 Separation and fracture of internal Kevlar/epoxy paddle and external carbon/epoxy sleeve of failed helicopter blade

Test Procedures and Results. Visual analysis of the failed blade revealed that the top surface of the paddle had a smooth, glossy surface, except for two strips along the length of the paddle, which exhibited duller fracture features. Examination of the glossy areas on the surface of the paddle at low magnification revealed relatively featureless fracture surfaces (Fig. 2). By comparison, the dull areas had a number of areas with resin fracture as indicated by the arrows in Fig. 3. Examination of the glossy surface at higher magnification revealed small rounded globules (Fig. 4), while the dull surfaces at higher magnification revealed considerable plastic deformation (Fig. 5).

Fig. 2 Low magnification SEM view of shiny areas on Kevlar/epoxy paddle surface. 48×

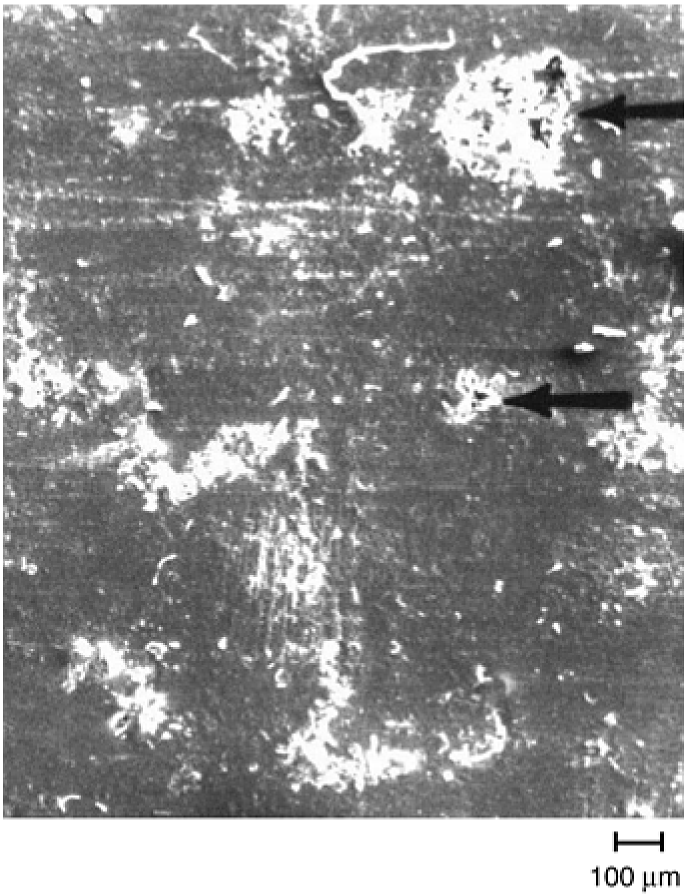

Fig. 3 Low magnification SEM view of dull areas on Kevlar/epoxy paddle surface. 48×

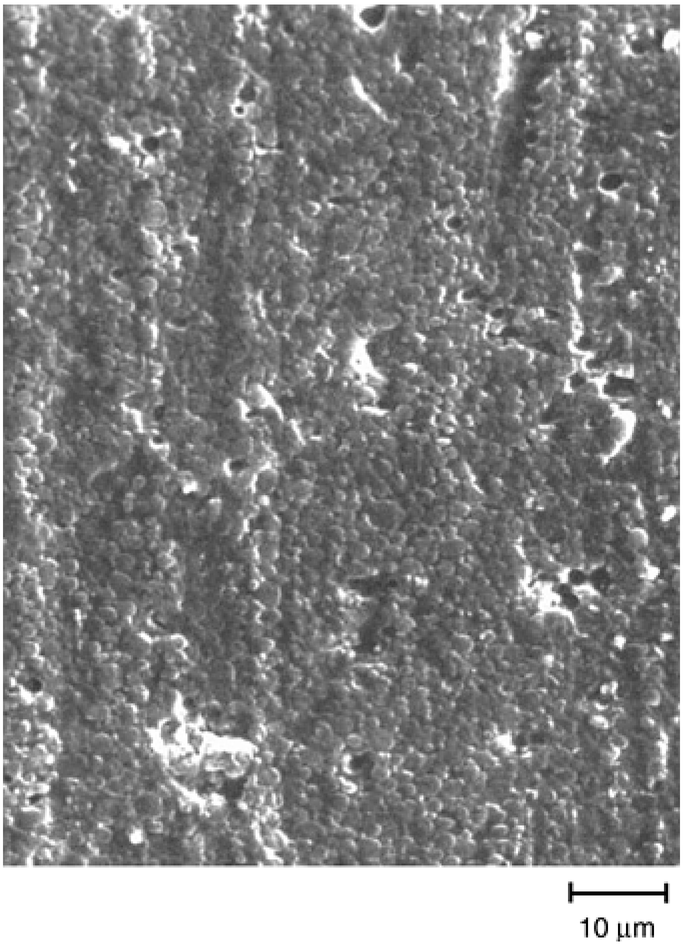

Fig. 4 Higher magnification SEM view shiny surface of Kevlar/epoxy paddle showing resin swelling and no resin fracture. 720×

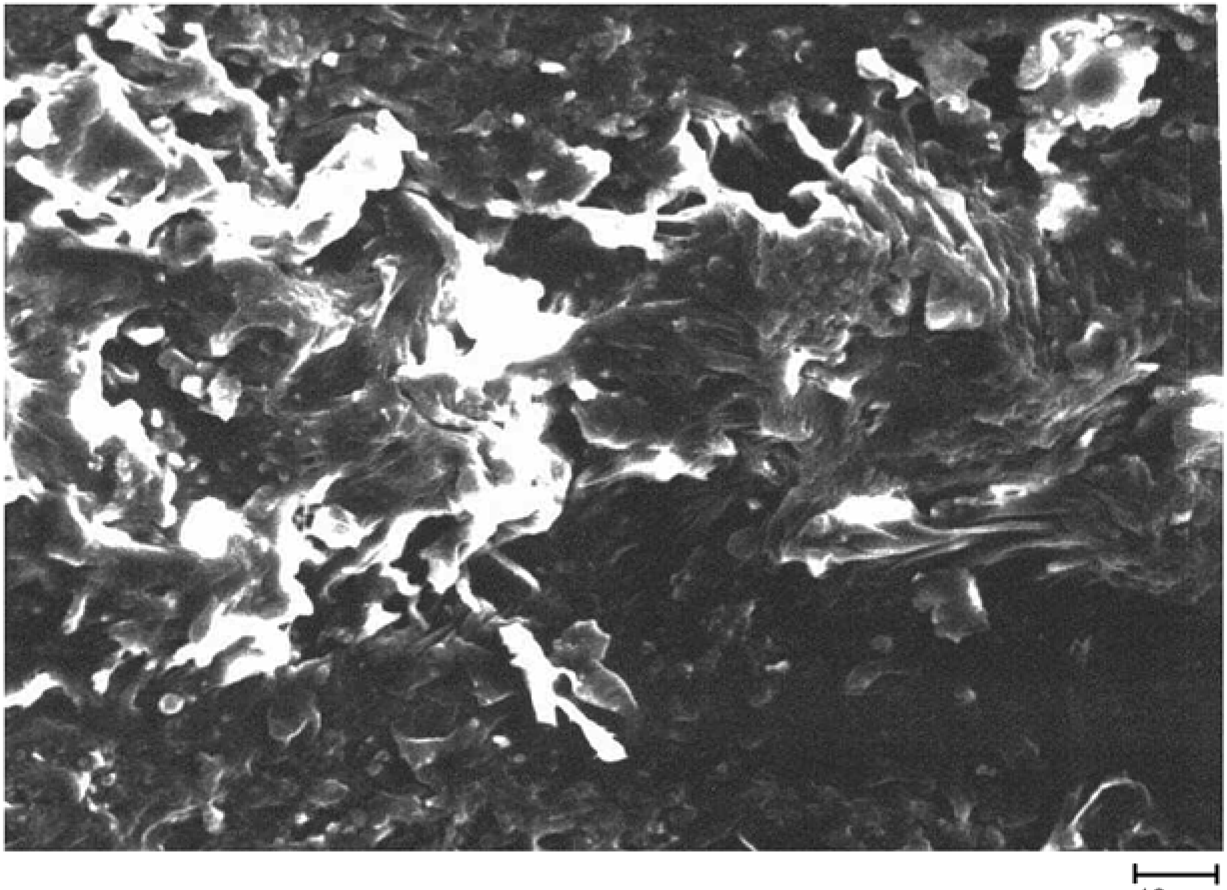

Fig. 5 Higher magnification SEM view of dull surface of Kevlar/epoxy paddle showing significant resin deformation and fracture. 720×

Fourier transform infrared (FTIR) analysis of the paddle surface showed that the spectrum is typical of that for an epoxy resin, but also contains an additional peak at 1741 cm^{-1}, which is indicative of a carbonyl band (Fig. 6). Electron spectroscopy for chemical analysis (ESCA) of the surface of the paddle revealed unexplained silicon peaks as shown by the small peaks to the right in Fig. 7.

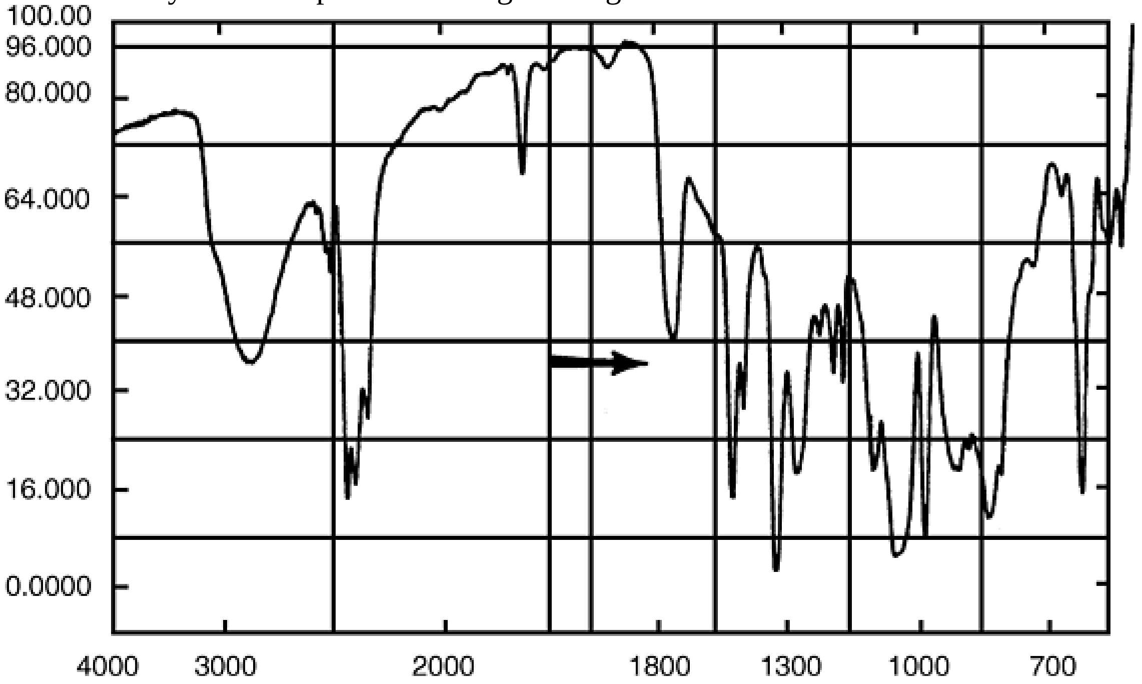

Fig. 6 FTIR spectrum of Kevlar/epoxy paddle surface showing additional carbonyl peak (arrow) at 1741 cm^{-1}

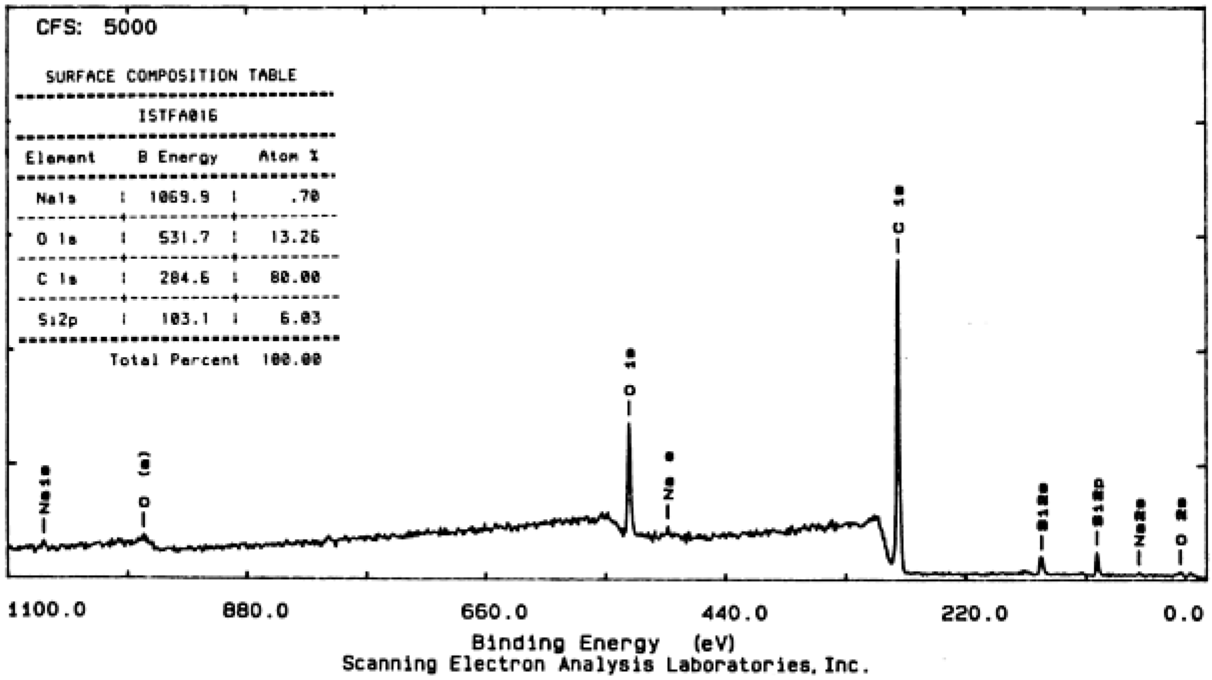

Fig. 7 ESCA analysis of Kevlar/epoxy paddle surface showing silicon peaks (small peaks on the right)

Evaluation and Conclusions. Both the glossy surface appearance and the presence of silicon indicated the possibility of inadequate sanding of the paddles prior to the adhesive-bond operation. Additional paddles from the manufacturer (both before and after the sanding operation) were evaluated to verify or disprove this hypothesis. Paddle surfaces prior to the sanding operation exhibited smooth, glossy surfaces, intact fibers, and

silicon contamination, as well as rounded globules indicative of resin swelling. By comparison, sanded paddles exhibited a dull, whitish surface finish, fiber damage, resin deformation, and no evidence of silicon contamination.

Further analyses of the other fractures were limited. In addition to the debonding of the paddle from the sleeve, the paddle and sleeve also exhibited transverse fractures. These fractures occurred at approximately the same lengthwise location, but investigators were unable to determine the mode of fracture. The fact that the sleeve failed in the same location as the paddle appears to indicate that these two transverse fractures were related or occurred at nearly the same time and/or under the same loading conditions.

Overall visual evaluation of the fractured components appears to indicate that the paddle debonded from the sleeve prior to the transverse fracture of either subassembly. Transverse fracture of either portion of the blade prior to a debond most probably would have revealed some damage, such as markings on either the inside surface of the sleeve or on the outer surface of the paddle, which is not the case. If the transverse fracture occurred first in both the sleeve and the paddle together, there would have been no reason for a disbond to occur at all. Therefore, the most likely scenario is that the disbond occurred prior to any transverse fracture. Debonding between the paddle and the sleeve would significantly reduce the stiffness of the blade; reduced stiffness in both the paddle and the sleeve may have resulted in the transverse failure of the paddle and the sleeve under normal loads. It is believed that premature debonding occurred as a result of either inadequate or incomplete sanding of the paddles prior to the bond operation. Inadequate sanding resulted in a contaminated surface having a slick, glossy finish, which is unsuitable for subsequent bonding of the paddle to the sleeve.

Case Histories

Composite Wing Spar Failure

Circumstances Leading to Failure. A wing spar on a small aircraft failed prematurely; the aircraft reportedly had some flight time prior to failure, but no overloads on the wing were believed to have occurred. The spar section is shown in Fig. 8; the leading edge of the wing is at the bottom and the aft edge at the top of the photo. The wing spar is in the shape of a box spar with upper and lower carbon/epoxy and glass/epoxy caps and shear webs made of Nomex honeycomb core and glass/epoxy skins.

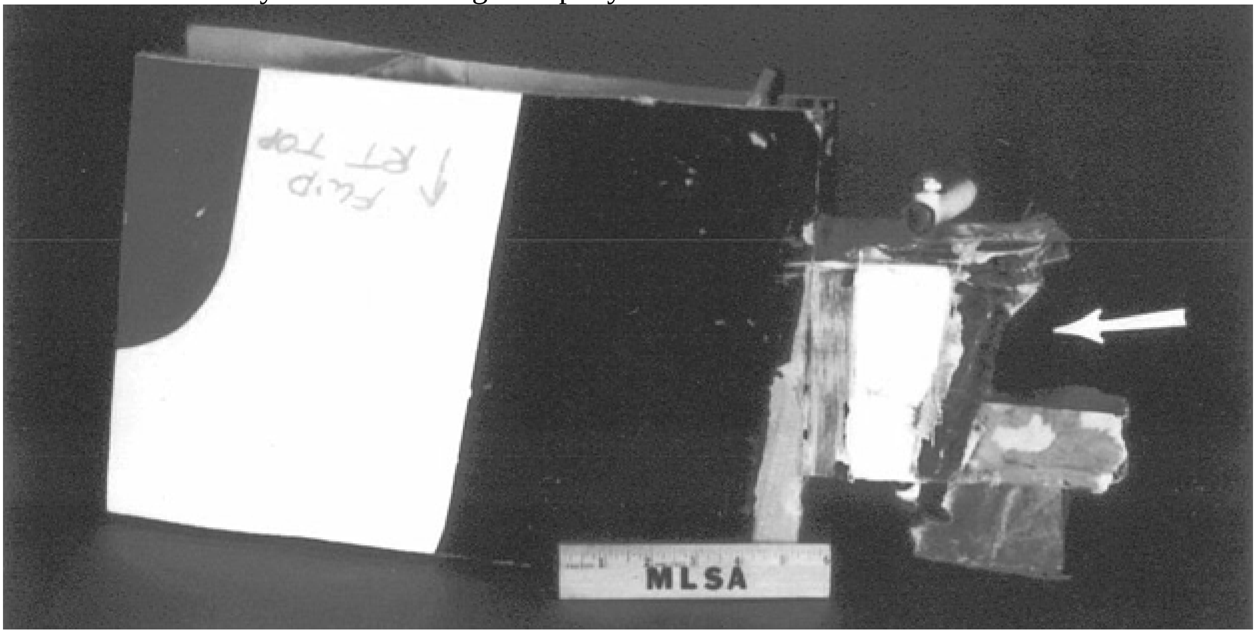

Fig. 8 Section of failed wing spar

Test Procedures and Results. Further examination of the spar revealed a flexural failure, with the lower cap exhibiting tensile failure and fibers bent aft (Fig. 9) and the upper cap exhibiting compressive failure with the fibers bent forward (Fig. 10). This analysis is consistent with a wing bending upward and twisting forward.

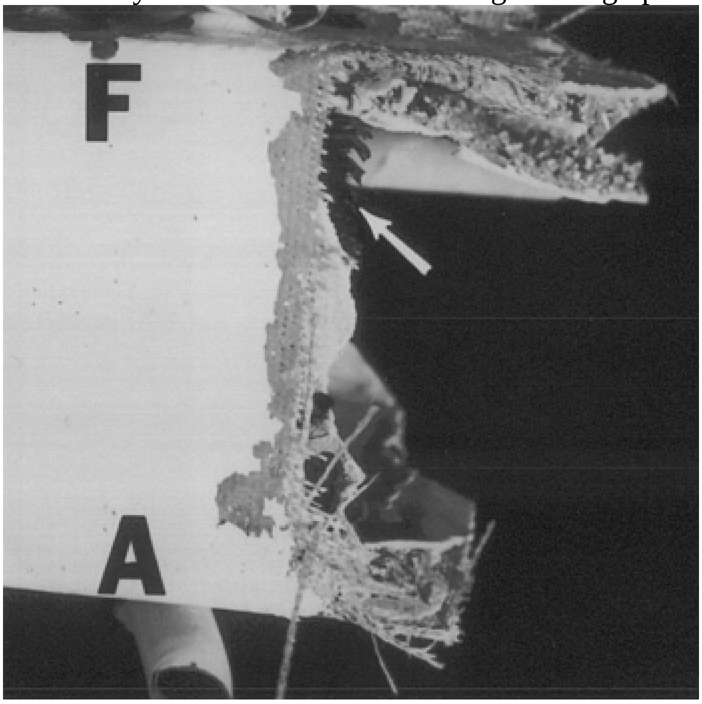

Fig. 9 Lower spar cap showing tensile failure and fiber distortion aft (arrow). F: forward, or leading edge; A: aft, or trailing edge

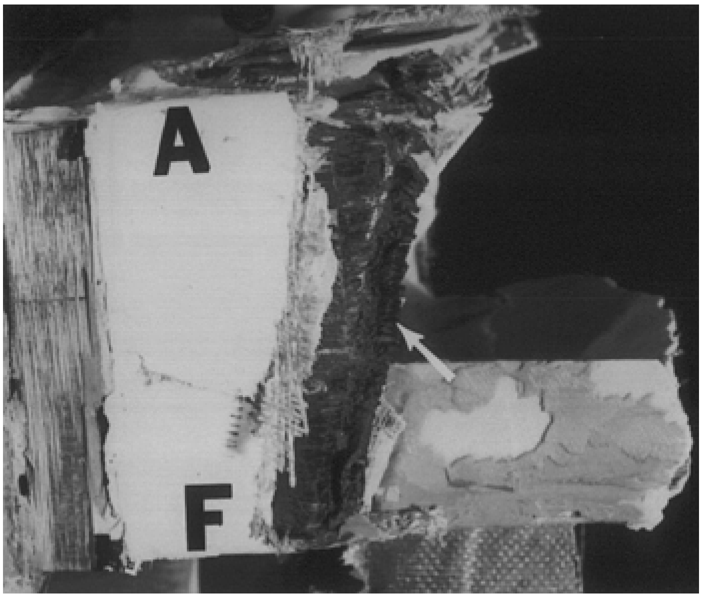

Fig. 10 Upper spar showing compressive failure and fiber distortion forward (arrow). F: forward, or leading edge; A: aft, or trailing edge

Nondestructive evaluation of the wing spar using x-radiography did not reveal any evidence of damage in the component except for the visually apparent fracture. Following visual and nondestructive evaluation, fracture surfaces were removed for examination using scanning electron microscopy (SEM). Scanning electron microscopy evaluation revealed fiber radials, which are indicative of tensile failure in the lower cap, and fiber chop marks and debris, which are indicative of a compressive failure of the upper cap; these results further support the occurrence of a bending failure of the spar.

A cross section of the spar near the fracture revealed that the upper and lower caps were manufactured using unidirectional carbon/epoxy prepreg, with several glass/epoxy plies on either side. The number of plies, their orientation and layup were as specified by the manufacturer. The shear webs were manufactured using Nomex honeycomb core with glass/epoxy skins, which are subsequently bonded to the upper and lower caps. The cross

sections of the upper and lower caps reveal several significant manufacturing anomalies including a large amount of fiber waviness (Fig. 11), a 12% void content (Fig. 12), and an abnormally low fiber volume fraction of only 45%.

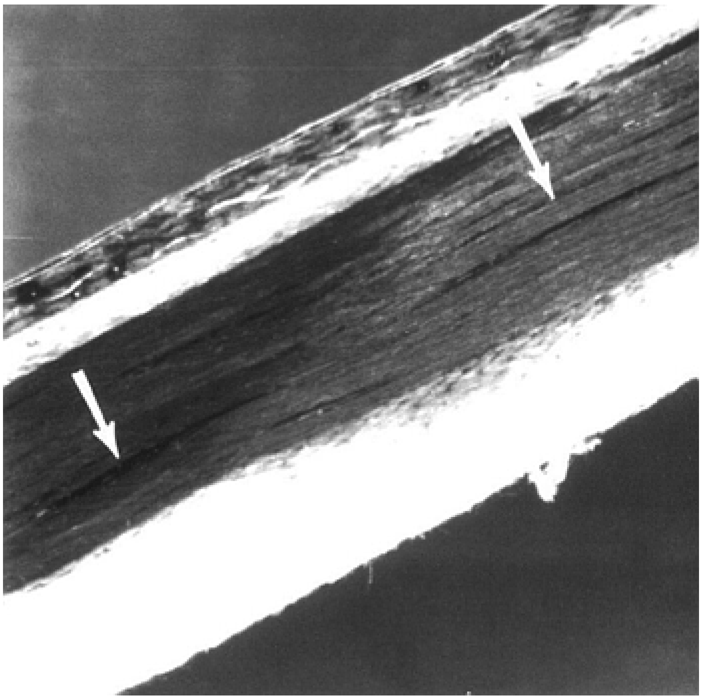

Fig. 11 Wing spar cross section showing delaminations (arrows) and excessive fiber waviness. 3.5×

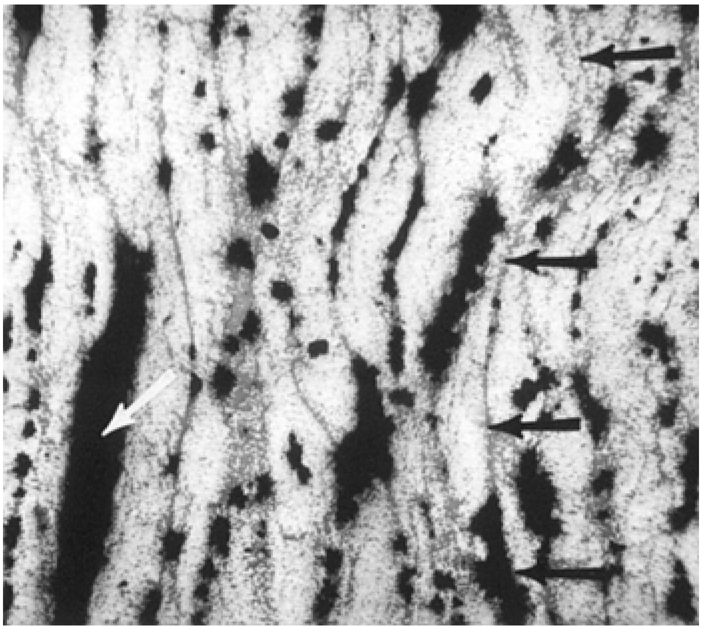

Fig. 12 Higher magnification of spar cap cross section showing excessive fiber waviness (black arrows) and high void content (white arrow). 40×

Thermal-mechanical analysis of the carbon/ epoxy cap indicated a glass transition temperature of 115 °C (239 °F), which is slightly on the low side for a 120 °C (250 °F) carbon/epoxy system. Differential scanning calorimetry did not reveal any exothermic reactions, indicating a full cure of the composite spar.

Further fractographic examination of several interlaminar fracture surfaces revealed evidence of striations, which are indicative of fatigue (Fig. 13). Most of the striations are found in the upper cap, but some also are present in the lower cap.

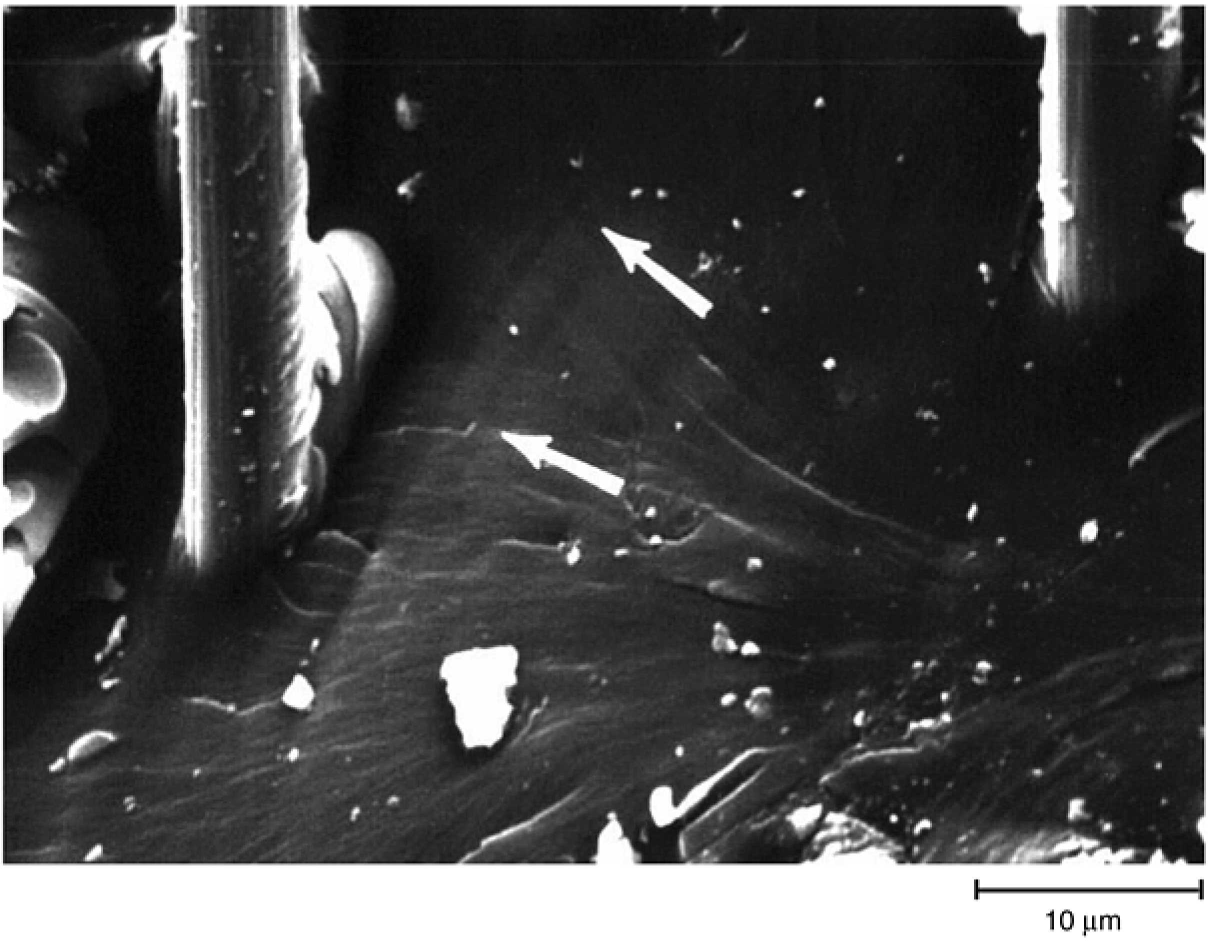

Fig. 13 Striations (arrows) in resin of fractured surfaces, indicative of fatigue failure. 2000×

Test specimens were sectioned from the spar to determine mechanical property data. Five 0° tensile (ASTM D 3039-76) and five 0° compressive (ASTM D 3420-87) specimens were machined from the carbon/epoxy portions of the upper and lower caps, respectively. Average tensile and compressive strengths of the test specimens were determined to be only 670 and 267 MPa (97.3 and 38.7 ksi), respectively. These values are significantly lower than the 0° tensile strength of 1585 to 1792 MPa (230–260 ksi) and 0° compressive strength of 1516 to 1723 MPa (220–250 ksi) reported by the materials supplier.

A compression-compression fatigue test (R = 0.1) was conducted by loading the specimen at 80% of the average ultimate compression strength determined from the prior compression test. Ultimate failure occurred after only a few cycles. A second compression-compression fatigue test was conducted at a maximum compression load of only 192 MPa (27.8 ksi), or 72% of the ultimate compression strength of the spar cap. In this case, failure occurred after approximately 156,619 cycles.

Evaluation and Conclusions. The fractographic evidence indicates that the failure of the spar is consistent with bending fatigue, with evidence of compressive failure on the upper cap of the spar and tensile failure on the lower cap. The bending fatigue in the spar may have initiated and propagated due to either higher than anticipated fatigue loads on the spar or to anticipated fatigue loads in conjunction with a reduction in the fatigue strength resulting from a number of manufacturing anomalies.

Manufacturing anomalies in the spar noted during the investigation include significant fiber waviness, high porosity, and low fiber volume fraction. According to the materials supplier, resins used in the manufacture of this particular spar generally were formulated for use in autoclave or press molding. However, the manufacturer noted that composites were successfully processed using this resin and vacuum bag molding techniques, stressing that the component must be debulked regularly to extract trapped air from the layers.

Whatever method was used in the manufacture of this spar, it resulted in manufacturing anomalies and relatively low mechanical properties, which may have contributed to the premature fatigue failure of the spar.

Patricia L. Stumpff, Hartzell Propeller Inc.

Aircraft Rudder Failure

Circumstances Leading to Failure. The skin from a composite rudder assembly separated from the core. Visual analysis revealed that the right side of the rudder (Fig. 14) had undergone almost complete skin/core separation; only a small piece of composite skin remained attached to the rudder at the trailing edge. The separated skin was lost and not available for evaluation. The adhesive, still attached to the aluminum core, did not exhibit any visible fracture features, although porosity is evident throughout. The adhesive itself is a consistent shade of light gold over most of the fracture surface, except under the remaining section of skin, where the adhesive is white in color.

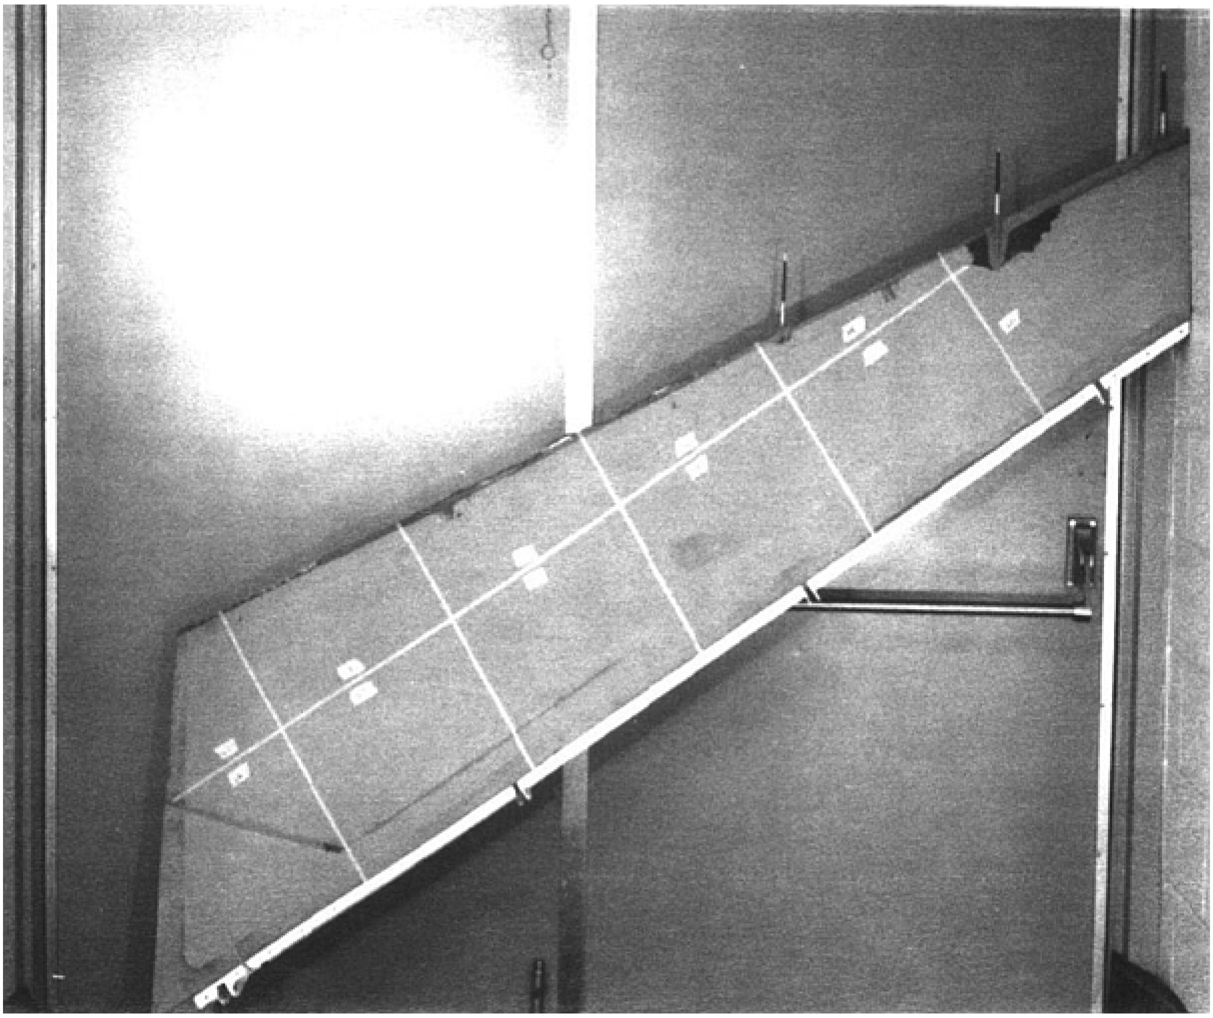

Fig. 14 Loss of the outer skin (except small section near the antennae at the top of the photograph) on right side of composite rudder

The left side of the rudder was intact. Markings found on the leading edge of the intact left side of the rudder are believed to be indicative of a disbond/delaminated area previously detected by nondestructive evaluation. Examination of adhesive on the left side of the rudder after removing a small section of skin revealed characteristics similar to those on the right side, that is, porosity with no visible fracture features. This adhesive also is white in color, similar to the adhesive under the remaining skin on the right side of the rudder.

Test Procedures and Results. Background information on this particular rudder revealed that nondestructive evaluation after manufacture showed no evidence of any skin/core disbond or skin delamination. Rudders manufactured after the one being evaluated exhibited some small disbonds/delaminations on their leading edges following manufacture. Other rudders exhibited some small disbonds/delaminations after some time in service.

However, the rudder under investigation was said to be the first to undergo a complete, in-flight skin/core separation.

Rudder construction consists of an aluminum frame and honeycomb core with carbon/epoxy face sheets containing a single glass/epoxy fabric ply on the either side of the carbon/epoxy skin. The skins are precured and then subsequently bonded to the aluminum substructure. During manufacture of the skins, polyester peel plies are added to the exterior skin surfaces and are removed just prior to bonding the skins to the aluminum frame and honeycomb core. The removal of a peel ply generally results in clean, roughened, fractured surfaces, immediately suitable for bonding. The precured composite skins are then bonded to the aluminum substructure using a typical aircraft adhesive manufactured for composite and aluminum bonding.

Pulse-echo ultrasonics was used to verify whether there was any damage actually present on the leading edge on the left side of the rudder. The test revealed a disbond/delamination in the marked area and a small delamination at the other end on the leading edge of the rudder, but no other damage.

A portion of the remaining glass/epoxy composite skin and its mating adhesive on the right side of the rudder was removed and examined using SEM. For comparison, a small piece of skin and its mating adhesive surface from the left side of the rudder also were examined following separation by peel forces. Similar fracture characteristics were identified at both interfaces on both sides of the rudder. Figure 15 depicts the adhesive surface characteristics on the right side of the rudder. The adhesive takes on the shape of the peel ply imprints that were left on the skin surface upon removal of the peel ply. Examination of the adhesive surface at higher magnification reveals some evidence of epoxy from the composite skin surface (the short, wide arrow in Fig. 16) adhering to the adhesive at the interstices of the peel ply imprints. Mating fracture characteristics were found on the surface of the composite skin samples that were originally attached to the adhesives.

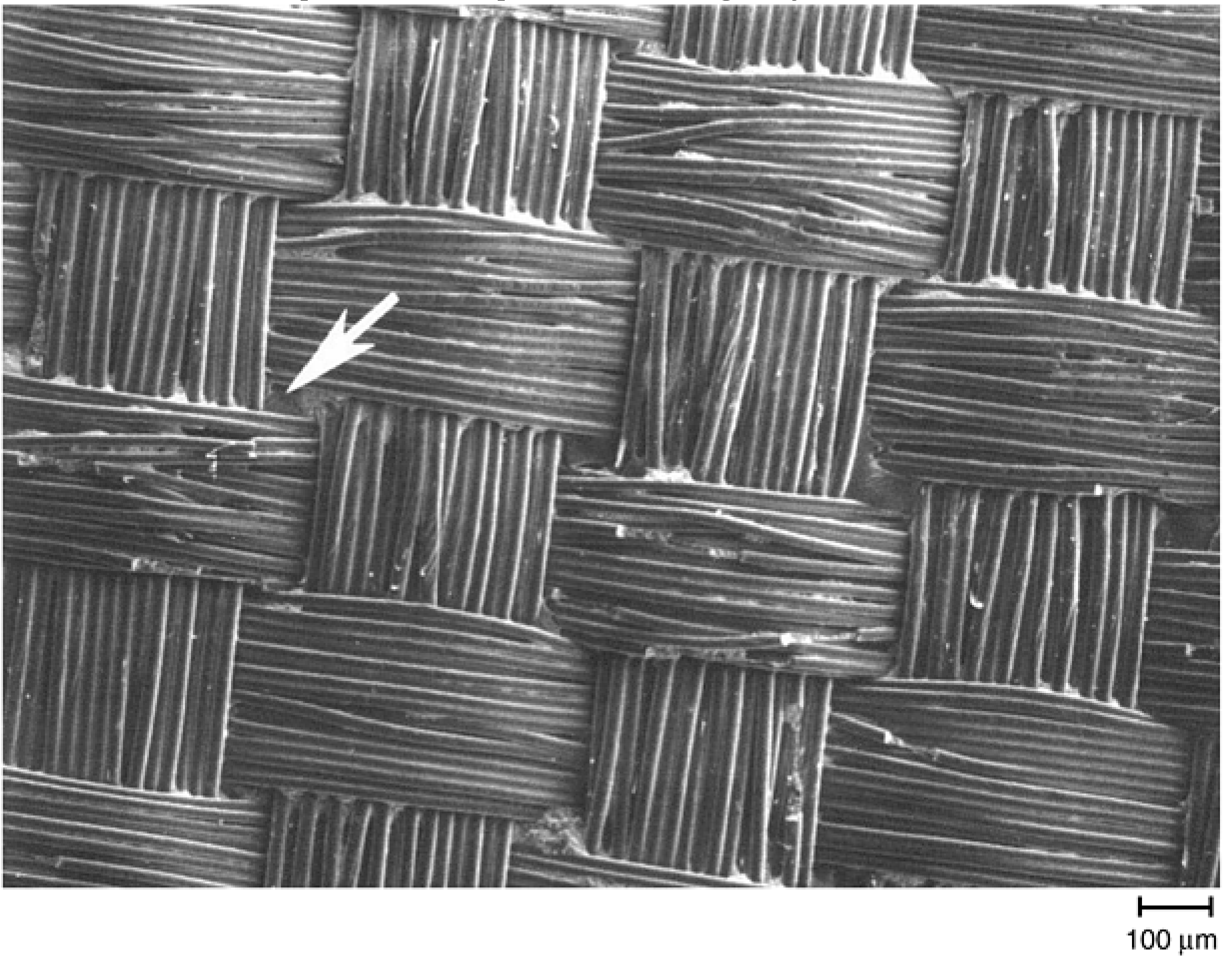

Fig. 15 Adhesive surface showing mirror image of peel ply imprints on glass/epoxy skin surface (river patterns at interstitial areas of weave indicated by white arrow). 66×

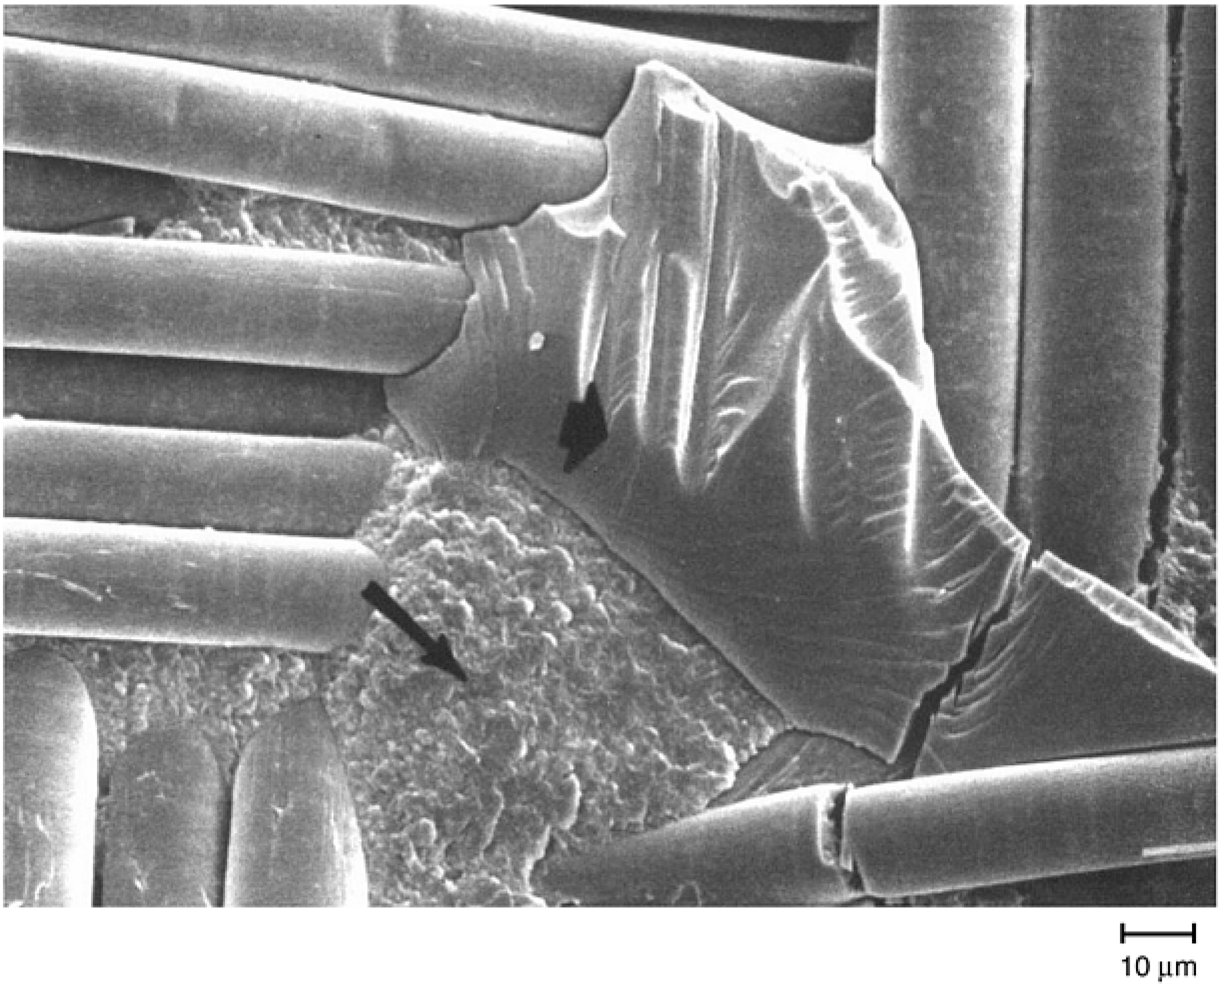

Fig. 16 Higher magnification view showing river patterns in epoxy resin at interstitial areas (short arrow) and fracture of the adhesive (long, thin arrow). 600×

Although the adhesive itself does not exhibit any features indicative of fracture mode or direction, river patterns—indicative of peel forces—were evident in the epoxy matrix that remained attached to the adhesive. The river patterns, often located in the epoxy at the interstices of the peel ply imprints, were used to determine the direction of skin separation and indicated that the origin of the failure on the right side of the rudder is at the lower leading edge, or forward corner. Crack growth proceeded from the lower forward leading edge corner toward the top and trailing edge of the rudder, as identified in the schematic, in Fig. 17. Crack growth direction in the crosshatched area of the schematic could not be determined because fracture at this location occurred at the interface of two adhesive layers. Two layers of adhesive are used in this location of the rudder, and because fracture of this particular adhesive does not exhibit river patterns, no crack growth direction could be determined in this area.

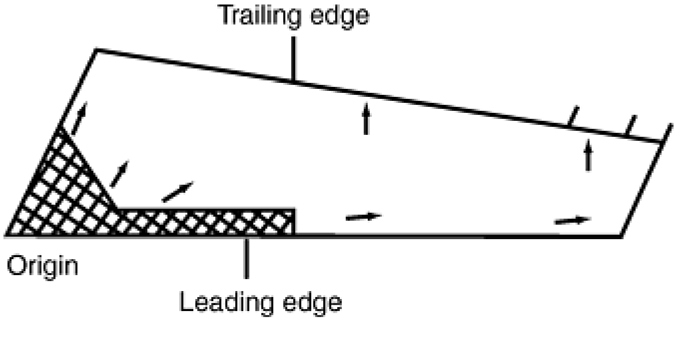

Fig. 17 Schematic of direction of skin separation (small arrows) on horizontal stabilizer from lower leading edge to upper trailing edges

Fourier transform infrared spectroscopy was used to identify the adhesive system. Although no exact match could be found in the reference database, the spectra obtained bore some similarity to modified, inorganic,

filled epoxies. Differential scanning calorimetry tests conducted on the adhesive showed no significant exothermic reactions, indicating the adhesive samples were fully cured.

Electron spectroscopy for chemical analysis (ESCA) was used to analyze the glass/epoxy skin and adhesive surfaces from both sides of the rudder to determine if there was any contamination present on the right side of the rudder that might have contributed to the failure. The spectra for the adhesive/glass interface on the right side of the rudder showed 70% C and 30% O. Similar results were obtained on the left side of the rudder (following peel fracture), indicating surface contamination did not contribute to the separation of the skin from the rudder.

Investigation of the color variation in the adhesive showed that humidity aged an adhesive sample at a slightly elevated temperature; the white adhesive turned to a light golden yellow, similar to the color of the adhesive on the right side of the rudder.

Evaluation and Conclusions. The almost complete separation of the skin of the rudder from the core is believed to be the result of inadequate adhesive bonding of the skin to the aluminum core and possible moisture intrusion into the bondline. Inadequate bonding of the skin to the core was evident particularly at the lower forward leading edge corner of the rudder where the fracture initiated. The two layers of adhesive noted in this location, a history of delaminations in this area in manufactured rudders, and evidence of a delamination in this same location on the opposite side of the rudder support this conclusion. Poor bonding is also suspected because the majority of the failure was interfacial in nature; only about 5% of the adhesive fracture surface had epoxy on it. Additionally, it was noted that the bonded side of the skin surfaces exhibited smooth, mirror images of the peel plies that were not removed prior to the adhesive-bonding operation. Bonds that are manufactured using laminates that have smooth, reflective surfaces following peel-ply removal generally have poorer mechanical properties than bonds manufactured using laminates that have roughened fracture surfaces following peel-ply removal.

There is also evidence of possible moisture intrusion into the bondline. Moisture intrusion is suspected because the adhesive on the delaminated surface changed color from white to light gold, similar to the color change experienced by adhesive specimens upon exposure to moisture and temperature in the humidity chamber. It is suspected that the moisture entered the bond at the delamination at the leading edge and helped propagate the failure over time, mainly because the color change was evident only on the delaminated portion of the fracture.

Fatigue Properties and Quantitative Fractography of Metal-Matrix Composites

Bruce Crawford, Deakin University, Australia

Introduction

FATIGUE PROPERTIES of particle-reinforced metal-matrix composites (PR-MMCs) and the quantitative examination of their fracture surfaces are the principal concerns of this article. The general properties of MMCs are not described here. A full review of these can be found in Ref 1 and in the article "Properties of Metal-Matrix Composites" in this Volume. The experimental and fractographic techniques described here resemble those used with unreinforced metallic alloys, but the fracture surfaces of MMCs contain features, such as fractured and decohered reinforcement particles, that distinguish them from those of unreinforced materials.

Bruce Crawford, Deakin University, Australia

Fatigue Properties of Metal-Matrix Composites

This section reviews the fatigue properties of MMCs in terms of mechanisms of crack initiation, fatigue life, and fatigue crack growth.

Mechanisms of Crack Initiation

The initiation of cracks in SiC and Al_2O_3 reinforced MMCs has been extensively studied. Most of these studies have concentrated on MMCs with aluminum alloy matrices. Four major sources of crack initiation have been identified. These are:

- *Fracture of the reinforcement particles (Fig. 1a):* Reinforcement particles are typically very brittle. They fracture in the initial stages of fatigue, sometimes in the first loading cycle, and rapidly initiate microcracks in the surrounding matrix. This is due to the high strain concentration produced by the intersection of microcracks in reinforcement particles with the surrounding matrix. This mechanism is most commonly observed in composites reinforced with Al_2O_3 particles or fibers (Ref 2, 3, and 4).
- *Decohesion of the reinforcement from the matrix:* This can occur either at the interface between the reinforcement and the matrix or in the matrix near the reinforcement-matrix interface. It is most common in SiC-reinforced composites (Ref 5, 6, 7, 8, 9, 10, and 11), but it has also been observed in alumina-reinforced composites (Ref 12). In many cases, cracks are initiated from particle clusters (Ref 5, 7, 8, and 10). These typically act as a single, large particle as plastic flow of the matrix material within the cluster is heavily constrained. Also, in MMCs prepared using liquid metallurgy techniques,

poor penetration of the matrix material into particle clusters can lead to poor particle-matrix bonding within the cluster, which increases the likelihood of decohesion (Ref 13).

- *Fracture of large particles*, other than reinforcement particles: Examples of such particles include large inclusions and intermetallics. These are very prone to fracture because of their large size relative to the reinforcement particles (20 to 100 μm) and brittle nature. This mechanism is common in composites with Al-Cu-Zn (2*xxx*) matrices because of the high alloy content of these materials (Ref 9, 12). In general, these particles fracture in the early stages of fatigue and rapidly initiate cracks.
- *Porosity* (Fig. 1b): Fatigue cracks can initiate from porosity in composites (Ref 4, 8) just as they do in unreinforced metals (Ref 14). As the size of the pores increases, so does their effectiveness in initiating cracks relative to the other mechanisms described here. An MMC containing large pores will typically fail due to a fatigue crack initiated from one of these pores (Ref 4). For liquid metallurgy MMCs, pores typically arise from incomplete penetration of the matrix material into particle clusters.

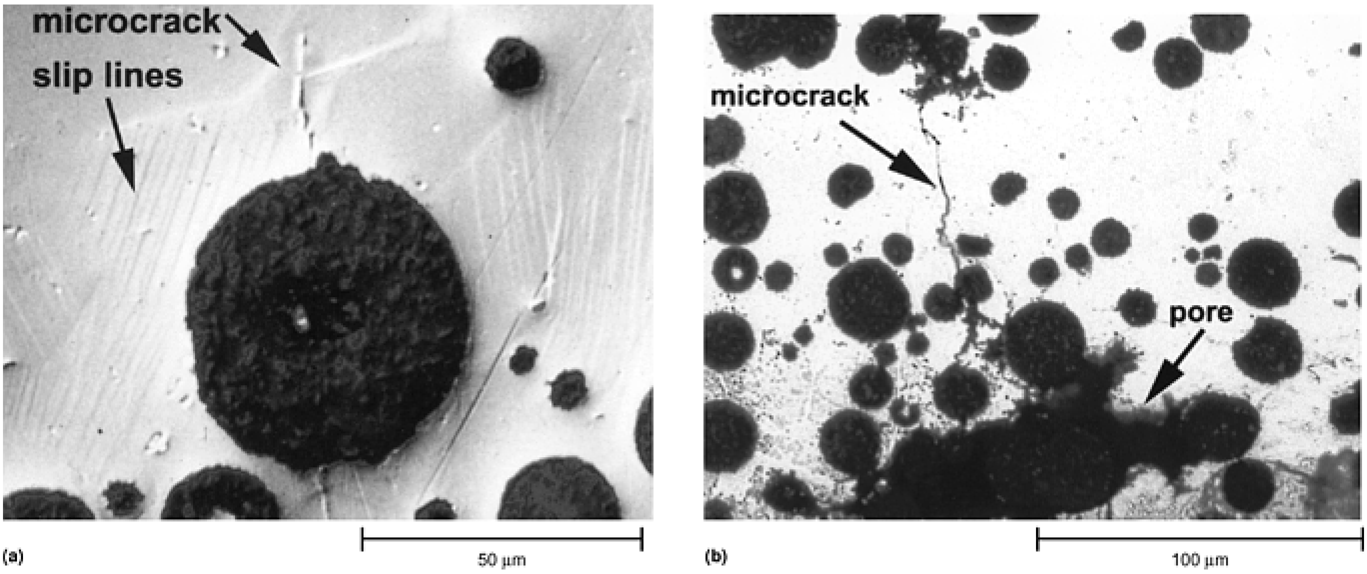

Fig. 1 Initiation of fatigue microcracks in metal-matrix composites. (a) A fatigue microcrack initiated from a fractured Micral-20 (mullite-alumina) reinforcement particle in Comral- 85 (6061-20% Micral-20). Note that the reinforcement particle has fractured across its vertical equatorial plane, perpendicular to the applied load. (b) Initiation of a fatigue microcrack from a large pore in Comral-85

Fatigue crack initiation typically occurs at or near the surface of a material (Ref 10, 11), regardless of the nature of the initiating defect. This is because surface defects are exposed to higher cyclic plastic strains and, once fractured, to higher stress-intensity factors (K) than defects located within the bulk of the material. As a consequence, cracks will initiate far earlier from surface defects than from bulk defects and will grow faster once initiated.

Fatigue Life

The increased stiffness and strength of MMCs increase their fatigue life under the load-control conditions of a typical fatigue life test (Ref 10). This increased life is most pronounced under high cycle conditions. In contrast, under strain- control conditions, the fatigue life of MMCs is often worse than that of the corresponding matrix alloy (Ref 10). The reason for this change is the higher elastic modulus of MMCs compared to their base alloys. Under load-controlled conditions, the higher modulus of the MMC means that the strain imposed on the matrix is reduced. This increases the fatigue life. The opposite occurs under strain control. In this case, the strain is the same in both materials, but the stress is higher in the MMC. This increases the probability of reinforcement fracture or decohesion, which, in turn, encourages the initiation and growth of fatigue cracks that reduce the fatigue life of the composite.

Fatigue Crack Growth

The interaction between reinforcement particles and the fatigue crack controls the local direction of crack growth in MMCs. This is because reinforcement particles modify the stress field surrounding the crack tip. The exact nature of this modification depends on whether the particles fracture, decohere, or remain intact during fatigue. The main factors controlling the fatigue of MMCs are therefore:

- Reinforcement type (composition and shape)
- Reinforcement volume fraction and size
- Matrix aging condition

The residual stresses produced by thermomechanical treatment also influence the fatigue of MMCs. The effects of residual stresses are discussed in the section “Long Fatigue Crack Growth” in this article.
Reinforcement Type. It is difficult to find any direct comparisons between the fatigue behavior of similar alloys reinforced with different types of reinforcement particle. This is principally due to the pre-eminence of SiC as a reinforcing particle for MMCs. A similar problem exists for the effect of particle shape, as SiC particles are significantly larger than SiC whiskers. In general, however, elongated particles (such as SiC whiskers) will inhibit crack growth when the crack is growing perpendicular to the particles and accelerate growth when the crack is parallel (Ref 5, 15).
Reinforcement Volume Fraction and Size. The effect of reinforcement volume fraction varies with the mean size of the reinforcement. An increase in volume fraction decreases fatigue crack growth rate in composites reinforced with large (>10 μm) particles (16, 17 18) and increases the fatigue crack growth rate in composites reinforced with very small (<3 μm) particles (Ref 19, 20). The difference arises from the way in which reinforcement particles of differing size react to an approaching fatigue crack. Fine particles are resistant to fracture, which tends to constrain the crack path. This produces a flat fracture path, low levels of roughness-induced closure, and faster fatigue crack growth. At a given reinforcement volume fraction, larger reinforcement particles are spaced further apart and are, by virtue of their larger size, more prone to fracture. Fractured particles attract the fatigue crack, which, when combined with the increased particle spacing, produces a rougher fracture surface and higher levels of roughness-induced crack closure. This effect is, therefore, most pronounced near the fatigue threshold, and so MMCs containing fine particles tend to have lower fatigue thresholds than those containing coarser particles.
Matrix Aging Condition. In unreinforced aluminum alloys, the fatigue threshold decreases with increased aging (Ref 21). This is because aging alters the slip character of the matrix. Reinforcement particles suppress this effect in MMCs (Ref 22). This occurs because fatigue cracks avoid uncracked particles while seeking out cracked particles. Therefore, the crack path is controlled by the size, spacing, and fracture behavior of the reinforcement particles. As aging treatments cannot alter these parameters, fatigue properties of the MMCs remain unchanged.

Fatigue Properties and Quantitative Fractography of Metal-Matrix Composites

Bruce Crawford, Deakin University, Australia

Fatigue Testing of MMCs

Specimen Preparation

As described previously, the fatigue life of MMCs and the initiation of cracks in them during fatigue have been extensively studied. The techniques, samples, and equipment used for this work resemble those used with unreinforced metallic alloys. However, the reinforcement particles in MMCs mean that tungsten carbide or diamond-coated tooling is required for specimen machining. In addition, the difference in hardness between the matrix and reinforcement can cause surface relief to develop during polishing. This surface relief should be avoided as it can decrease the fatigue endurance of MMCs. This can be achieved by using polishing cloths with a low nap during polishing.

Microscopy

Fatigue crack initiation and short crack growth in MMCs can be readily studied using an optical microscope. Detailed methodology is found in the article "Microscopy" in this Volume. The use of Normarski interference contrast greatly aids the identification of fractured reinforcement particles and fatigue microcracks in polished initiation samples of MMC. This is due to the distortion of the surface of the sample by the plastic zones surrounding these fatigue microcracks. The resultant surface relief is quite obvious under Normarski interference contrast conditions (see Fig. 1a). Crack initiation and growth can also be studied using acetate or rubber molding compound replicas. These have the advantage of providing a more complete record of the surface of the specimen than optical microscopy can.

Another method of studying crack initiation and short crack growth in MMCs is using a scanning electron microscope (SEM) equipped with a cyclic loading stage. This allows very detailed study of the interaction between reinforcement particles and fatigue cracks. However, the rarity of the cyclic loading stages makes this method unavailable to most researchers.

Long Fatigue Crack Growth

The long fatigue crack growth behavior of MMCs can be evaluated using the test methods and specimens used for unreinforced metallic alloys. Most of the published fatigue crack growth data for MMCs has been obtained using either compact tension or tensile single-edge notch specimens as described in ASTM E 647 (Ref 23). However, MMCs have several features that must be accounted for if they are to be tested successfully. The most important of these are described subsequently.

Macroscopic Residual Stresses and Consequent Crack Bowing Induced by Heat Treatment. Macroscopic residual stresses are significantly higher in MMCs than in unreinforced alloys (Ref 24). As a result, MMCs are prone to increased crack-front bowing. The edges of the crack can grow unevenly, with one side being a millimeter or so ahead of the other (in a crack of between approximately 10 and 50 mm, or 0.4 and 2.0 in., in length). In extreme cases, the center of the crack can grow several millimeters ahead of its edges. This contravenes the requirements of ASTM E 647 (Ref 23) and should be minimized. This can be achieved, with various degrees of success, by prestraining after either solution treatment or aging, annealing out the residual stresses in the MMC, reducing their effect during testing, or by compensating for the resultant crack bowing

during analysis after testing is complete. Prestraining the MMC before testing can reduce residual stresses (Ref 25, 26). This, however, increases the yield stress of the MMC and decreases its ductility, which will bias the collected fatigue results. Despite this, prestraining is widely used. It is less problematic if performed after solution treatment, where the low strength of the matrix reduces damage to the reinforcement particles. Annealing to remove the residual stresses is impractical, because the temperatures required exceed those used in artificial aging in aluminum alloys. The effect of residual stresses during testing can be minimized by using high load ratios ($R \geq 0.4$, where R is P_{min}/ P_{max}, the ratio of minimum load to maximum load in cyclic loading) (Ref 24). This increases the crack-opening displacement, which reduces crack closure and crack-front bowing. This approach, however, does not allow the fatigue properties of the MMC to be fully evaluated. Finally, the effect of crack bowing can be compensated by recalculating K based upon measurements of crack-front curvature collected after the completion of testing. This approach has been successful in reducing the scatter in fracture toughness results for an aluminum alloy and for an alumina-reinforced MMC (Ref 27, 28). The use of this method with fatigue cracks and MMCs, however, has not been validated.

Increased Electrical Resistance and Decreased Compliance Compared to Unreinforced Materials. Automatic crack-length measurement methods use either the electrical resistance or compliance of the specimen to estimate the length of the fatigue crack. Therefore, changes in these values due to reinforcement must be accounted for if these methods are to be used successfully. Additionally, the compliance of MMCs can change due to damage in the process zone ahead of the crack tip. This will cause compliance methods to overestimate the true crack length. The magnitude of this error increases with increasing K_{max} due to the fracture of reinforcement particles ahead of the crack tip. For this reason, automatic crack-length measurements should be supplemented with visual measurements to confirm their accuracy.

Fatigue Properties and Quantitative Fractography of Metal-Matrix Composites

Bruce Crawford, Deakin University, Australia

Fractography of MMCs under Plane-Strain Conditions

Observed Features of MMC Fatigue Fracture Surfaces

A major feature of the fatigue fracture surfaces of MMCs produced under plane-strain conditions is that the area fraction of reinforcement particles on the fracture surface (A_f) is proportional to K_{max}^2 (Fig. 2) (Ref 11, 26). This suggests that A_f is controlled by the size of a process zone preceding the fatigue crack (Ref 10, 11, 26). Fractographic evidence (Fig. 3) from Comral-85, an MMC consisting of a 6061 matrix reinforced with mullite-alumina microspheres, supports this supposition (Ref 26). Note that several of the reinforcement particles visible in Fig. 3(a) are surrounded by plateaus, which are microcracks initiated by the reinforcement particle during fatigue. These plateaus are characterized by river lines radiating from the perimeter of the reinforcement particle. Closer examination shows that these lines initiate from surface features of the reinforcement particle at the center of the plateau. These lines, and the plateaus on which they appear, indicate that the reinforcing particles fractured ahead of the main crack tip. Figure 4 shows the effect of a change in K_{max} on the fracture surface of a MMC reinforced with SiC particles (Ref 29). These fracture surfaces are similar to those of Comral-85 except that there is no SiC visible on the fracture surface at low (< 8 MPa $\sqrt{m}$, or 7 ksi $\sqrt{in.}$) stress-intensity factors (Fig. 4a).

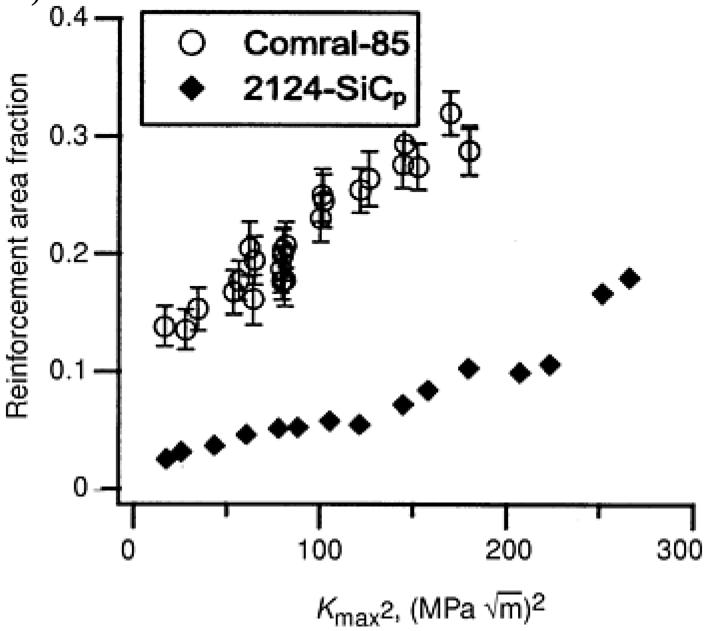

Fig. 2 Area fraction of reinforcement on the fatigue fracture surface of a SiC-reinforced MMC (Ref 11) and Comral-85, a Micral-20- (mullite-alumina) (Ref 25) reinforced MMC as a function of K_{max}^2

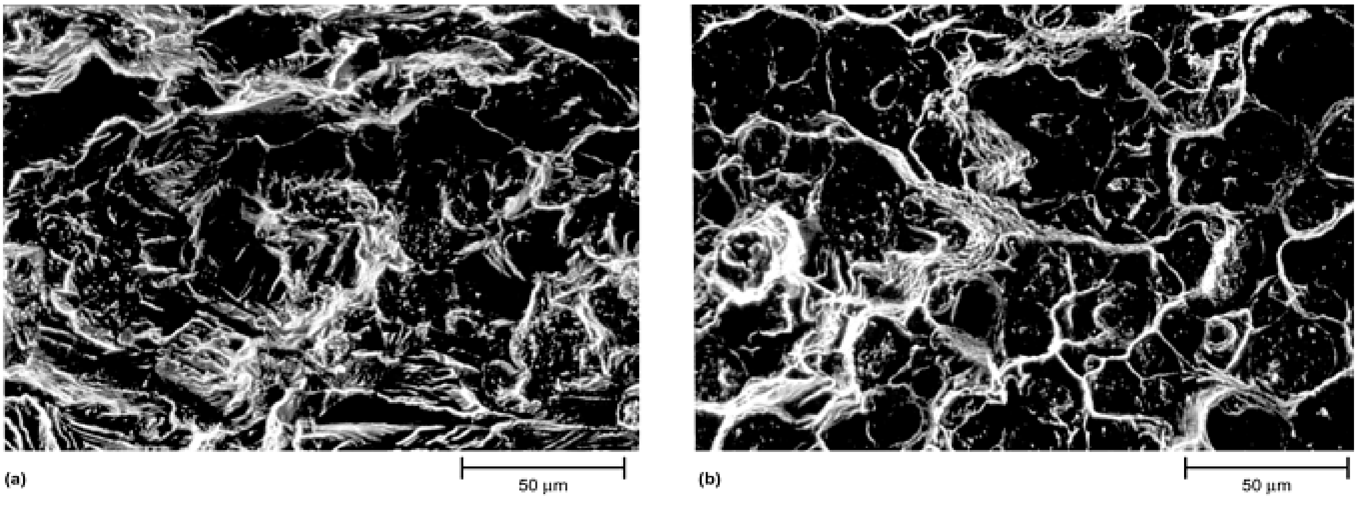

Fig. 3 Comparison of fatigue fracture surfaces for (a) low (K_{max}= 4.04 MPa$\sqrt{m}$, or 3.68 ksi$\sqrt{in.}$) and (b) high (K_{max}= 13.0 MPa$\sqrt{m}$, or 11.8 ksi$\sqrt{in.}$) values of K_{max} in Comral-

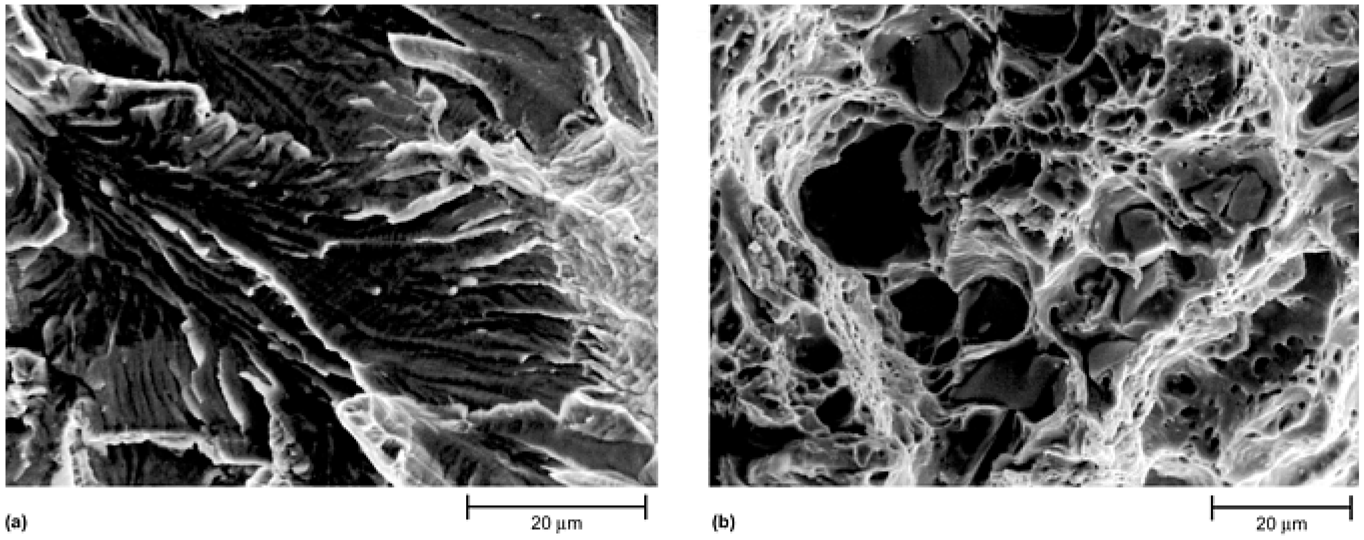

Fig. 4 Comparison of fatigue fracture surfaces for (a) low (ΔK< 8 MPa $\sqrt{m}$, or 7 ksi $\sqrt{in.}$) and (b) high (ΔK> 11 MPa$\sqrt{m}$, or 10 ksi$\sqrt{in.}$) values of ΔK in Duralcan F3A.20S, an Al- 7%Si cast alloy reinforced with 20 vol% SiC particles. Courtesy of J. Baïlon. Source: Ref 28

In addition to K_{max}, the type, size, shape, and volume fraction of reinforcement, the aging state of the matrix material, and the stress state under which fatigue crack propagation occurred influence A_f (Ref 11, 26). A_f also depends on K_{Ic} because this is the highest value of K_{max} possible for a given material. In contrast, A_f is independent of ΔK and R, as shown in Fig. 5 for Comral- 85 (Ref 26). Similar results for SiC-reinforced composite are currently unavailable.

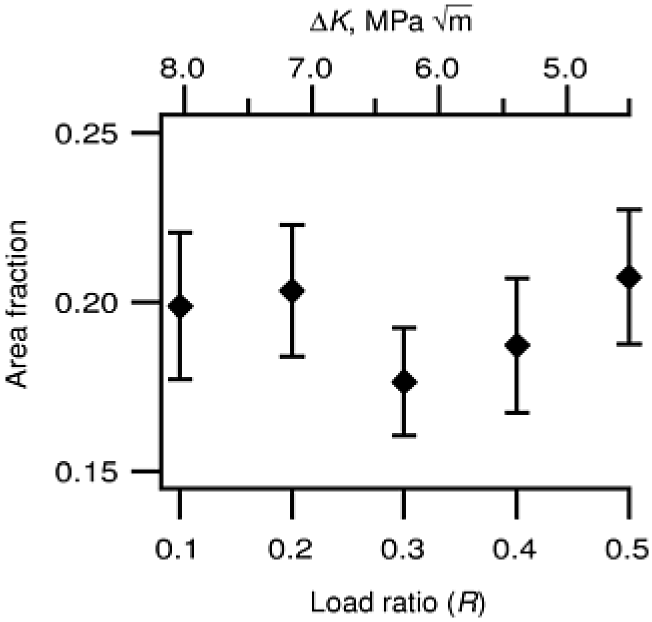

Fig. 5 Area fraction of reinforcement on the fracture surface of Comral-85 as a function of load ratio at constant K_{max}= 8.9 MPa$\sqrt{m}$, or 8.1 ksi$\sqrt{in.}$

Using four variants of a 2124 A1/20 vol% SiC_p composite, Hall et al. (Ref 11) demonstrated that A_f increases with the mean size of the reinforcement particles. This increase is most likely due to the decreased resistance to fracture of larger particles. Hall et al. (Ref 11) also observed that A_f increased as the reinforcement volume fraction increased. This increase in A_f, however, was not proportional to the increase in V_f and is therefore not

merely a result of the increased amount of reinforcement in the composite. Instead, the proportion of A_f as a function of the reinforcement volume fraction of the composite decreased as the volume fraction increased.

The appearance of the fracture surface around the reinforcement particles changes dramatically between threshold and fast fracture (Ref 11, 26). (Compare Fig. 3a with 3b and Fig. 4a with 4b.) Near the fatigue threshold the fracture surface is quite flat, with the exception of river marks growing from those reinforcement particles that are visible on the fracture surface. The regions between the plateaus are characterized by shear steps. Striations are visible on the fracture surface of the SiC-reinforced composite (Fig. 4a). As ΔK increases into the Paris Law region*, the plateaus around the particles shrink and the steps between the plateaus become rougher and more distinct. Toward the upper end of the Paris Law region, the plateau boundaries take on the appearance of ductile knife edges. By this stage, however, the plateaus are very small, because the spacing between the reinforcement particles has dropped dramatically. Eventually, the plateaus disappear, leaving a fracture surface consisting entirely of fractured or decohered reinforcement particles surrounded by ductile knife edges. This occurs at K_{max} values approaching K_{Ic}. At this stage, the fracture surface can no longer be distinguished from that produced by fast fracture.

The presence of reinforcement particles in MMCs prevents the formation of the regular striations observed in some aluminum alloys (Ref 26). However, some irregular striations may be observed in areas free of reinforcement particles (Ref 26, 28). Striations can be seen in the center of Fig. 4(a). The lack of regular striations indicates that the crack front in MMCs is highly irregular. This is consistent with the plateaus described previously. Together these features indicate the initiation of microcracks ahead of the main crack front.

Method of Observation

The fracture surfaces of MMCs are most efficiently examined by studying areas of the surface produced under known loading conditions. This is best achieved by determining the areas of interest using an initial visual examination followed by examination under a microscope. After this, the fracture surface can be examined in the SEM. In general, MMCs should be considered to be nonconductive. Therefore, they should be carbon coated prior to SEM examination and examined at accelerating voltages between 5 and 10 kV to minimize beam charging.

Location of Specific Points and Calculation of K_{max}. In examining the fracture surfaces of MMCs, it is vital that the loading conditions at the point being examined are known or can be confidently estimated. The method used to achieve this varies with the type of specimen being examined. If the specimen is a fatigue life specimen, then the methods used in Ref 10 and 11, which are based on a K-calibration developed by Raju and Newman (Ref 30), are appropriate. For fatigue crack growth specimens, the loading conditions at a specific point can be determined from the records of fatigue testing. Automated crack-length measurements should be backed up with visual crack-length measurements (if available) so that the extent of crack- front curvature is known.

The typical examination method for fatigue life samples is to record a sequence of overlapping fractographs from the crack origin in a straight line to the boundary of the fatigue region and beyond (Ref 10, 11). The distance between the crack-initiation site and any point of interest can be measured directly from this sequence, and K can be determined from standard calibrations (Ref 30). It should be noted that valid values of K can only be determined when linear elastic fracture mechanics apply, and prior to fast fracture. The first of these conditions means that K is undefined near the initiating defect due to short crack effects. The second condition arises simply because K_{Ic} is the maximum stress-intensity factor that a material can withstand under plane-strain conditions. K is also undefined if gross section yield occurs in the remaining ligament of the specimen.

The examination method for fatigue crack growth (FCG) specimens is somewhat more involved. The fracture surface of a FCG sample often consists of multiple regions, each of which was produced at different values of ΔK and/or R. It is therefore necessary to have a method of locating required points on fracture surfaces. A suitable method, which is based on a coordinate transformation between FCG specimen and SEM stage position coordinates, is described in Ref 31. The advantage of using FCG specimens is that they provide a much larger fracture surface than fatigue life samples. As a result, the data obtained from their fracture surfaces can be much more reliable than those from fatigue life specimens. In addition, in FCG testing it is possible to produce a region of fracture surface of constant loading (ΔK and R) conditions. This increases the accuracy of the K_{max} value of the fracture surface being examined and reduces transient effects.

It should be noted that there has been no direct comparison of fractographic data obtained from fatigue life and fatigue crack growth samples. This may be a significant oversight, given that stress state is known to influence A_f (Ref 26).

Measurement of Reinforcement Area Fraction. The area fraction of reinforcement particles appearing on a fracture surface of an MMC can be estimated using techniques similar to those used on plane-polished sections (Ref 11, 26). The point-counting method outlined in ASTM E 562 is suitable in this case (Ref 32). It allows both the area fraction of reinforcement and the error in these estimates to be determined with statistical reliability. This has been a weakness of previous research into the relationship between area fraction and loading conditions. This weakness is a result of the limited fracture surface area available on fatigue life samples that have been used in most of the fractographic studies of metal-matrix composites (Ref 10, 11).

An appealing alternative to visual examination is to analyze the x-ray emissions from fracture surfaces. Such a method was used by Baïlon and Tong (Ref 29), who found that the intensity (*I*) of an x-ray peak due to SiC increased as a function of crack growth rate in an MMC reinforced with SiC_p. This indicates an increase in the amount of SiC on the fracture surface. At this stage, no conversion between *I* and A_f is available, other than a comparison with the *I*-value obtained from a plane-polished surface. When such a conversion becomes available, this method is likely to significantly increase the speed with which MMC fracture surfaces can be quantitatively examined.

Footnote

* *The Paris Law region is the central portion of the da/dN versus ΔK curve where the curve can be modeled as $da/dN = C(\Delta K)^m$, where da/dN is the crack growth rate, ΔK is the stress- intensity factor range, and C and m are constants.

Failure Analysis of Ceramic-Matrix Composites

Michael G. Jenkins, University of Washington—Seattle; Raj N. Singh, University of Cincinnati

Introduction

INTERPRETATION OF FAILURES of ceramic-matrix composites (CMCs), and in particular continuous fiber reinforced ceramic-matrix composites (CFCCs) is complicated by the complex structure of the composite material. To perform successfully (that is, to exhibit damage tolerance without undergoing catastrophic brittle failure), CFCCs often must incorporate three constituents (fiber, matrix, interphase between the fiber and matrix) for use in room-temperature applications and up to four constituents (fiber, matrix, interphase between the fiber and matrix, and an environmental and/or thermal barrier coating over the entire composite) for use in high-temperature applications. In addition to the thermomechanical performance of the composite and each of its constituents, attention must be paid to the chemical compatibility of the constituents. The complex composite structure of a CFCC is necessary, because without a debonding interphase between the brittle ceramic matrix and the brittle ceramic fiber, brittle fracture of the CFCC would result with none of the nonlinear behavior and inherent damage tolerance. An example of this composite structure is shown in Fig. 1 (Ref 1).

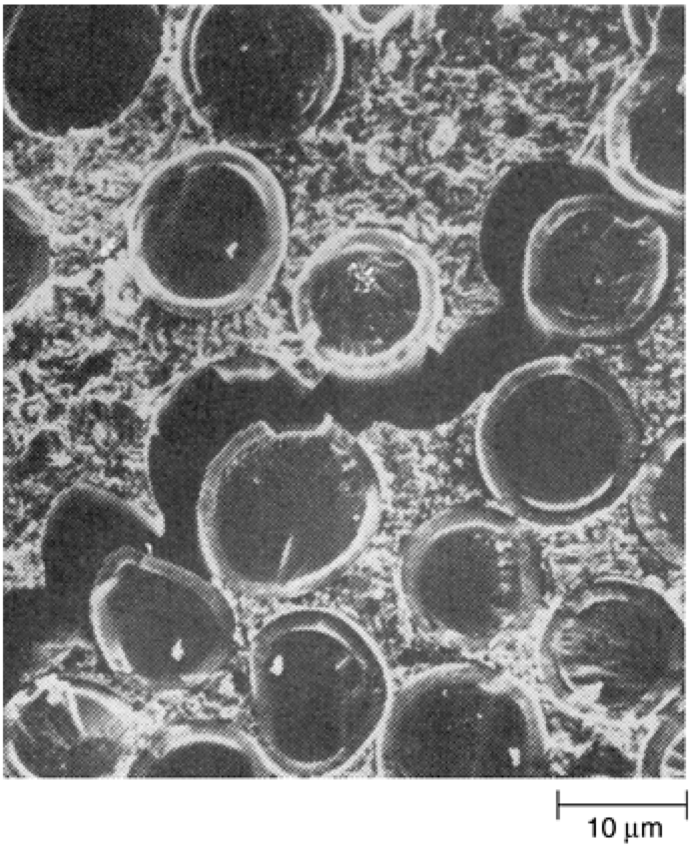

Fig. 1 Scanning electron micrograph of a CMC with a thick interphase (Nicalon fibers, SiC-BN-SiC interphase, and $ZrTiO_4$ matrix). Source: Ref 1

Although CMCs and CFCCs can exhibit many of the basic failure modes of other composite laminates: in-plane and out-of-plane failures (Ref 2), this article concentrates on those failure mechanisms unique to CMCs, in particular those involving interaction of the constituents.

Characteristic Failure

Continuous fiber reinforced ceramic-matrix composites retain many of the characteristics of monolithic advanced ceramics (for example, erosion and corrosion resistance, stiffness, and high-temperature properties) while avoiding the main drawback of monolithic ceramics (that is, brittleness) by exhibiting increased toughness and, therefore, increased reliability. Figure 2 illustrates this increased toughness, contrasting the lower strength but nonlinear energy-absorbing quasi-ductile behavior of ceramic composites with the linear-elastic but brittle behavior of monolithic ceramics.

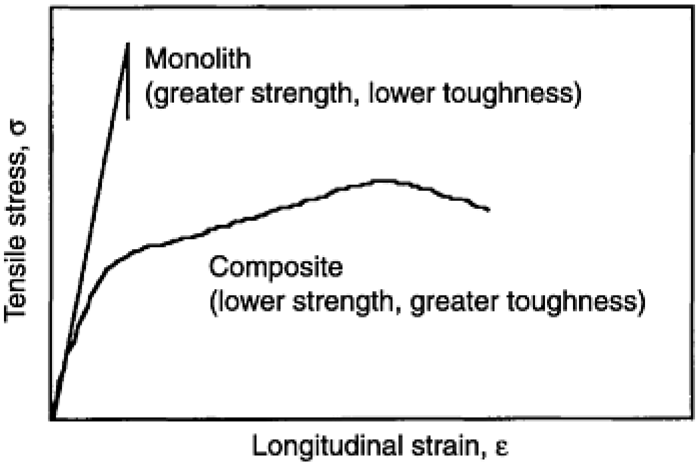

Fig. 2 Tensile stress-strain curves for a monolithic ceramic and a ceramic-matrix composite. Source: Ref 3

A key characteristic feature of the fracture surfaces of the energy-absorbing nonlinear stress-strain behavior is a “brushy” appearance with many pulled-out fibers as shown in Fig. 3. Note in Fig. 3 that not only are long fiber lengths apparent, but also many holes are visible from which fibers have been pulled out. It is important to note that the nonlinear stress- strain behavior occurs because of debonding of the fiber/matrix interface and subsequent fiber pullout due to fracture of the interphase and fibers. If a strong or highly fracture-resistant interphase is present, or if no interphase is present, such that the fiber is tightly bonded to the matrix, then the composite will behave in a brittle manner similar to the monolithic ceramic shown in Fig. 2. The resulting fracture surface will show little or no fiber pullout; the nearly featureless fracture surface is shown in Fig. 4.

Evidence of Failure Mechanisms

Fractography can reveal evidence of individual fracture mechanisms, as well as the overall fracture behavior shown in Fig. 3 and 4. For example, the onset of nonlinearity (proportional limit stress) indicated in the stress-strain curve for the ceramic composite shown in Fig. 2 is often equated to a matrix cracking stress. Figure 5 shows evidence of matrix cracking, often first occurring around the fibers oriented 90° to the loading direction

(Ref 4). The nature of fracture surface appearance of individual fibers can also be related to fiber strength, fiber fracture resistance and fiber degradation (for example, surface defects) as shown in Fig. 6 (Ref 6). Degradation of fibers at elevated temperatures is indicated by changes of the fracture mirrors and fracture origins (surface or volume). These changes in fracture surface appearances are consistent with changes in fracture strength for fibers.

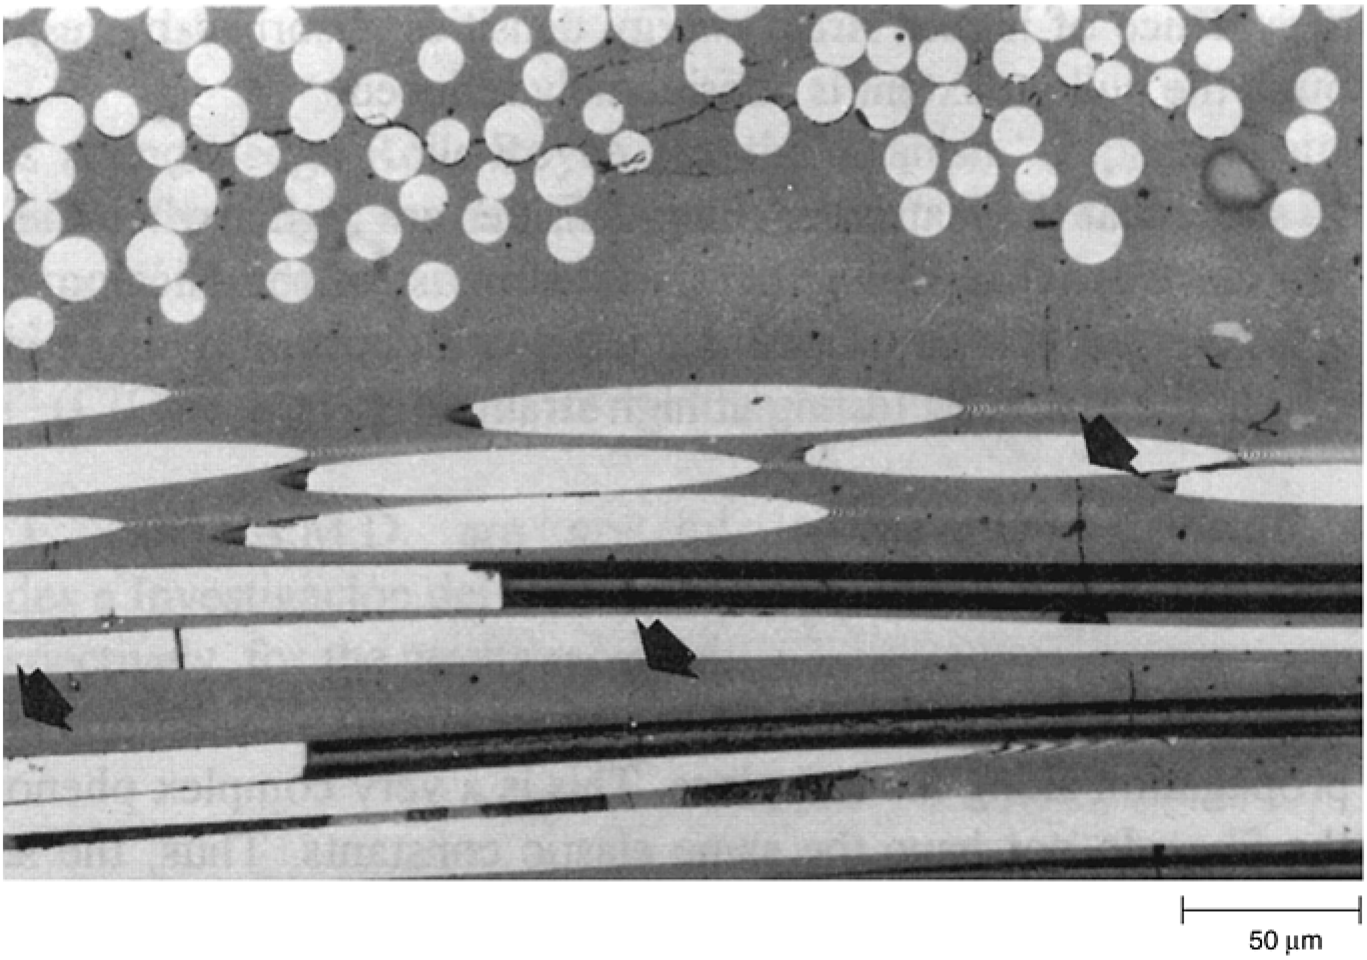

Fig. 5 Matrix cracks related to the proportional limit stress and onset of nonlinearity of the stress-strain curve; arrows indicate matrix cracks in 0°/90° laminate Nicalon fiber reinforced CAS glass-matrix composite. Source: Ref 4

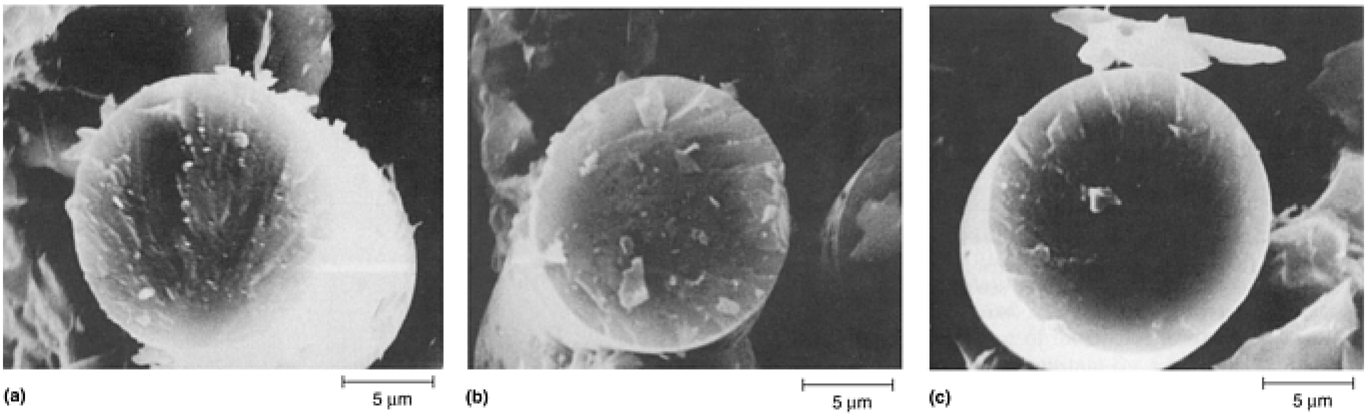

Fig. 6 Fracture mirrors on pulled-out fiber fracture surfaces of Nicalon fiber reinforced SiC-matrix composites with carbide interphase. (a) 298 K. (b) 800 K. (c) 1200 K. Source: Ref 6

Changes in macroscopic fracture features can often be related to environmental degradation of the composite. For example, in Fig. 7 low- magnification scanning electron microscopy (SEM) reveals changes in fiber-dominated fracture (Fig. 7a) at room temperature to matrix- dominated transverse fracture at elevated

temperatures (Fig. 7b and c). Such overall changes in fracture features often cannot be discerned at high magnification. Figure 8 indicates that fatigue loading results in multiple cracks in the matrix, spaced about 300 μm apart. Such microcracking can eventually lead to environmental degradation and possible brittle fracture of the composite.

Introduction to Recycling and Disposal of Composites

Nicholas J. Gianaris, Visteon Corporation

THE RECYCLABILITY of all materials, components, and systems has gained increased international emphasis, and this is certainly true of structural materials including composites. Composite materials have traditionally been selected for increased performance, mass reduction, safety, and ease of manufacturing for all applications including transportation, civil, as well as military. However, with the recently increased regulatory and ecological emphasis on recycling, composite materials must now be examined for their potential as recyclable and reusable materials.

Many drivers, including energy usage, greenhouse gas minimization, cost, and waste stream management, have escalated the emphasis on recycling. The Kyoto Protocol to the 1992 Climate Change Treaty has placed the responsibility on the United States, Japan, and the European Union to create open- and closed-loop material recycling schemes that decrease greenhouse gas emissions from 1990 levels to lower levels by 2008 to 2012. Additionally, the European Union passed a directive in 2000 for member nations to adopt by 2002 that requires all used automobiles to be 100% reusable or recyclable by 2007, with all costs borne by the automotive manufacturers. This also includes having vehicles manufactured with reusable or recyclable components that constitute 85% of the mass of the vehicle by 2006, and 95% of the mass of the vehicle by 2015. This directive is intended to force automotive manufacturers to use ecologically friendly materials and design schemes. As one can observe, regulatory and environmental factors will more greatly influence the decision of material use for all applications.

The choice of low-density and high-strength materials such as composites has always been viewed as the ultimate solution for mass reduction and increased fuel economy of automotive as well as aerospace vehicles. If, however, the recyclability of composite materials is not well understood and advantageously demonstrated, then the use of composites for all applications can be limited by the regulatory and ecological drivers, as stated previously. It is important, therefore, that the scientist and engineer be presented with the most comprehensive and timely information on the recycling and disposal of composite materials.

The articles presented in this Section give the reader the most recent developments in the open- and closed-loop recycling of polymer and metal matrix composites. Much of the innovation presented is based on developing processes that take existing materials and reuse them at equivalent or less value than the previous loop in which they were used. There also are material innovations presented that allow the engineer to use high-quality structural composites that are easily processed at high production volumes and can be closed-loop recycled for equivalent or even higher value new applications. Such developments are exciting and are featured in this Section.

The automotive industry is the focus of recycling efforts due to high-volume production, and this will be emphasized most heavily in this Section. This information is also designed so that it may be applicable to the use of composites in any area.

Recycling and Disposal of Polymer-Matrix Composites

John M. Henshaw, The University of Tulsa

Introduction

RECYCLING AND REUSE of fiber-reinforced polymer-matrix composite materials can be difficult, although much progress has been made. These materials obtain their useful and unusual blend of properties from their constituent phases: fibers, organic resins, and fillers. That these disparate phases are so finely interspersed in composites accounts for some of the difficulties in recycling postconsumer and factory-generated scrap. Nonetheless, many researchers have attempted to develop technically feasible, economically viable, and environmentally acceptable recycling processes for polymer-matrix composites. This article reviews those processes after first discussing the driving forces for composites recycling.

Recycling and Disposal of Polymer-Matrix Composites

John M. Henshaw, The University of Tulsa

Driving Forces for Recycling of Composites

Why recycle composites? The answers are much the same as for other commodity materials, such as aluminum and glass, for which recycling processes are older, better established, and more successful. Some of these reasons include: to conserve non-renewable natural resources (both materials and energy), to reduce solid wastes (in particular, to reduce landfill volumes), to reduce hazardous wastes, to make money, and to comply with governmental regulations. Each of these driving forces for the recycling of composites is briefly discussed subsequently.

Composites Contribution to Solid Waste. Where do polymer composites fit into the total plastics picture? The data in Fig. 1 show that while total plastics production in the United States exceeds 35 × 10^9 kg (77 × 10^9 lb) and is increasing, the total for polymer composites is only about 1.4 × 10^9 kg (3.1 × 10^9 lb), or about 4% of the total plastics mass (Ref 1). A breakdown of the polymer composites fraction is included in Fig. 2.

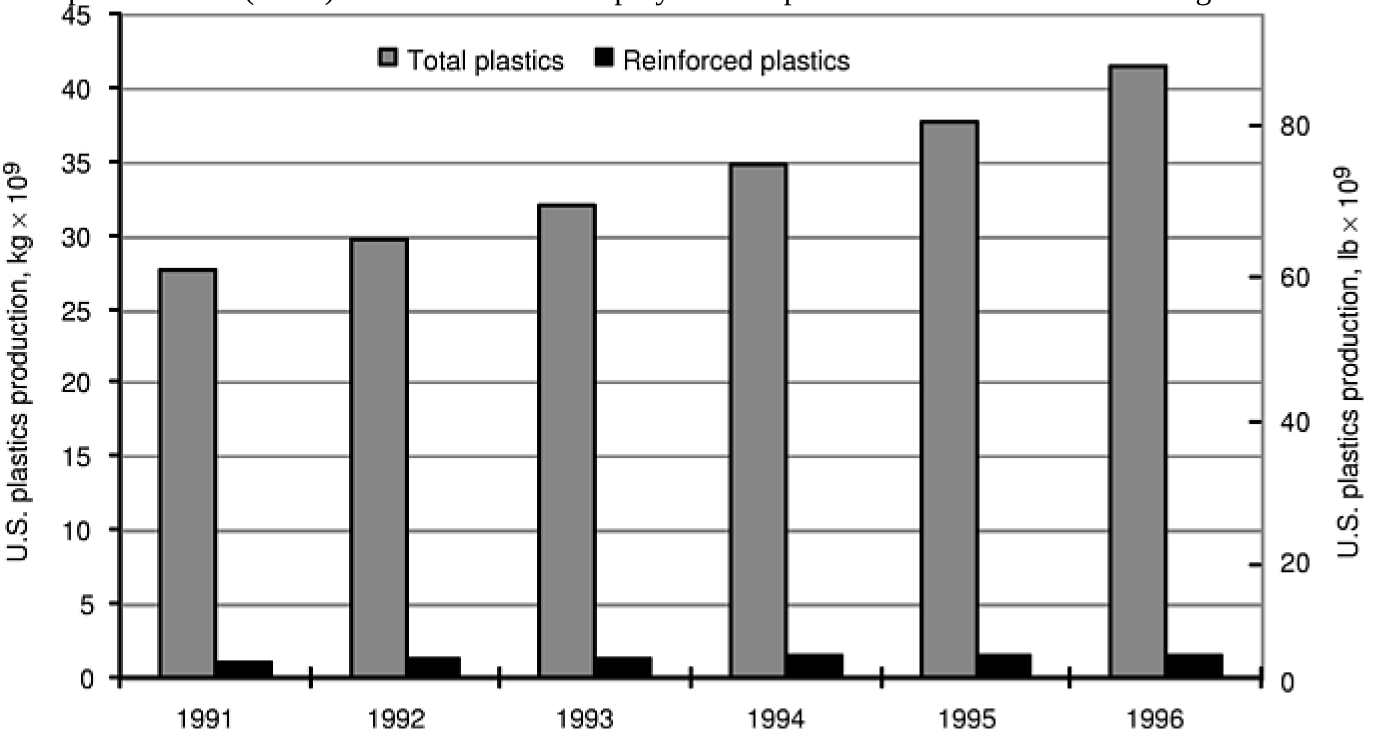

Fig. 1 Comparison of reinforced plastics production to total plastics production in the United States

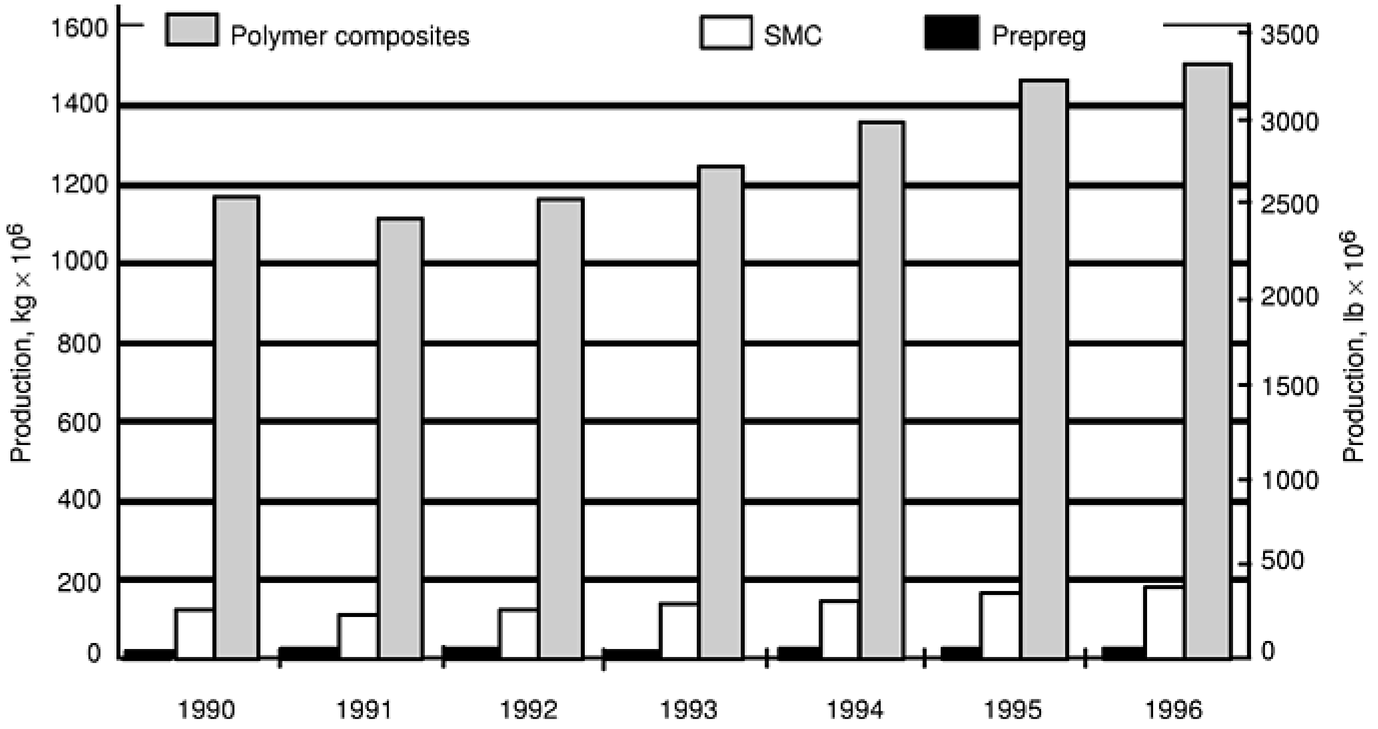

Fig. 2 Sheet molding compound and prepreg production versus total reinforced plastics production in the United States

It is also important to consider the uses and types of composites currently being produced. Figure 2 shows the total weight of composites produced along with the weight of sheet molding compound (SMC) and advanced composites prepreg for comparison (Ref 1). The figure shows that disposal issues for prepreg (traditionally an aerospace material) are not driven by production volume. In other words, it may be important to recycle prepreg composites, perhaps because of their value, but not because their sheer mass or volume are creating societal problems.

More surprising, perhaps, than the low fraction of prepreg in the total composites stream shown in Fig. 2 is the relatively low fraction of total composites production made up of SMC. Even within the automotive industry, SMC comprises only about 50% of total composites use.

The totals for composites production, shown in Fig. 2, may also be broken down by industry, as shown in Fig. 3. The data in Fig. 2 and 3 are presented to show that polymer composites represent a broad class of materials employed in a wide range of applications. This can make recycling more difficult, because it complicates the collection and separation of composites scrap and can result in recycling feedstock of widely varying composition.

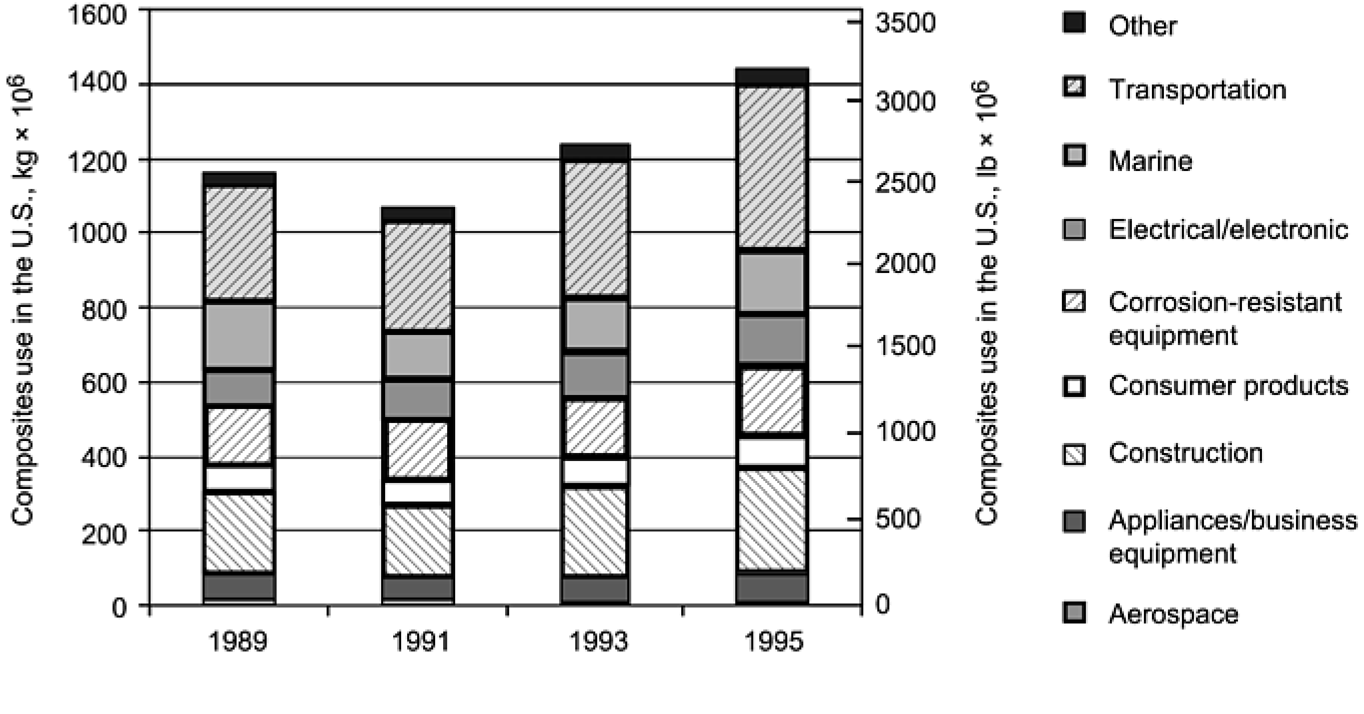

Fig. 3 Composites use by industry in the United States

Composites Contribution to Conservation of Nonrenewable Resources. Reprocessing polymer composites into usable products represents the reuse of a non-renewable natural resource, namely hydrocarbons. In the hydrocarbon life cycle, non-renewable resources are extracted and refined into fuels and nonfuels. The fuel stream accounts for 86% of hydrocarbon production (Fig. 4). Nonfuels or petrochemicals represent only 14% of the hydrocarbon stream. Petrochemicals include plastics, synthetic fibers, solvents, lubricants, detergents, paints, and other products. Petrochemicals can be disposed of by burning, burying, or reusing them (Ref 2). Just as composites represent a small fraction of the total plastics stream, plastics represent a small fraction of the hydrocarbon stream. In terms of resource conservation, then, the recycling of reinforced plastics has extremely limited utility compared to reduction of fuels usage or the recycling of unreinforced plastics. Figure 4 also shows why the burning of waste plastics and composites for energy recovery is so appealing to some, because that is what society does with the vast majority of hydrocarbon products in the first place.

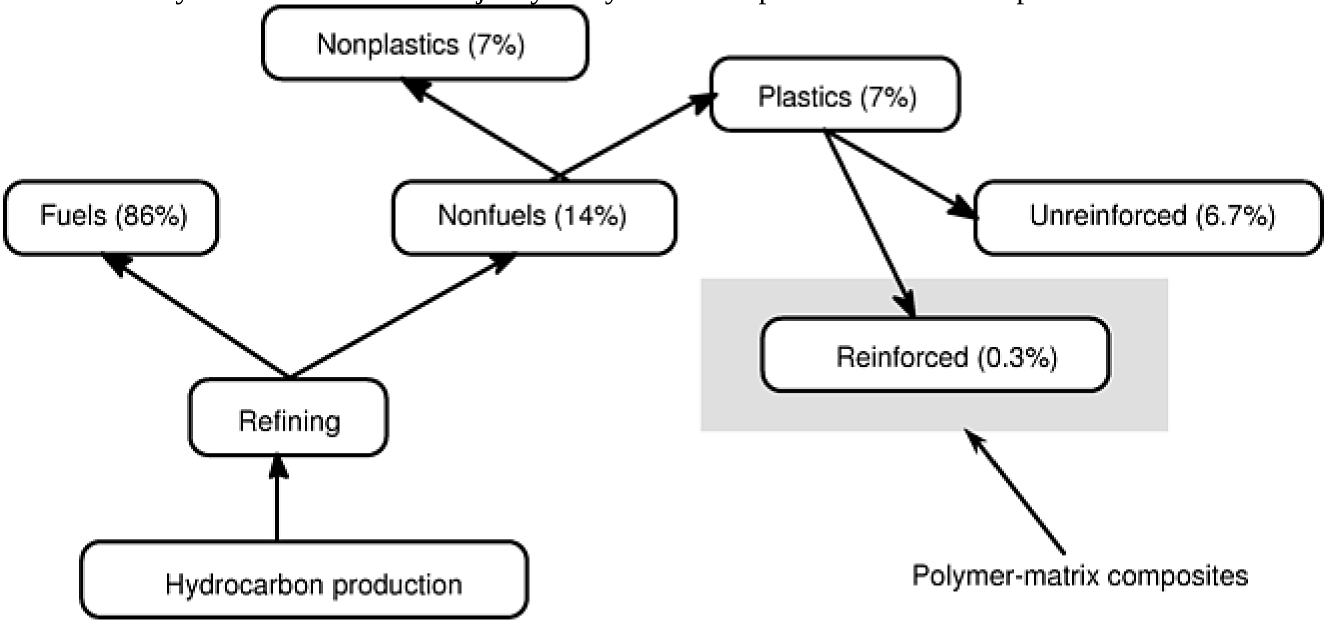

Fig. 4 Relation of polymer-matrix composites to the overall use of hydrocarbons

Hazardous Waste Reduction. There are some cases in which composites waste material can be considered as hazardous waste. Automobile shredder residue (ASR), the fraction of materials left over from the automated shredding and recovery of materials (mostly metals) from cars, is considered as hazardous waste by some European countries (Ref 3). The same is true of uncured composite scrap, such as SMC or prepreg.

Economic Incentives. Recycling is traditionally an economic activity. Historically, environmental pressures to recycle materials are relatively recent. Most successful recycling efforts, such as that involving aluminum cans, are also successful economically. Composites recycling efforts will eventually have to show acceptable economic returns, particularly in the absence of strict governmental regulations mandating recycling.

Governmental Regulations. Governmental regulations have influenced the development of composites recycling. For example, as noted previously, ASR is considered as hazardous waste in some European countries.

Disposing of Composite Scrap

Having described some of the driving forces for recycling composites, it is appropriate to briefly consider the options for dealing with solid waste in general. According to William Rathje, all options for handling solid wastes can be divided into four categories: burying, burning, reusing, or using less in the first place (Ref 2). Burying generally refers to landfilling methods. Landfilling is under pressure due to shortages of landfill space in some areas and to environmental problems, particularly with older landfills. Burning refers to combustion processes used to dispose of solid wastes, often accompanied by energy recovery. Reuse refers to the direct reuse of a discarded item or to the reprocessing of the material into raw materials for use in a manufacturing process. The fourth option listed, using less of a material, is of particular interest for composites. This option is sometimes referred to as “source reduction.” Composites are frequently employed because they save weight over other materials that could be specified. If by saving weight in an automobile, for example, a composite component can be shown to improve fuel economy, that component has source-reduced the use of fuel in that car. Considered from a life cycle perspective, this type of source reduction is important for polymer composites. If polymer composites can reduce the overall amount of hydrocarbons consumed during the life cycle of the product they are a part of, then, in life cycle terms, the composite part may have an advantage over a heavier (metal) component that is more readily recycled. The evaluation of the life cycle merits of saving fuel versus ease of reuse fall under the category of “life cycle analysis,” which is somewhat beyond the scope of this article; an overview of life cycle concepts is available in the article “Life Cycle Engineering and Design” in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

The Recycling Chain. Having briefly considered the generic ways in which scrap composites can be handled, the remainder of this article focuses on techniques for the reuse/reprocessing of polymer composites. A number of technologies have been or are in the process of being developed. These processes use scrap composites as feedstock for the production of a variety of useful materials. Whatever the merits of these particular processes, they are only one element in an overall recycling system for composites.

The successful recycling of composites depends on a sequence of events, each of which is crucial to the overall success of the system. Reprocessing techniques are an important part, but only a part, of that system. The recycling chain is shown schematically in Fig. 5. There are five necessary elements in a recycling system for composites, or indeed for any recycling system: (1) a source of materials to be recycled, (2) a means to collect those materials and (3) deliver them to a reprocessor, (4) efficient means to reprocess those materials, and (5) economical markets for the reprocessed materials. If any one of those elements is missing, economically nonviable, or otherwise unsuitable, the entire recycling system will fail. In this respect, composite materials are no different from aluminum beverage cans or other materials. While most of the research and development efforts for composites have focused on the reprocessing techniques themselves (as does the remainder of this article), it must be recognized that those techniques by themselves do not constitute “recycling.”

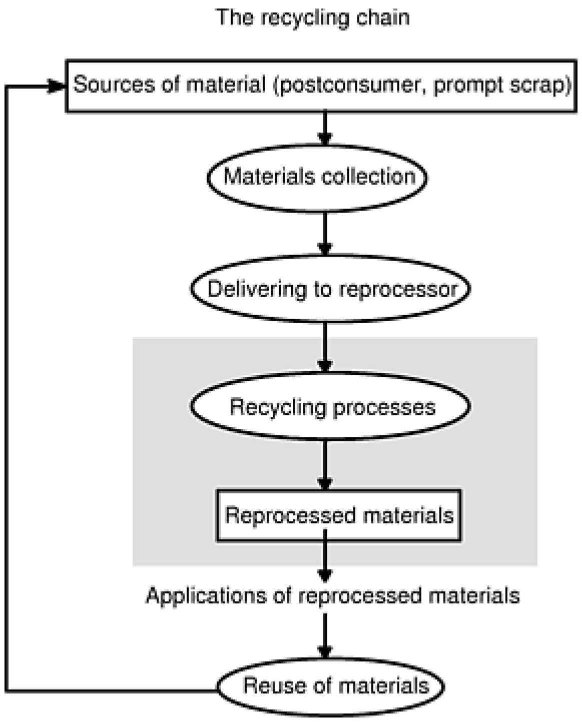

Fig. 5 Flow chart for the recycling and reuse of materials

The reprocessing of thermoset- and thermoplastic-matrix polymer composites are considered in the sections that follow.

Recycling and Disposal of Polymer-Matrix Composites

John M. Henshaw, The University of Tulsa

Recycling of Thermoset-Matrix Composites

Figure 6 shows an overview of some of the main options for recycling thermoset-matrix composites. Table 1 summarizes specific recycling technologies for these composites. The first column in the table lists the process name and associated literature references. The second column lists the feedstocks to the recycling process, while the third shows the major products produced by the process.

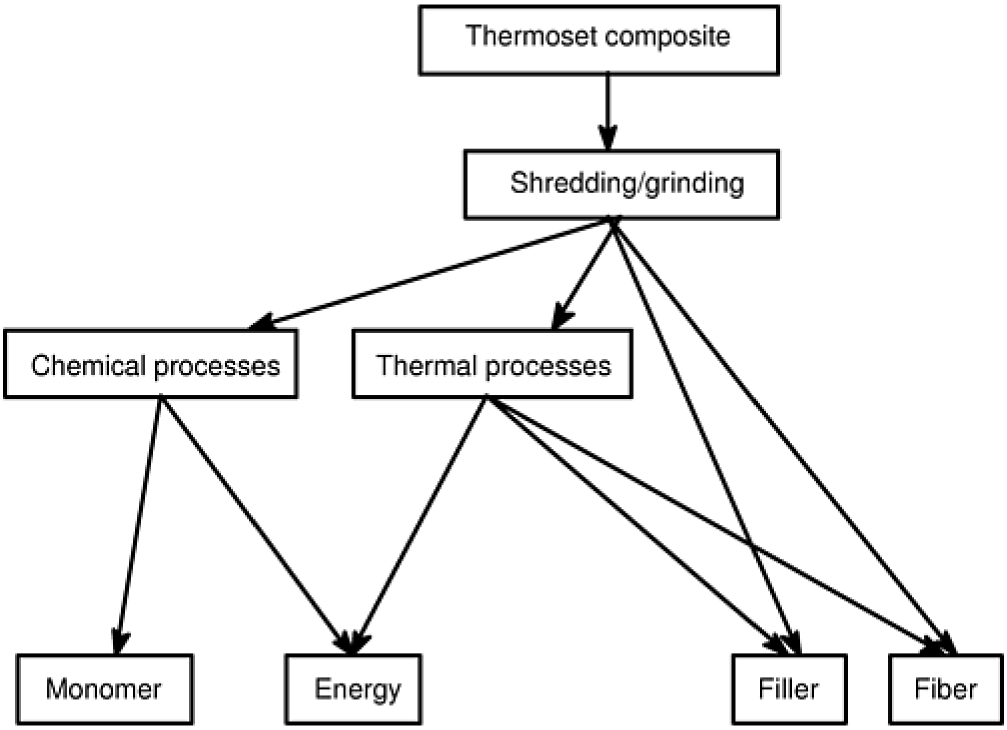

Fig. 6 Thermoset composites recycling

Table 1 Thermoset composites recycling processes

Process	Feedstock	Products/wastes
Pyrolysis (Ref 12)	In-house or postconsumer SMC	Fuel gas, oil, inorganic solid
Pyrolysis and milling (Ref 8)	SMC	Fuel gas, oil, inorganic solid
Pyrolysis (Ref 14)	Polyurethane foams, ASR	Gas, oil, solid waste
Hydrolysis (Ref 10, 11)	Foams, RIM resin, and elastomers	Monomers of the input material
Fluidized bed combustion (Ref 14)	RIM	Energy recovery, solid and gaseous wastes
Rotary kiln combustion (Ref 13)	RIM	Energy recovery, solid and gaseous wastes
Incineration (Ref 11, 15)	ASR “pellets,” mixed polymer waste, fuel supplement	Energy recovery, solid and gaseous wastes
Incineration in pure O_2 (Ref 11)	Auto battery plastics scrap, ASR	Energy recovery, solid and gaseous wastes
RIM regrind (Ref 4, 5)	In-house or postconsumer RIM polyurethane	Ground particles for use as filler
Phenolic regrind (Ref 1)	Phenolic scrap parts, other thermosets	Ground phenolic for use as filler
SMC regrind (Ref 6, 7)	In-house (cured) or postconsumer SMC	Ground particles for use as filler
Vitrification/energy recovery (Ref 1)	ASR	Glassy solids for use in asphalt/concrete, energy
Fluidized bed and separation (Ref 9)	SMC, filament-wound pipe, or glass-reinforced sandwich panels	Short fibers, fillers, and energy

ASR, automobile shredder residue; RIM, reaction injection molding; SMC, sheet molding compound

The processes for recycling of thermoset-matrix composites listed in Table 1 fit into several broad categories. These include regrind processes, chemical processes, energy recovery processes, and other thermal processes for fiber and filler recovery. As is seen, some overlap exists among categories. These categories are discussed subsequently.

Regrind Processes for Recycling of Thermoset Composites. A great deal of research, development, and commercial activity has revolved around the shredding and regrinding of thermosetting composites, particularly SMC, into particles suitable for use as filler in materials such as SMC and bulk molding compound (BMC). A number of investigations has shown this type of process to have technical merit. At least one commercial

enterprise in North America, Phoenix Fibreglass of Canada, was able to commercialize a process of this type, although the company closed its operations in 1996.

In general, regrind processes for thermosetting composites begin with “shredded” composite components—the pieces of which have dimensions on the order of 100 mm (4 in.). To date, most of this type of recycling has been done on postindustrial (cured) scrap and not on postconsumer scrap. Such materials may contain molded-in metallic components, but are typically free of adhesives and coatings. Magnets separate out ferromagnetic materials at several stages in the process. The shredded feedstock is further shredded into smaller pieces and passed through several more metal-separation processes. In the next step, the material is shattered in a process that allows much of the fiber content of the material to be separated from the fillers and polymer matrix. At the former Phoenix Fibreglass operation, separation was accomplished through proprietary screening processes that allowed Phoenix to market products consisting of filler (pulverized polymer and calcium carbonate), chopped-strand glass fiber, and discrete fibers in several length categories. The recycled filler product was milled down to an average particle size, as specified by the customer. In a process such as this, the finer the particle size, the more expensive the product, but the more suitable it will be for recycling as filler for “class A” automotive components. (Class A components require a very smooth surface finish and thus, a finer particle size for their filler component.)

Recycled filler has been used in a number of production SMC and BMC automotive applications. Recycled content of 5 to 15% by weight has been achieved, with up to 25% believed to be possible. (Virgin SMC contains up to 40% filler by weight.) The recycled material has the added bonus of weight savings, because a blend of powdered polymer and calcium carbonate is less dense than 100% calcium carbonate. Recycled content of 25% in an SMC component is said to yield a weight savings of almost 10% over virgin SMC.

Recycling of other composites has been investigated, using related regrind-to-filler technology. Developmental work on recycling reaction injection molded (RIM) polyurethane automotive scrap is ongoing. One technique involves regrinding RIM scrap and then using approximately 10% of the regrind as filler in other molding processes (Ref 4).

Compression molding of these materials is limited to simple shapes and requires very high pressures. The Polyurethanes Recycle and Recovery Council announced plans to establish pilot facilities to develop similar recycling processes. Phenolic scrap containing glass fibers or carbon fibers has been shown, by phenolic suppliers, to be capable of being pulverized into suitably sized particles and then used as fillers and extender in molding compounds (Ref 5). Rogers Corporation has shown that it is possible for cured phenolic compounds to be ground and reformulated into other phenolic-based compounds. The properties of the compounds containing recycled phenolics are similar to virgin materials. Besides structural reaction injection molded (SRIM) and RIM materials, regrinds of thermoplastics such as acrylonitrile-butadiene- styrene (ABS) and polypropylene have also been used as fillers. Test results show a significant increase in modulus of elasticity. Researchers claim that the cost of the final part may be reduced because of the substitution of recycled RIM or SRIM into the virgin material (Ref 5). Union Carbide Chemicals and Plastics Company has results showing that the properties of the thermoplastic-matrix composites containing recycled SMC as fillers can be as good as or better than those containing virgin materials (Ref 6). Owens-Corning Fiberglass Corporation has reported that fully cured SMC scrap can be shredded, ground, and milled into powder and then used directly as a filler and reinforcement in BMC and thermoplastic polyolefin molding compounds (Ref 7).

Chemical Processes for Recycling of Thermoset Composites. Included in this category of recycling processes for thermoset-matrix composites are processes such as pyrolysis and hydrolysis that result in the chemical and thermo- mechanical decomposition of composites into gases, liquids, and solids. Some of these decomposition products have economic value, while others must be disposed of as waste.

Pyrolysis. Pyrolysis of polymers and their composites involves thermal decomposition of organic materials at high temperature in the absence of oxygen. Typical pyrolysis processes involve melting vessels, blast furnaces, autoclaves, tube reactors, rotary kilns, and fluidized bed reactors. Rotary kilns and fluidized beds are among the most widely used pyrolysis processes for use in recycling. The reaction products of the pyrolysis of polymers include various hydrocarbons that can often be used as fuels or as feedstocks for petrochemicals. Pyrolysis processes may eventually become a feasible alternative in the market for recycling thermosetting composites, if the waste composites can be collected in large quantities. Attempts to pyrolyze cured and uncured SMC in-house manufacturing scrap have been carried out. Three trial SMC pyrolysis runs were completed at a converted tire pyrolysis facility (Ref 16). Based on a pyrolysis project sponsored by the SMC Automotive Alliance, the pyrolysis yielded about 30% by weight gas and oil and 70% solid by-product. The solid residue

was milled to a particle size suitable for use as filler. The mechanical property data for SMC using pyrolyzed and milled SMC have demonstrated that pyrolysis followed by milling is a technically feasible recycling technology (Ref 8).

A difficulty with pyrolysis of glass-reinforced composites such as SMC is the large inorganic fraction (mainly glass and calcium carbonate) that must be dealt with following pyrolysis. The SMC Automotive Alliance concluded that recycling of cured in-house SMC scrap by pyrolysis is less cost-effective than simply grinding scrap SMC to a powder and using it as filler (Ref 8). Uncured prompt scrap seems to be a better candidate for pyrolysis. It is possible that postconsumer SMC will be a better candidate for the direct regrind and milling process than for pyrolysis, or perhaps for the thermal process for fiber and filler process (Ref 9) described subsequently.

Some research has been done on pyrolysis of ASR. Auto shredder residue is what remains after automobiles have passed through the shredding process and after a variety of metals have been separated out. Auto shredder residue contains an increasing fraction of polymer composites as composites use in cars becomes more common. One major difficulty with the pyrolysis of ASR is the variability of the feedstock. Unlike pyrolyzing SMC prompt scrap, pyrolyzing ASR requires dealing with a constantly varying mix of polymers and other materials, making the process difficult to control.

Hydrolysis. Recycling through hydrolysis can be used for recovering the monomers of materials manufactured by various polymerization reactions. Polymers capable of recycling through hydrolysis include polyesters, polyethylene, polyurethanes, polyamides (Ref 10), and the composites of these polymers—for both thermosets and thermoplastics. The polyester polyethylene terephthalate can be hydrolyzed using water and an acid or base catalyst, producing terephthalic acid and ethylene glycol. Success of this type of process requires the scrap materials to be separated by polymer type, and is thus not applicable to ASR (unless the ASR can be separated by polymer type—a difficult proposition) (Ref 11). In the 1970s, General Motors Corporation and Ford Motor Company extensively investigated hydrolysis of polyurethane foams. General Motors found that flexible polyurethane foam was hydrolyzed to a diamine, a polyol, and CO_2, and discovered that high-pressure steam would hydrolyze flexible foam rapidly at temperatures of 232 to 316 °C (450 to 600 °F). The diamines could be distilled and extracted from the steam and the reclaimed polyols recovered from the hydrolysis residue. Ford explored the hydrolysis of polyurethane flexible foam seat cushion material at a lower temperature than that of General Motors. Bayer AG patented a continuous hydrolysis process using a specially designed extruder (Ref 12).

Most hydrolysis research on recycling has been directed toward unreinforced polymers. Extension to composites should be possible, although the presence of the inorganic phases (fibers and fillers) complicates the process.

Energy Recovery Processes for Recycling of Thermoset Composites. Like unreinforced plastics, composites have an appreciable energy content (although the frequently inorganic reinforcement phase significantly lowers the specific heat content). For example, it was estimated that the energy equivalent of the 1990 RIM production in North America alone would be 30 to 35 million liters (8 to 9 million gallons) of crude oil (Ref 13). The potential for energy recoverable from waste plastics is thus significant. The most common energy recovery methods are fluidized bed, rotary kiln, and mass burn. Dow Chemical Company conducted a study of the combustion of RIM materials. The Dow facility included a rotary kiln with a burner operating temperature of 870 to 1200 °C (1600 to 2200 °F). A multipass boiler was used to recover heat from the gases from the incinerator. The gases then went through a quench chamber and scrubber to remove acid gases and particulates (Ref 13). The Miles, New Martinsville WV plant used a waste- energy fluidized bed combustor to burn RIM. The facility operated at 900 °C (1650 °F). The unit used 12,700 kg (28,000 lb) of silica sand, which provided very high combustion efficiency. A three-stage boiler was used to recover the heat. The cooled gases were then led to an electrostatic precipitator and a two-stage scrubber to remove particulate and acid gas (Ref 14).

Auto shredder residue can be used as a substitute or supplement for fossil fuel, because its heat value is typically equivalent to that of a low- grade coal. EnerGroup has reported that ASR, for 12 samples used, has an average heat value of 12.6 MJ/kg. The mass of ASR may be reduced 50% by incineration—thus reducing disposal costs and landfill volumes (Ref 15). Japanese researchers have suggested separating the combustible portion of ASR, mixing with resin, and compressing the mixture into briquettes (Ref 11). Others proposed a similar process that would generate steam from the incineration of ASR in pure oxygen as an energy source for the shredder mill itself (Ref 3). While the use of pure oxygen instead of air for combustion is more expensive, it is compensated for by a reduction in reactor size and reduced emissions. For most ASR incineration schemes, a

flue gas scrubber is still necessary due to the concentration of chlorine and sulfur. The solid wastes from such a process (with ASR as a feedstock) are said to consist of an inert slag that has applications as a building material.

Some investigators believe that incineration processes are the only practical solution for the disposition of certain types of mixed plastic/nonplastic wastes (Ref 3). Composites are an important component in many such types of waste, including ASR. In fact, it is possible that separating such mixed wastes and employing a recycling process designed to reuse the material (rather than just capturing its energy content) is more costly in energy terms than simply producing more of the material in virgin form (Ref 3). If that is true, then incineration processes for recycling of composites-rich mixed plastics do represent an important option, provided the incineration processes themselves are environmentally acceptable.

Thermal Processes for Fiber and Filler Recovery. A recently developed thermal process shows promise for the recovery of both fibers and fillers from thermoset-matrix glass-fiber composites (Ref 9). This process, shown schematically in Fig. 7, uses a low-temperature (450 °C, or 840 °F) fluidized bed reactor to separate fibers and fillers from the resin-matrix materials in shredded composite feedstock. The organic matrix is volatilized in this process. Novel separation techniques are then used to separate fibers from fillers, while a second, higher-temperature (1000 °C, or 1830 °F) reactor combusts the volatilized organic materials. Heat is then recovered from this last reaction and the resulting gaseous emissions are scrubbed and released.

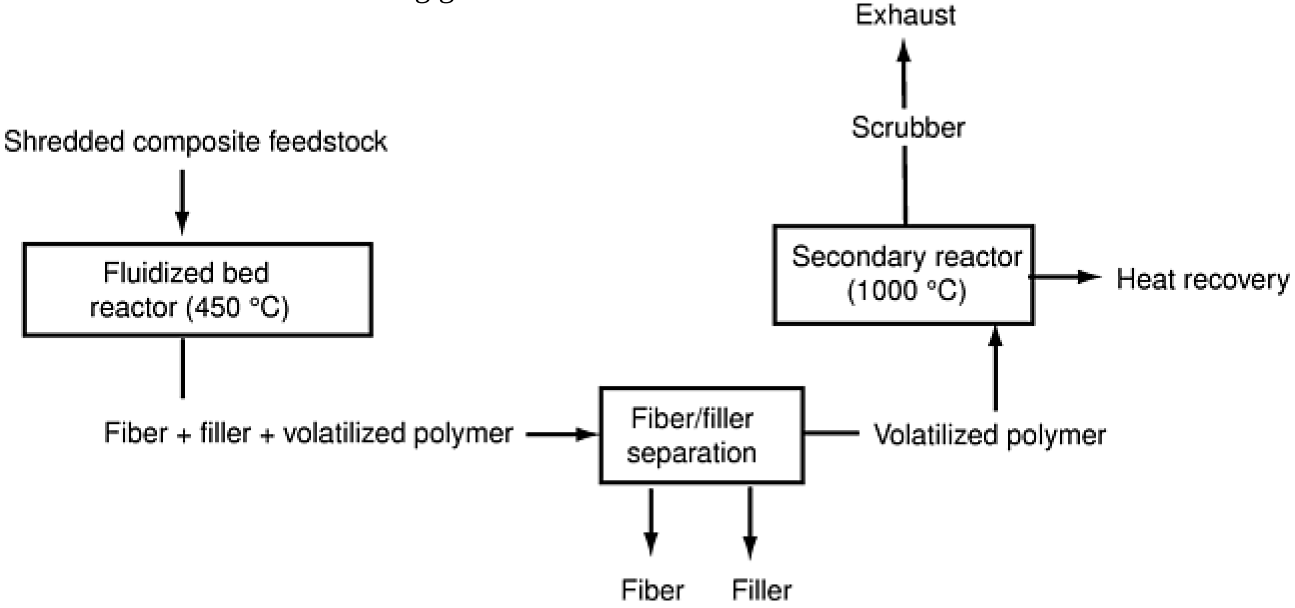

Fig. 7 Schematic of thermal recycling process for thermoset composites. Source: Ref 9

This process has been tested separately on feedstocks of SMC (25% polyester, 22% E- glass, 35% calcium carbonate, and 15% aluminum hydroxide), filament wound pipe (35% polyester, 34% E-glass, and 31% silica filler), and on an E-glass/polyester automobile body sandwich panel (polyurethane foam core with about 15% E-glass and 15% calcium carbonate as a weight percent of the total panel weight). The sandwich panels also contained some molded-in aluminum inserts and were also primed and painted.

Initial experimental results for this process are promising. Fiber yields for the three feedstocks (SMC, pipe, and sandwich panel) were from 40 to 46% of the fiber content of the feedstock. The organic content of separated fiber and filler recyclates varied from 3 to 10%. This was due to incomplete volatilization of the feedstock in the first reactor.

Fibers recovered from this process were recycled into two different kinds of products to investigate the quality of recycled material. Molded components containing 50% recycled fiber content showed no significant change in molding characteristics or mechanical or electrical properties. Incorporation of recycled fibers into veil products resulted in significant reduction in veil strengths. In addition, recycled fibers were incompatible with virgin fibers due to the difference in surface chemistry of the two types of fibers.

An economic analysis of this recycling process showed that, within the assumptions of the model, revenues could exceed expenses for throughputs in excess of 8×10^6 kg (18×10^6 lb) per year. Assumptions included that all scrap would be collected within 80 km (50 miles) of the plant at a cost equivalent to landfill charges in the United Kingdom. Recovered fiber was assumed to retail at 80% of the price of virgin chopped-glass strand, and recovered filler at the same price as calcium carbonate.

Recycling of Thermoplastic-Matrix Composites

Thermoplastic-matrix fiber-reinforced composites have several potential advantages over thermoset-matrix composites. Toughness and damage resistance are among these properties. Because of the fundamental ability of thermoplastics to be reshaped upon heating, there are, at least potentially, some recycling advantages as well. A schematic overview of recycling of thermoplastic composites is shown in Fig. 8. Specific processes and references are shown in Table 2. Because of the nature of thermoplastic polymers, several processes exist for the recycling of thermoplastic-matrix composites that do not exist for thermoset composites. However, it should not be assumed that all the thermoset-matrix recycling processes listed in Table 1 are also feasible options for thermoplastics.

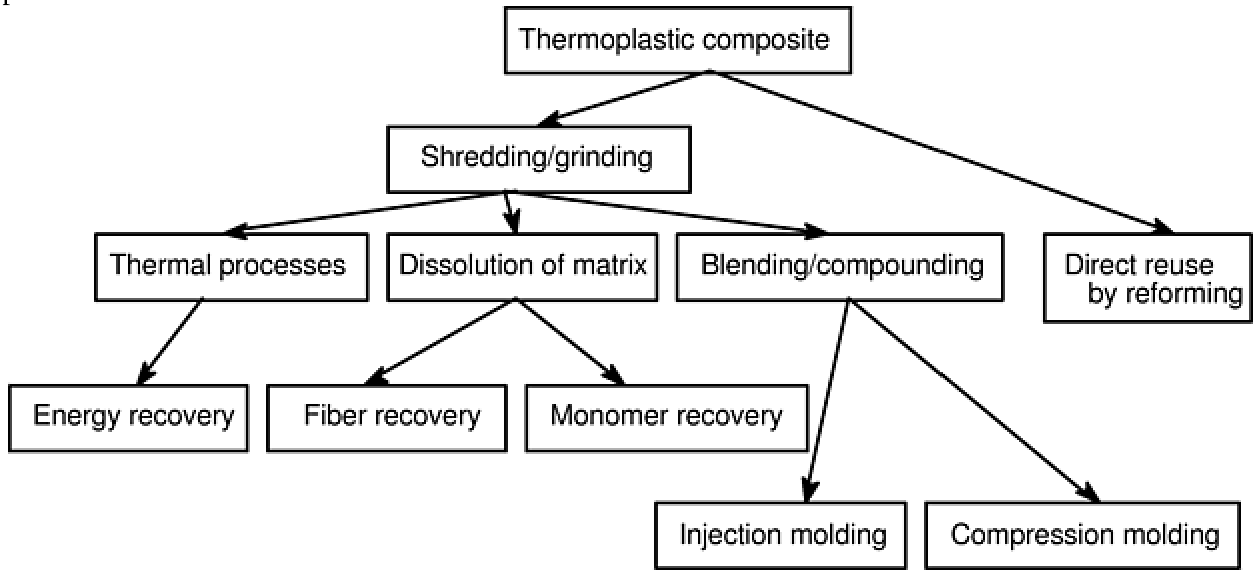

Fig. 8 Thermoplastic composite recycling

Table 2 Thermoplastic composites recycling processes

Process	**Feedstock**	Recycled products
Regrind/compression molding (Ref 17, 18, 19, 20, 21, and 22)	Short- or long-fiber thermoplastic composites	**Flake for use in compression molding**
Regrind/extrusion-injection molding (Ref 17, 18, 19, 20, 21, and 22)	Short- or long-fiber thermoplastic composites	**Injection molding pellets**
Regrind followed by extrusion-compression molding (Ref 19)	**Short- or long-fiber thermoplastic composites**	**Pellets for use in compression molding**

Most thermoplastic composite material recycling investigations have involved variations on the following processing sequence. First, a virgin composite, either short- or continuous-fiber-reinforced, is shredded, cut, and/or ground into relatively small pieces. This regrind is then compounded with virgin unreinforced thermoplastic. The thus-reformulated material is then extruded into either injection or compression molding pellets. Injection or compression molded parts are then produced and their properties compared to virgin composites of similar composition.

Regrinding Thermoplastic Composites. The regrinding process has been investigated by many researchers. Schinner and coworkers compared hammer mills to knife-like cutters for reducing continuous-carbon-fiber-reinforced polyetheretherketone (PEEK) laminates to pieces small enough for recompounding and recycling (Ref 17). Before entering the hammer or cutter mills, large laminates had to be shredded to thumb-size pieces. Analysis of the resulting ground composites showed that the cutter mills resulted in a more uniform distribution of fiber lengths, with over 60% of the fibers being 0.5 mm (0.02 in.) or longer. Hammer milling resulted in over

80% of the fibers being shorter than 0.5 mm (0.02 in.). The researchers noted a high wear rate on the cutter blades as a result of chopping the carbon fibers. Hammer mill components seemed to hold up better.

Compounding/Blending and Reprocessing. Schinner and coworkers blended reground PEEK with virgin PEEK resin to produce injection molding pellets. This technique was found to be satisfactory for fiber contents from 30 to 50 wt%. Tensile strength, tensile modulus, and elongation at break were found to compare favorably with virgin PEEK/carbon injection molding materials with similar fiber contents.

Cutter-mill reground PEEK was also reprocessed directly by press molding, thus avoiding the recompounding step. As expected, properties were reduced from those of the continuous-fiber- reinforced virgin PEEK laminates. However, the mechanical properties of the press-molded recycled laminates were both consistent and useful and exceeded the properties of comparable virgin injection molded materials.

Other researchers have considered the effects of service life on the properties of recycled thermoplastic composites. Van Lochem and coworkers investigated various types of artificial aging designed to simulate ten years service life (Ref 18). The materials evaluated were injection molded polyphenylene sulfide (PPS) and polybutylene terephthalate (PBT) reinforced with 30 or 40 wt% glass fibers. Tensile bars of virgin material were injection molded and then aged in a variety of environments, including elevated temperatures, high humidity, and high and low pH. Aged materials were physically and mechanically characterized, and then the composites were reground, blended with varying amounts of virgin material, and remolded.

The results of this research were mixed. The aged-then-recycled PPS composites generally performed better than the PBT composites, particularly when a fiber-matrix coupling agent was blended with the material during compounding. The PBT composites were deemed unsuitable for use in applications for which the virgin material was intended.

Chu and Sullivan investigated the recyclability of several different glass-reinforced thermoplastic-matrix composites (Ref 19, 20). The composites investigated included a woven glass fabric-reinforced polycarbonate and a continuous strand mat glass-reinforced PBT. The virgin materials were ground in a cutting-type granulator and prepared for recycling. Some of the reground materials were treated with various types of silane coupling agents to assess the need to improve fiber-matrix interface in the recycled materials. Reprocessing was then accomplished using either injection molding, compression molding, or a hybrid process called extrusion-compression molding. This latter process was developed to improve the homogeneity of the final compression molded product, but without the attendant reduction in molecular weight and fiber length associated with injection molding. Results showed that the silane coupling agents improved the properties of the recycled materials. The properties of the recycled PBT composite were generally better than that of a virgin 35 wt% Valox (General Electric Company) reference material, as shown in Table 3, but inferior to those of the continuous-fiber virgin material.

Table 3 Comparison of properties of recycled PBT composites to virgin materials

Material	**Reprocessing technique**	**Tensile strength**		**Tensile modulus**		**Maximum**	Notched Izod impact strength	
		MPa	**ksi**	**GPa**	**10^6 psi**	**elongation, %**	**J/m**	ft · lbf/ft
Virgin continuous swirl mat (35 wt% glass)	…	103	15	9.0	1.3	2.1	700	**159**
Virgin Valox (35 wt %)	Injection molded	126.4 ± 2.6	18.3 ± 0.4	10.2 ± 0.8	1.5 ± 0.12	3.5 ± 0.4	86.1 ± 5.2	**19.6 ± 1.2**
Recycled with silane(a)	…	131.9 ± 2.3	19.1 ± 0.3	10.2 ± 0.9	1.5 ± 0.13	1.8 ± 0.1	115.2 ± 9.0	**26.2 ± 2.0**
Recycled with silane(a)	Extrusion-compression molded	97.2 ± 6.5	14.1 ± 0.9	12.0 ± 1.9	1.7 ± 0.28	1.3 ± 0.2	105.9 ± 5.4	**24.1 ± 1.2**

Steenkamer and Sullivan investigated the recyclability of a liquid molded cyclic thermoplastic composite (Ref 21). The material investigated was a novel cyclic PBT. This polymer may be prepared as a low-molecular-weight, relatively low-viscosity liquid that can be processed by one of the liquid molding processes (resin transfer molding, etc.). Once inside the mold, the resin polymerizes into PBT in a proprietary process. Recyclability was one of the strong driving forces behind the development of this material by General Electric Company and Ford. Liquid molded panels with glass-fabric reinforcement were prepared and then reprocessed by grinding/compounding/injection molding. The properties of the recycled material compared very favorably to those of a virgin commercial PBT injection molding material with the same glass content.

Ramakrishna and coworkers also recycled continuous-fiber carbon/PEEK composites by shredding, grinding in a cutting mill, and then compression molding the resulting ground composite. The mechanical properties of the recycled moldings were once again found to be greatly reduced from those of the virgin continuous-fiber laminates, but were nonetheless considered to be useful (Ref 22).

Recycling and Disposal of Polymer-Matrix Composites

John M. Henshaw, The University of Tulsa

Properties of Recycled Composite Fibers

Allred and coworkers investigated the properties of carbon fibers reclaimed from a chemical recycling process that had been applied to uncured, out-of-date carbon/epoxy unidirectional prepreg and cured carbon fabric/epoxy factory scrap (Ref 23). Single-fiber mechanical tests were performed on fibers reclaimed from the cured scrap and compared to virgin fibers of the same type. The reclaimed fibers showed about a 10% reduction in tensile load capacity, with a similar Weibull statistical distribution as the virgin fibers. The investigators attribute most of the fiber degradation to other factors in the life cycle of the fiber-weaving, molding, part fabrication, and shredding prior to the reclaiming process—and not to the reclaiming process itself. For example, they cite a typical 5 to 10% strength reduction due to weaving alone.

The same investigators also analyzed the surface chemistry of reclaimed AS4 carbon fibers and compared it to virgin AS4. No significant differences in surface chemistry were noted. This is important if the fibers are to be reused in composites applications, where fiber/matrix adhesion is critical.

Kennerley and coworkers (Ref 24) investigated the properties of glass fibers reclaimed through the use of thermal processes for fiber and filler recovery similar to those described earlier (Ref 9). They found that the strength of single glass fibers subjected to 450 °C (840 °F) was only 44% of that of untreated fibers. Treatment at 650 °C (1200 °F) reduced residual strength to only 5% of the untreated value. Longer times at the various temperatures resulted in greater strength loss. Fiber modulus was relatively unaffected by the various treatments. Reclaimed glass fibers were successfully used in semistructural molded products and veils (Ref 24).

Finally, Steenkamer and Sullivan investigated the substitution of recycled A-glass fibers for E- glass in composite applications (Ref 25). A-glass in the form of bulk glass cullet (predominately broken bottles, jars, and car windows) is an industrial commodity. These researchers investigated the use of fiber spun from A-glass and then incorporated in polymer-matrix composites. A- glass has inferior mechanical properties compared to E-glass. For example, the elastic modulus of A-glass is 66 ± 0.5 GPa (9.6 ± 0.007 × 10^6 psi), while that of E-glass is 78 ± 0.8 GPa (11.3 ± 0.12 × 10^6 psi). The strength of A-glass is 863 ± 301 MPa (125 ± 44 ksi), while that of E-glass is 1261 ± 517 MPa (183 ± 75 ksi) . These property differences are reflected in the composites that are produced from the two types of fibers. The study concluded that A-glass fibers produced from recycled material are capable of producing acceptable composites with a predictable and somewhat lower performance than their E-glass counterparts. It was further concluded that the use of recycled A-glass fibers could thus increase "recycled content" in products, such as automobiles. Recycled content can be an important marketing factor for environmentally conscious consumers and could potentially be the subject of governmental regulation.

Recycling and Disposal of Metal-Matrix Composites

David Weiss, Eck Industries Inc.

Introduction

THE NEED TO RECYCLE metal-matrix composites (MMCs) to reduce cost and meet environmental goals becomes more important as these materials are used increasingly in higher-volume applications, including the automobile industry. The worldwide market of MMCs reached 2.5 million kg in 1999 (Ref 1). Metal matrix materials can have an initial cost of two to more than 100 times the cost of the base alloy. The ability to recycle into a usable metal matrix composite therefore becomes a significant overall cost driver for their use. Most of the significant tonnage in metal matrix composites is done in aluminum-base materials, and the most progress in recycling and recovery has been done in the aluminum matrix composites as well.

1. "Metal Matrix Composites in the 21st Century: Markets and Opportunities," Business Communications Co., Inc., Norwalk, CT, 1999

Recycling of Aluminum MMCs

Aluminum matrix composites typically consist of an aluminum matrix and a high-performance second phase. In the most common production alloys, a hard second phase such as silicon carbide (SiC) or aluminum oxide (Al_2O_3) is used. Other reinforcements include graphite, boron, boron carbide, fly ash, and titanium carbide. The alloys can be discontinuously reinforced with particles and whiskers or continuously reinforced with fibers and filaments or compacted preforms. The type and method of reinforcement influences the ability of the alloys to be recycled for reuse. The manufacturing methods used to produce the composite shape and subsequent use and environmental exposure also impact recyclability. Since the cost of metal matrix composites is greater than that

of the matrix alloy, it is desirable to recycle for direct reuse whenever possible. In most cases it is possible to recover at minimum the matrix alloy for reuse or sale.

Discontinuous SiC Reinforced Aluminum MMCs. Recycling procedures will vary with product form and manufacturing methods. The efficiency of the recycling effort in terms of product loss and quality of the final product can be quite variable. This variability impacts final product cost through material and quality costs. Manufacturing with recycling in mind reduces that variability.

Die-cast scrap that is produced as a by-product of the casting process is usually remelted directly without further processing. Experiments (Ref 2) have shown that the type and quantity of die and plunger lubrication affect the recovery rates of die-cast remelt. Heavy, oil-based lubricants that are trapped on or in the castings can reduce recovery rates to 80%. Castings made with water-based graphite lubricants have recovery rates in excess of 95%. Castings that show signs of surface grease or lubricant can be degreased by heating to 540 °C (1000 °F) for 6 h prior to remelting.

Foundry Scrap. The amount of work required to yield fully reusable material depends on the type and condition of the scrap. Foundry scrap, gates, risers, and clean, uncoated parts can be grit or shot blasted, blown clean, and melted with new ingot. Since the production of castings often creates some oxides in the finished product, excessive amounts of recycled materials may contribute to excessive oxides in the melt, reducing fluidity and part integrity. Good casting techniques direct oxides into the gate and riser system. Therefore, a more conservative approach would be to process gating separately with the fluxing procedure outlined below. Extra cleaning is required as the level of SiC in the alloy increases, since even low levels of oxides in alloys containing 20% or more volume content of SiC significantly reduces the ability to cast the product successfully (Fig. 1). Critical castings requiring very good mechanical properties; thin wall parts and parts cast with 30% SiC require the use of either all new material or material processed using dry argon cleaning.

Fig. 1 Casting misrun due to low fluidity caused by presence of oxides in SiC/Al matrix MMC

Dirty Scrap, Gates, and Risers. Dirty scrap can be recovered using a fluxing and degassing procedure originally developed by Duralcan USA (Ref 3). This procedure uses a diffuser wand to introduce dry argon into the bath of molten metal (Fig. 2). The detailed procedure is as follows:

1. Mix the composite for approximately 20 min at a temperature of 700 ° C (1290 °F).
2. Preheat the end of the diffuser wand to ensure that it is dry. Diffuser wands are typically graphite or silica.
3. Begin a flow of dry argon (less than 3 ppm water) through the diffuser wand at approximately 0.14 m^3/h (5 ft^3/h). With the mixing impeller off, slowly immerse the diffuser wand in the composite bath to a level at or slightly below the end of the impeller, letting the argon bubble through the composite (Fig. 3).
4. Restart the mixing impeller and increase the argon flow rate through the wand to the flow rate of the degassing curve shown in Fig. 4. During the degassing the dross should be skimmed and discarded.
5. When dross formation ceases, remove the wand and stop the gas flow.

6. Allow the molten composite to sit for 40 to 60 min without mixing to allow any remaining entrapped gas to rise to the surface.
7. Manually stir the SiC from the bottom of the furnace, start the stirrer, and mix for at least 10 min before casting.

Very dirty scrap, scrap containing ceramic filters, or scrap that no longer contains the proper amount of reinforcement can be recovered for its aluminum content in the foundry or scrap yard. Specific procedures for aluminum recovery are discussed in the section "Continuous Reinforced Aluminum MMCs" in this article.

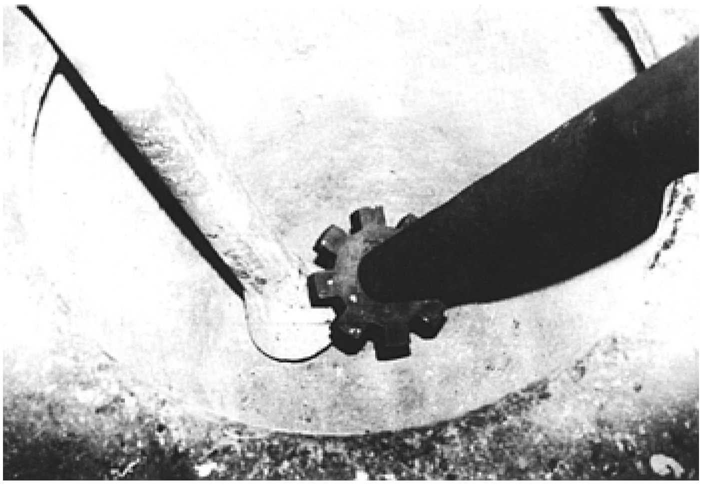

Fig. 2 Molten SiC/Al-matrix MMC fluxed and degassed by introducing dry argon gas via diffuser wand

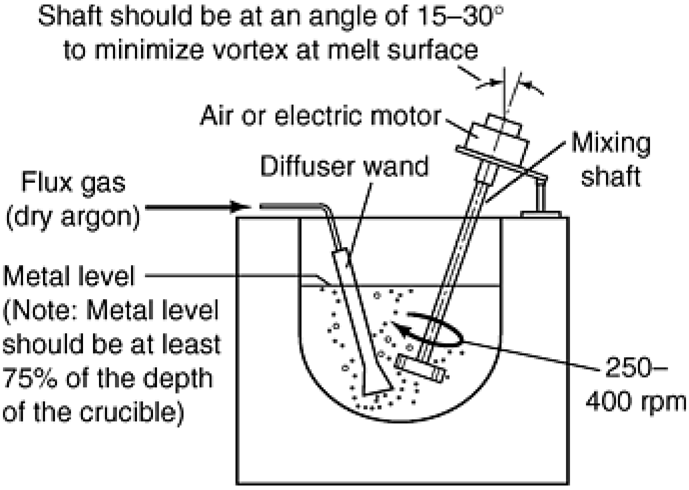

Fig. 3 Orientation of mechanical stirring device and degassing tube for crucible-style furnace

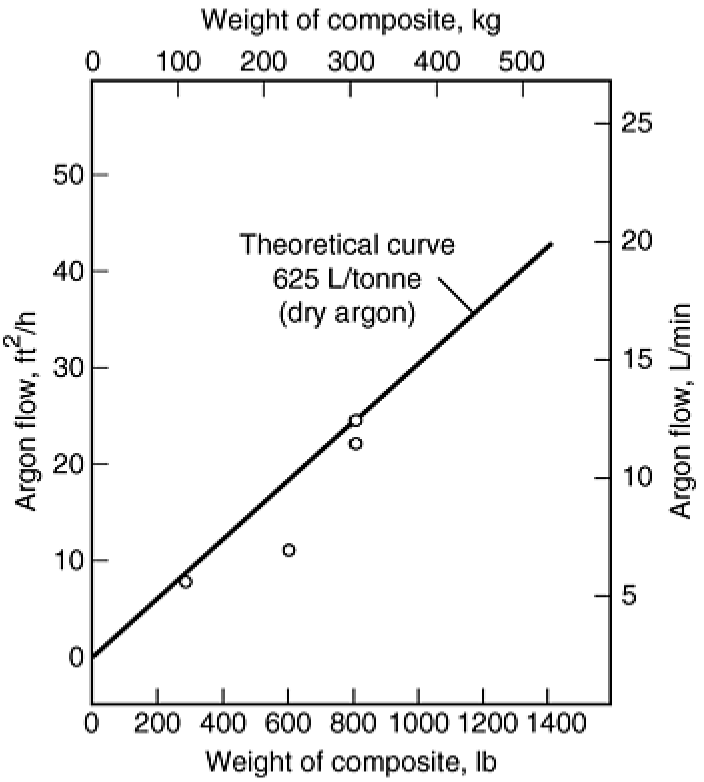

Fig. 4 Degassing curve based on degassing for 20 min

The techniques described here for discontinuous SiC-reinforced aluminum MMCs are generally useful for most gravity and die-castable particulate reinforced aluminum-matrix composites. Alumina foundry composites may experience dewetting during the recycling procedure and are generally recycled to recover the aluminum alloy only.

Continuous Reinforced Aluminum MMCs

Aluminum alloys can be continuously reinforced with fibers or filaments of graphite, boron, SiC, and Al_2O_3. In order to separate these reinforcements from the matrix aluminum, a material must be used that has a smaller free energy than that of the matrix material when the material contacts the reinforcement (Ref 4). In the molten state, this material infiltrates into the interface and if the material is not soluble in the matrix metal, separation of the reinforcement from the matrix metal will begin. Various salts and salt combinations that are typically used for removing oxides from molten aluminum have lower surface energies than aluminum:

Material	Surface energy, mJ/m^{-2}
Aluminum (Al)	**860–900**
Sodium chloride (NaCl)	**190.8**
Potassium chloride (KCl)	**155.2**
Barium chloride ($BaCl_2$)	**162.6**

Sodium (Na)	**151**
Potassium (K)	**86**

Experiments conducted by Nishida et al. (Ref 5) using a $NaCl \cdot KCl \cdot Na_2SiF_6$ (ratio 40:40:20) showed separation rates of matrix material from alumina short fibers of 50 to 60% by adding flux during agitation of the molten metal. Separation rates of only 20% were found when recovering aluminum from 0.6 μm SiC whiskers. This type of flux gives off chlorine and fluorine gas as the flux decomposes in molten aluminum. These gases serve an important role in pushing the molten matrix from the composite. It has long been recognized that fluxing with chlorine gas will effectively strip the SiC from particulate reinforced composite. Other gases have been used with mixed effectiveness to remove particulate reinforcements, although their uses for recycling continuous reinforced aluminum MMCs have not been documented.

Aluminum that has had the reinforcement phase removed is generally filtered to remove oxides and traces of reinforcement, checked for chemistry, and recovered in ingot form. Reinforcement phases are generally not reused, but are benign waste products that can be disposed of in a landfill.

Aluminum MMCs Containing Preforms. Preforms can be considered a special type of continuous reinforcement. One of the advantages to the use of preforms is the possibility of selective reinforcement of a component. Preforms are primarily ceramic, but may contain metallic reinforcement separately or in combination with the ceramic. Recycling can be done in two stages, with the reinforcement area sawed or otherwise removed from the component followed by recovery of the aluminum trapped in the preform. If the area of the reinforcement cannot be determined precisely, it may be possible to melt the surrounding product from it using a dry- hearth-type furnace (Fig. 5). A dry hearth furnace has a separate melting chamber connected to the bath by a slanted channel. The aluminum will melt and run down the channel, leaving the preform in the melting chamber. The preforms can later be removed by using a tool to pull them from the chamber or waiting to remove them until after the furnace cools.

Quality Issues

Most recycling of metal matrix composites occurs during manufacture of the products, typically as a way to recover gates, risers, stubs, or scrap. Material control at the point of manufacturing makes alloy identification and separation easy to maintain. However, repeated melting of MMCs or repeated melting of aluminum recovered from MMCs can change the chemistry of the base alloy as well as the amount and distribution of reinforcement.

Base alloy chemistry should be checked using optical emission spectroscopy or similar technique. Magnesium, an important alloying element in aluminum casting alloys, is lost through successive remeltings and alloy cleaning procedures. Iron may be picked up through repeated contact with skimming and stirring devices and furnace cleaning tools. Materials may be inadvertently mixed that will cause the alloys to be out of specification.

When recycling composite alloys for direct reuse, sampling of the base alloy can be done in a number of different ways. The reinforcement phase can be allowed to settle or float, and a base alloy sample can be pulled from the segregated melt, which is then checked using spectrographic techniques. For the SiC reinforced composites, techniques have been developed (Ref 3) to check both particle loading and elemental chemistry using optical emission spectroscopy with a spectrometer equipped with a carbon line.

Repeated remelting of particulate reinforced composites can lead to gradual loss of particles from particle settling or particle removal by melt cleaning methods. Particle loading can be determined through wet chemistry, optical emission spectroscopy for some alloys, or ultrasonic testing.

Properties of Recycled Aluminum MMCs

The recycling techniques developed for aluminum MMCs are meant to ensure adequate mechanical properties for recycled materials. However, repeated recycling using the best techniques can eventually add dispersed oxides that may affect the tensile properties of the materials. Weiss et al. (Ref 6) have demonstrated the correlation between oxides in the microstructure and mechanical properties. Mechanical properties of permanent mold test bars produced from virgin material versus a melt prepared from 100% recycled scrap castings (Ref 7) are shown in Table 1. Generally, a mixture of 50% new ingot and 50% recycled materials will yield acceptable mechanical properties under most conditions.

Table 1 Property comparison for castings made of virgin and recycled material

Al MMC type F3S.20S-T71	**Tensile strength**		Yield strength		
	MPa	**ksi**	**MPa**	**ksi**	Elongation, %
100% virgin ingot	241–262	35–38	200–214	29–31	**1–2**
100% remelt castings	**220–241**	**32–35**	**200–214**	**29–31**	**1–2**

Disposal of Aluminum MMCs

Good particulate reinforced composite material or aluminum recovered from composite materials is often directly reused. Aluminum that has been stripped from the reinforcement can also be sold to secondary aluminum processors for alloying and subsequent resale. Particulate, continuous reinforcements and preforms removed from the aluminum are not generally reused and are typically sent to a landfill. Commonly used reinforcements do not present an environmental hazard. Often these reinforcements are mixed with other rich dross and sent to secondary reprocessors for further removal and recovery of the aluminum.

Recycling and Disposal of Metal-Matrix Composites

David Weiss, Eck Industries Inc.

Recycling Other MMCs

Other ferrous and nonferrous metals have been used as matrix materials for a wide range of metal matrix composite materials. A partial list of these materials includes:

Reinforcement	Matrix alloys
Boron fiber	**Aluminum, titanium**
Silicon carbide fiber	**Aluminum, titanium, magnesium, copper**
Graphite Fiber	**Aluminum, magnesium**
Aluminum oxide fiber	**Aluminum, magnesium**
Tungsten fiber	**Nickel, cobalt, iron**

Generally, recycling of these materials is based on recovery of the matrix materials and disposal of the reinforcement. Little information has been documented on the particular techniques used with titanium, magnesium, copper, superalloy, and iron-base composites. Filtering, exploitation of density differences, and chemical separation techniques have been discussed as possible techniques. Chemical composition of the base alloy needs to be verified since some reinforcements and reinforcement coating can cause a change to base alloy chemistry.

Introduction to Applications

Tia Benson Tolle, Materials and Manufacturing Directorate, Air Force Research Laboratory; Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.

Introduction

APPLICATIONS of advanced composite materials have demonstrated significant system- level benefits over conventional materials to a point where they are now accepted engineering materials. This Section highlights selected applications of polymer-matrix composites (PMCs), metal-matrix composites (MMCs), and ceramic-matrix composites (CMCs). The focus is on important applications that are representative of the current state of practice.

Introduction to Applications

Tia Benson Tolle, Materials and Manufacturing Directorate, Air Force Research Laboratory; Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.

Advanced Polymer-Matrix Composites

Although the basic concepts of composite materials were understood from a technical sense early on, it was in the 1940s that glass-reinforced plastics came into existence as an industrial material. Their potential benefits for structural applications were recognized in 1941 when the first task force was initiated at Wright-Patterson Air Force Base to examine fiber-reinforced plastics for aircraft applications. In 1943, the first reinforced composite airframe structures were demonstrated at the Wright-Patterson Air Force Base Structures and Materials Laboratory, where the aft fuselage of the Vultee BT-15 trainer aircraft was designed and fabricated in composites, based on development and analysis. Testing proved the composite structure to be approximately 50% stronger than a metallic or wooden construction. Since then, advanced composite materials have found many applications in aeronautical and spacecraft structures. Their inherent characteristics offered new capabilities and dramatic improvements to many aerospace structures and ensured their widespread application in performance-driven systems. Sports and recreation equipment also exploited the characteristics of composites. Glass-reinforced PMCs have found wide use in marine applications since the late 1940s and have begun to migrate into automotive applications.

Today, advanced composites continue to be extensively used in aerospace applications and are becoming increasingly utilized in non-aerospace applications such as infrastructure and automotive structures. Although advanced composites are not yet a commodity material, they have reached the level of an accepted specialty engineering material. New application areas such as infrastructure offer the opportunity for composites to become more of a commodity material with widespread and diverse usage. These applications are based on a foundation of research, development, and experience that spans over 50 years. Advanced composite technologies continue to be developed, and new and significant applications can be envisioned for the future, based not only on new markets, but also on the continual understanding of new materials and processes and associated capabilities.

Tia Benson Tolle, Materials and Manufacturing Directorate, Air Force Research Laboratory; Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.

Metal-Matrix Composites

Advanced composites based on metallic matrices have a somewhat more recent history than PMCs, yet the opportunities look no less promising. The first MMCs were developed in the 1970s for high-performance applications using continuous fibers and whiskers for reinforcement. Specialty applications in the space shuttle, Hubble telescope, and other systems have been seen. Increasing emphasis on lower-cost composite systems was driven by the interest of the automotive industry in cost-effective performance. Aluminum-matrix composites employing ceramic-particle reinforcement and amenable to inexpensive net shape processes such as casting and extrusion have led to the application of these materials in automotive brakes, drive shafts, and cylinder liners. The recent recognition that additions of ceramic reinforcement enable tailoring of physical as well as mechanical properties of MMCs has led to increasingly widespread use of these materials in electronic-packaging and thermal-management applications. Recent market forecasts for MMC use suggest the prospect for accelerating growth as the materials are more widely understood and costs decrease, suggesting a bright future for this class of materials.

Introduction to Applications

Tia Benson Tolle, Materials and Manufacturing Directorate, Air Force Research Laboratory; Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.

Ceramic-Matrix Composites

Current applications for CMCs include cutting tool inserts and other wear-resistant parts, aerospace and military applications, and various industrial applications, including engines and energy-related applications. Advanced continuous-fiber CMCs are now emerging from laboratories and show potential for high-performance applications. Currently these materials are considered to be expensive. However, their high-temperature stability, corrosion resistance, and toughness make continuous-fiber CMCs attractive for a wide range of potential applications in both the aerospace and industrial sectors.

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

Introduction

COMPOSITE MATERIALS have a history that parallels that of the automotive industry since the 1940s. Henry Ford first demonstrated the “soybean” car in 1941 when he swung an axe against it during a media demonstration (Fig. 1). The body panels were constructed of cellulose-fiber reinforcement in a soybean-resin matrix. The ability for composites to withstand impact loads was confirmed, curb weight was reduced by 900 kg (2000 lb), and the opportunity to use environmentally friendly natural fiber technologies was shown (Ref 1). The ingenious design and manufacture of composites in automotive and aerospace in parallel was shown when

Convair built the Flying Car in 1946 (Fig. 2). Six of these auto-aerospace vehicles were manufactured with a glass-epoxy structural composite body and chassis (Ref 1). Composites were subsequently used for various prototype automotive vehicles. Perhaps the most famous use of composites in the automotive industry was the use of fiberglass reinforced composites for the body panels of the Chevrolet Corvette, starting in 1953 (Fig. 3).

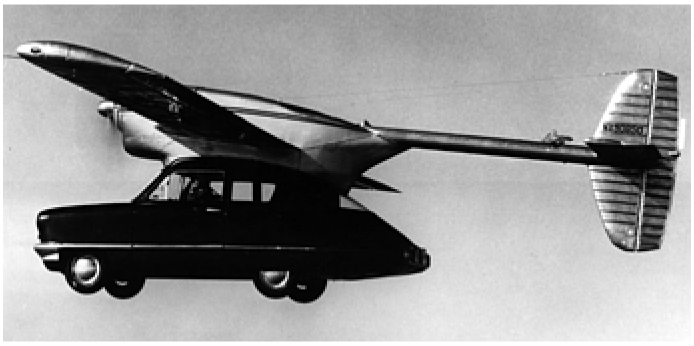

Fig. 2 Convair Flying Car. Courtesy of W. Brandt Goldsworthy & Associates

Fig. 3 Chevrolet Corvette. Courtesy of W. Brandt Goldsworthy & Associates

Today, structural polymer-matrix composites (PMCs) are seen as a material critical to achieving the goals of an optimally designed car that uses a systems engineering approach in a simultaneous engineering environment. The energy crises of the 1970s and 1980s, the implementation of corporate average fuel economy regulations in the United States for domestically produced vehicles, and the high rate of taxation on automotive fuels in most countries has resulted in a focus on fuel economy. Improvements in fuel economy are most drastically realized through improvements in the efficiency of the automotive engine and powertrain reduction in weight, and through increased aerodynamic efficiency. This has resulted in an extensive use of emission control systems and the now-familiar look of aerodynamically sleek automobiles. Recently published reports by the United States Cooperative Automotive Research (USCAR) alliance have shown that a 30% mass reduction in the automobile can potentially increase fuel economy by 30%. The ripest areas for mass reduction have been shown to be the chassis area—which includes the suspension, driveline, braking, and steering components—and the body and underbody structural systems. The high strength-to-mass ratio of composite materials makes them a candidate materials system for successfully achieving mass reduction in the automobile. Because composite materials have different inherent properties and different manufacturing methods than the traditional materials used for automotive applications, pure materials substitution into metal-based designs will not allow an automotive engineer to realize the advantages of the high strength-to-mass ratio of composites. A cost penalty also may be incurred, which is one principal reason why composites have not yet become a dominant material in the automotive industry. Hence, design practices that focus on optimization of the material and the system design will allow structural composites to be successfully and cost-effectively implemented on automobiles, pick-up trucks, and sport utility vehicles.

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

Automotive Composites

Composite materials are those with any two or more distinct and identifiable constituent materials that differ in form or composition and whose combination results in properties that are superior to those of the constituent materials. When the composite material is engineered and optimized for structural applications, the constituent materials are typically a high-strength and an intermediate-to-high apparent modulus, high aspect ratio fiber

that is combined with a semicoherent or coherent matrix that usually serves as a binder. Typically, composites are engineered to withstand primary static and dynamic structural requirements and environmental factors. However, in automotive applications, composites are also engineered to satisfy appearance requirements, secondary structural needs (i.e., reduction of noise, vibration for harshness for structures such as body panels and hoods), high- or low-volume manufacturing and process drivers, cost, and crash safety. Secondary structural applications in many cases tend to trade off structural properties for appearance or high-volume, low-cycle manufacturing. Hence, these types of composites are considered as semistructural. The general properties of thermoplastic and thermoset composites are listed in Table 1. Multifunctional composites are those which take advantage of other nonstructural properties, such as conductivity, health monitoring, and sensing materials. These properties are underused in today's automobile, but will be important for future applications. The design and manufacture issues that are associated with PMCs are addressed subsequently.

Table 1 General characteristics of thermoplastic and thermoset composites

Property	Thermoplastic composites	Thermoset composites
Fiber content	Low to medium	Medium to high
Fiber type	Continuous and discontinuous	Continuous and discontinuous
Solvent resistance	Low	High
Heat resistance	Low to medium	Low to high
Molding time	Fast (<5 min)	Slow (typically $\frac{1}{2}$ to 4 h)
Molding pressure	High (>14 bar, or 1400 kPa)	Low (1 bar–7 bar, or 100–700 kPa)
Material cost	Low to medium	Low to high
Safety/handling	Excellent	Good
Storage life	Indefinite	Good (6–24 months with refrigeration)

Source: Ref 2

Design Drivers

Composites are generally regarded as structural materials that are suitable for stiffness-critical designs and have a great potential for automotive applications. One design driver for which PMCs are useful is mass reduction and distribution. Mass reduction of the total vehicle system helps to increase fuel economy. This is especially true of rotating unsprung mass at the hub, wheel, and brake system. The structural parts of the automobile, the body and the chassis, are also mass sensitive for vehicle dynamics and performance. The reduction of unsprung mass, or the mass that is not carried by the suspension system, improves vehicle performance much more than when mass is reduced for sprung, or suspended, mass. Hence, mass reduction of the chassis, especially the braking, and suspension systems, affects vehicle dynamics more favorably than the reduction of body mass. Additionally, the mass distribution from front to rear and side to side also greatly affects vehicle dynamics. If mass reduction results in an unbalanced chassis, then the performance and the feel of the vehicle are affected, despite any overall reduction of vehicle mass. Hence, fuel economy and vehicle dynamics are the critical drivers for lean mass automotive designs.

Noise, Vibration, and Harshness (NVH). Polymer-matrix composites also have the inherent advantage of increasing the natural frequencies of NVH produced in a vehicle while it is being driven. The high stiffness-to-mass ratios and damping characteristics of PMCs raise these frequencies to levels that are indistinguishable to the driver and passenger, hence increasing customer satisfaction. The use of PMCs eliminates the need for the addition of bushings, other damping materials, and spot welds that are added solely to increase structural stiffness and reduce noise transmission. Hence, total vehicle mass and cost is reduced.

Body and Chassis. Structural PMCs are applied mainly to the body and chassis areas. These areas of the automobile must carry internal and external static and dynamic loads. Hence, PMC designs based on rules of mixture and generalized Hooke's law can be used to provide globally—and locally—optimized strength and stiffness properties for the structural needs of the body and chassis. This design tailorability is one of the greatest advantages for the use of PMCs with automotive applications, but also is one of the greatest challenges.

Process and Materials Property Constraints. The advantages of structural composites can only be realized if process limitations are understood and if materials properties and differing design principles receive proper attention. Engineers who have designed applications using traditional linear, elastic, homogeneous, and

isotropic materials must remember that simple materials substitution is not sufficient to ensure a successful product. Systems engineering principles and discipline must be followed in a simultaneous engineering environment. The specific needs of an individual design should drive the selection of the optimal material and process, as opposed to using a specific materials system to meet all design requirements. A decision flow chart that shows this is in Fig. 4.

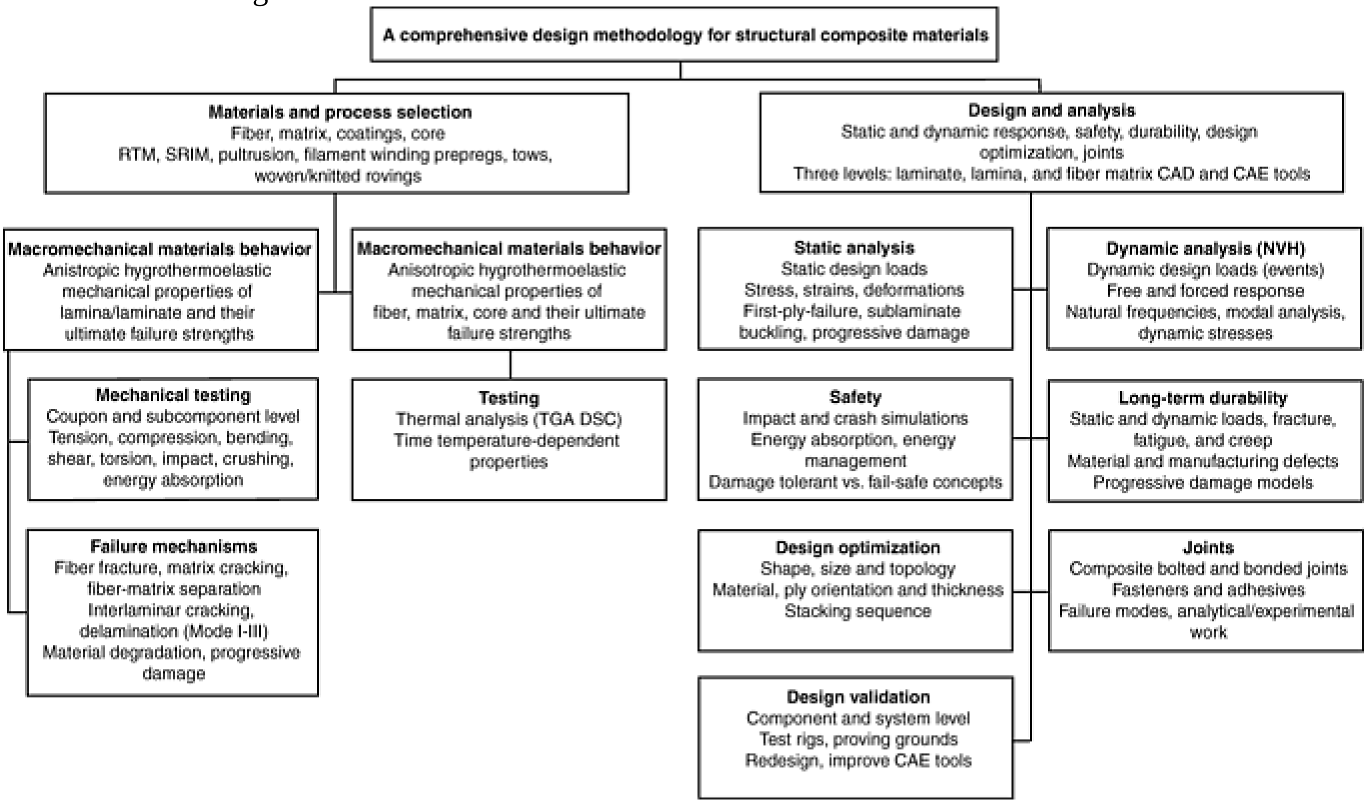

Fig. 4 Design methodology for automotive composite structures. RTM, resin transfer molding; SRIM, structural reaction injection molding; CAD, computer-aided design; CAE, computer-aided engineering; TGA, thermogravimetric analysis; DSC, differential scanning calorimetry

Safety and Reliability. Automobiles are consumer products that are regulated for safety and fuel economy. One of the most critical design safety drivers is the performance of the vehicle during a crash. The automobile must meet vehicle dynamic and performance expectations that differentiate it from its competition. The reliability and service costs associated with a particular automotive product are also quite important.

Design Optimization. The automotive industry must also develop optimized designs that push the processing technology envelope, as opposed to process-driven designs for which only semistructural materials may be used. The automotive industry has already successfully implemented the use of computer-aided design (CAD) and computer-aided engineering (CAE) tools for design and process optimization. Design CAE tools have been limited to linear, elastic, homogeneous, and isotropic materials assumptions. These tools have been quite effective in design optimization and finite-element analysis (FEA) studies, but the more complex models that are required for composite material design and optimization are just now becoming commercially available. Even more critical are the safety aspects of automotive designs. Crash computer simulation models have successfully been implemented in the automotive design community for metal designs, but are still in development for composites. The Automotive Composites Consortium group of USCAR has been making significant progress in this area.

Previous materials substitution successes and failures must be documented to lay the foundation for product improvements. Sometimes, structurally optimized properties typically require trade-offs with appearance requirements.

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

Design Challenges and Constraints

Polymer-matrix composites have been shown to have great potential for use in automotive applications; but their full range of potential advantages is not well understood in the automotive design community. One of the most common mistakes made is *direct materials substitution*, where a component that was originally designed for another materials system (i.e., steel, cast iron) is manufactured with PMCs without any changes. This is a poor approach because the design advantages of the PMC are underutilized, thus increasing the cost of a part that is using an already costly material. PMCs permit the designer to consolidate parts.

Structural and Appearance Requirements. Automotive applications have both structural and appearance requirements that have tended to change with time. High quality surface appearance on secondary structures, such as hoods and body panels, is required.

Automotive applications have stringent design and appearance requirements that are, at times, in conflict with each other. Fenders and fascias are primarily appearance parts, with only local strength and stiffness requirements for attachments and oil-canning resistance. Load floors and floor pans are structural, with only minor appearance needs. Hoods, roofs, and doors, however, contribute in varying degrees to the overall vehicle structure and must provide the same quality appearance as fenders and fascias.

Structural requirements can be subdivided into primary and secondary requirements. The primary structure reacts to major loads, such as static and dynamic external loads and component loads, while the secondary structure supplements the primary one by addressing local requirements, such as surface appearance, sealing, and carrying minor components. The secondary structure can act to stabilize the primary structure for an optimized overall design. Hence, if the load paths of the body and chassis structure are modeled with FEA and well understood, the anisotropic properties of continuous or long fiber PMCs can be used to optimize strength and modulus of the PMC material design.

In the automotive industry, the application of structural composites has been mostly limited to secondary structures and appearance panels. For example, doors contribute to crashworthiness, but are largely secondary structures. Aerospace and aircraft applications are often considerably different from automotive applications in that the exterior surfaces are often an integral part of the primary structure of the product. The fact that structural composites have been used extensively for both primary and secondary structures in aerospace applications is due to the low production rates and an emphasis on the reduction of weight as opposed to cost.

Computer Aided Engineering. Another area in which automotive design with PMCs has great emphasis is in the use of CAE. As previously stated, CAE models are used extensively for designing with linear, elastic, homogeneous, and isotropic materials, such as most metal materials. These computer tools are valuable in design optimization and simulation. Areas in which CAE tools have become invaluable include vehicle dynamics and crashworthiness simulations. Crash safety is driven by engineering standards and government regulations internationally and is expensive to validate due to the number of vehicles that must be tested for crash safety certification. Computer-aided engineering tools provide a significant potential for the digital validation of crashworthiness, but are limited mainly to linear, elastic, homogeneous, and isotropic materials systems. Automotive companies, including the USCAR consortium, are concentrating resources in order to develop CAE models for PMCs.

Recyclability. Recyclability of composites is also of concern to the international automotive community. In response to the Kyoto Summit and the European Economic Community, PMCs must be able to demonstrate closed-loop recycling. Other parts of this Volume are more specific on this area, but a great challenge exists in being able to use PMCs to their advantage while also being recyclable.

Life Cycle Assessment. Polymer-matrix composites have been compared with other materials to estimate the environmental burdens in automobile applications over the entire product life cycle. It was found that carbon- or glass- fiber-reinforced thermoplastic-matrix PMC had the lowest total life cycle environmental burden compared to steel, aluminum, or magnesium. This was despite the fact that carbon-fiber PMC has higher initial costs and energy burdens to produce the material. But, when taking into account life cycle energy use, greenhouse gas emissions, water emissions, solid waste, and hydrogen fluoride emissions, PMC imposed the lowest environmental life cycle burden (Ref 3).

Repair and Maintainability. Similar to the challenges with the use of composites in the aerospace area, the repair and the maintainability of automotive PMCs is a significant design as well as infrastructure challenge. Unlike other transportation applications, automotive maintenance is not limited strictly to certified mechanics. Most repairs are geared to steel-based procedures. However, with the evolution of the use of aluminum and modular electronics in automobiles, mechanics are becoming more versed in the special procedures that must be followed to service automobiles. This may provide promise for the servicing of technologically advanced automotive vehicles, but still entails the challenge of designing PMC automotive systems with servicing in mind. An excellent example of this is the LiteCast control link (National Composite Center), which provides a simple mechanism to indicate damage to the composite portion of the component (Fig 5). This mechanism is a stress concentrator at the end of the control link that induces failure at the composite-to-aluminum interface.

Fig. 5 LiteCast control link. Courtesy of National Composite Center

Processability. Processing of composites has been a constraint in being able to use fully optimized composite designs for automotive applications. Hand lay-up of composite structures is used to process racing vehicles, and this is still a primary process in aerospace manufacturing. Such a process that is touch-labor intensive and also wastes more than 1% of PMC material during production is quite prohibitive for automotive applications because of the cost involved. Thus, either highly automated processes or cost- effective labor-intensive processes must be used today to be able to produce design- and cost- optimized automotive vehicles. Examples of such processes are listed in Table 2. One step toward this goal is an automated process developed by the Automotive Composites Consortium (ACC) called P4 (which stands for programmable powder preforming process). This process has the potential for low-cost, high-volume production of optimized-design automotive PMC, due to its highly automated and low-waste method of applying chopped fiber to contoured surfaces. The fiber length and direction can be controlled, thus allowing for the design advantages of PMCs to be exploited (Fig 6). The P4 process is an example of how processes must be adapted to accommodate the design advantages of PMCs, instead of limiting the implementation of PMCs in automotive applications to existing high-volume processes.

Table 2 Characteristics of common processes for manufacturing polymer-based composites

Method	Fiber content, %	Resin content, %	Fiber geometry	Resins	Comments
Filament winding	60–70	30–40	Continuous, geodesic paths	Highly developed for thermosets, recently thermoplastics	Body revolves
Pultrusion	60 (varies)	40	Continuous, +90 an issue	Polyesters, others, some epoxy, recently thermoplastics	Constant cross section
Hand lay-ups	60	40	Continuous aligned and woven	Epoxy and thermoplastics	Airplane parts, surfboards
Hand lay-ups	40	60	Strand mat	Polyester	Boat hulls
Spray-up	30	70	Random chopped	Polyester, others	Fast, fumes
RTM and SRIM	20–50	50–80	Fiber preforms	Polyester, others	Low pressure, tooling issue
Compression molding (sheet molding compound)	20–50	50–80	Long, random	Polyester, others	Fiber orientation, surface finish issues
Stamping	20–60	40–80	Random coiled, continuous aligned	Thermoplastic	New developments
Injection molding	10–20	80–90	Short, random	Thermoplastic, polyester, polyurethane, others	Fast, RRIM, BMC, new developments

RTM, resin transfer molding; SRIM, structural reaction injection molding; RRIM, reinforced reaction injection molding; BMC, bulk molding compound.

An example of PMCs used to achieve low materials cost, short process cycle time, and part consolidation is DaimlerChrysler's composites vehicle (Fig 7). This vehicle was designed to use fiber-reinforced thermoplastic PMC and adhesives to achieve structural and surface finish requirements at a reasonable cost, due to part consolidation and process time reduction (Ref 6).

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

Design Environments

The design environment for automotive PMCs is still in the emerging technology stage for most applications that involve primary structure. Secondary structural applications are dominated by the use of sheet molding compounds (SMCs) and reinforced reaction injection molding (RRIM). Applications tend to emphasize body panel consolidation and the inclusion of special cosmetic design features, such as an integral step pad in a pick-up truck fender or header ports in a hood. Additionally, the design and processing knowledge and expertise lies mainly at the original equipment manufacturer (OEM) level, hence limiting "black box" designs at the tier one supplier level. Therefore, the design environment today is appearance dominated, with primary design responsibility at the OEM level. However, great potential exists for the PMC design environment to mature as primary structural and multifunctional applications are developed. A successful and proven design strategy will be one that used systems engineering principles and disciplines in a simultaneous engineering environment.

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

Application Drivers and Constraints

Production, Regulatory, and Consumer Attributes. The automotive industry sells vehicles that range from the utilitarian vehicles, such as pick-up trucks, to sports and sports-luxury vehicles. In all parts of this spectrum, the design advantages of PMCs lend themselves to fuel economy and vehicle dynamics and performance. Applications are differentiated by passenger and load capacity, in addition to regulatory classifications of vehicles. Today, PMCs tend to be used mostly in niche vehicle applications where production volumes are low and premium prices are charged per vehicle. This is because in the existing automotive design and assembly paradigm, the cost of PMC generally is not cost-effective over 50,000 units per year, despite lower tooling costs than those associated with metal material forming and processing. Sport utility and pick-up vehicles are obvious applications in which PMCs may be used, especially because fuel economy, vehicle dynamics, and NVH are more critical in these markets than they used to be. For example, SMCs are used in cross truck beams.

Implementation of PMCs in today's automotive environment has been mostly limited to areas such as the pick-up box area, although U.S. automakers recognize the need to increase the use of composites in order to meet fuel economy and safety goals for these vehicles. This can be accomplished at high-volume automotive line production rates if the total cost equation of material, tooling, design optimization, and ownership costs are addressed in order to take full advantage of the benefits of composites.

Cost. A consumer product, such as the automobile or the pick-up truck, can inspire endless application ideas, but the primary constraint of any application is cost. Materials cost is a significant constraint for PMCs in the automotive industry. With optimized design tools and practices, materials cost can be counterbalanced by reduced design and development cost, reduced capital investment and tooling cost, and enhanced value of the vehicle to the consumer. Thus, the total cost to the consumer becomes much more advantageous.

Automotive Applications

High-Volume Composite Descriptions, Properties, and Processes

Over 50% of automotive composites used in today's production vehicles consist of SMC and reaction injection molded (RIM) composites. Information is presented subsequently on the properties and processes of these automotive composite materials systems.

Sheet Molding Compounds. Sheet molding compounds are fiber-reinforced plastics that are fabricated in sheets and compression molded to final shape. They are reinforced in the plane of the sheet, but are not significantly reinforced in the through-thickness direction. The reinforcement may consist of continuous fibers (SMC-C), randomly chopped fibers (SMC-R), or a blend of both (SMC-C/R). The weight percent of fiber is generally indicated after the “C” or “R”.* Continuous fibers can be placed parallel to get maximum stiffness and strength in one direction, but at the price of very low properties in the direction normal to the fibers. A wide range of intermediate properties can be obtained by combining continuous and random fibers or by laying continuous fibers in an “X” pattern, oriented at a specific angle to get the desired directional properties (XMC). Of these types, SMC-R materials are the most widely used for automotive applications.

Properties of typical appearance-grade (SMC- R25), structural-grade (SMC-R50), mixed continuous/random (SMC-C20/R30), and ±7.5° X- pattern continuous (XMC-3) SMC compounds are given in Table 3. These properties are from compounds made from typical polyester resins with calcium carbonate filler and glass fibers.

Table 3 Typical properties of sheet molding compounds

Type	Specific gravity	Glass, wt%	Filler, wt%	Resin, wt%	Tensile strength		Elongation, %	Flexural modulus		Coefficient of linear thermal expansion, 10^{-6}/K
					MPa	**ksi**		**GPa**	**10^6 psi**	
SMC-R25	1.83	25	46	29	82.4	12.0	1.34	11.7	1.70	23.2
SMC-R50	1.87	50	16	34	164	23.8	1.73	15.9	2.30	14.8
SMC-C20/R30	1.81	50	16	34	…	…	…	…	…	…
Longitudinal	…	…	…	…	289	41.9	1.73	25.7	3.73	11.3
Lateral	…	…	…	…	84.0	12.2	1.58	5.9	0.86	24.6
XMC-3 ± 7.5° X-pattern	1.97	75	…	25	…	…	…	…	…	…
Longitudinal	…	…	…	…	561	81.4	1.66	34.1	4.95	8.7
Lateral	…	…	…	…	69.9	10.1	1.54	6.8	0.99	28.6

The SMC molding process involves placing an SMC charge in a heated mold and compressing the material at pressures of roughly 5.5 to 6.9 MPa (0.80 to 1.0 ksi). Polymerization of the partially reacted matrix is completed in the molding process. Faster dual-acting presses with accurately controlled parallelism, closing speed, and pressing force are also used in production. These presses have the potential to reduce press cycle time to less than 1 min. Molded coating can be applied during the molding cycle to fill surface porosity and to uniformly coat the surface for optimal surface appearance and quality.

Complex shapes and refined details that may be impractical with sheet metal are often easy to achieve with SMC. Parts may also be molded with varying thicknesses for local stiffness requirements. The design must be planned, however, so that all shape and detail is formed in a one-step molding process. While this can be an advantage over the multiple press-forming operations found in sheet metal fabrication, it must be understood that a molded SMC part cannot be reformed or flanged by a restrike operation, as is common with sheet metal parts.

It is critical that SMC parts be designed with sufficient draft to allow easy removal from the mold. Unlike parts made of more flexible polymeric materials, SMC parts cannot be designed with features that require parts to be snapped or peeled out of the mold. The use of lifters and slides to achieve features that are common in injection molded parts is more limited in SMC parts, because of the requirement for placing the uncured SMC material into the mold before it is closed.

Reaction Injection Molding. Reaction injection molding materials are prepared by polymerizing monomers or prepolymers during the process of molding finished parts. Milled glass fiber can be added to obtain reinforced RIM (RRIM). Milled glass RRIM tends to have directional properties due to fiber orientation during injection. Substituting glass flakes for the milled fibers can greatly reduce directional differences. As in SMC materials, reinforcement is primarily in the local plane of the material and not through the thickness. The RIM and RRIM materials described previously do not have significant structural applications, because their strength and stiffness properties are relatively low compared to those of SMC. Strength and stiffness properties similar to those of SMC can be obtained by placing fiber preforms in the mold before injecting and reacting the RIM matrix. This material is referred to as structural RRIM, sometimes called SRRIM or SRIM. Properties of typical RRIM and structural RRIM materials—commercial polyurethane and polyurea resins—are given in Table 4.

Table 4 Typical properties of reinforced reaction injection molding materials

Type	Specific gravity	Glass, wt%	Resin, wt%	Tensile strength		Elongation, %	Flexural modulus		Coefficient of linear thermalexpansion, 10^{-6}/K
				MPa	**ksi**		**GPa**	**10^6 psi**	
Polyurethane reinforced with milled glass	1.08	15	85	…	…	…	…	…	…
Longitudinal	…	…	…	19.3	2.80	110	0.538	0.0780	90
Lateral	…	…	…	17.9	2.60	140	0.331	0.0480	135
Polyurethane reinforced with flake glass	1.15	20	80	…		…	…	…	…
Longitudinal	…	…	…	24.1	3.50	25	1.34	0.194	54
Lateral	…	…	…	25.2	3.65	25	1.24	0.180	58
Polyurea reinforced with flake glass	1.18	20	80	…	…	…	…	…	…
Longitudinal	…	…	…	33.3	4.83	31	1.68	0.244	50
Lateral	…	…	…	30.5	4.42	31	1.72	0.250	53
Structural RRIM	1.5	37	63	172	24.9	4.2	12.4	1.80	12

The RIM process involves mixing the matrix reactants and injecting them into the mold. The reinforcing material can be injected with the reactants or can be placed in the mold as preformed mat before injection. Mold pressures are about 0.7 to 1.0 MPa (0.1 to 0.15 ksi) for RIM and RRIM, increasing to 1.4 to 2.0 MPa (0.20 to

0.30 ksi) for structural RRIM. Fast-acting polyurea and prepolymer chemicals are available that shorten reaction times to less than 10 s. New developments include equipment that provides precise temperature control, mixing ratios, and injection of filled and reinforced material.

As with SMC, the RIM processes permit complex shapes, refined details, and variations in thickness that would be impractical in sheet metal. Again, this is a one-step process, and secondary or restrike operations are not possible. An advantage of the RIM process is that it can use lifters and slides to achieve features common on other injection molding processes. The lower stiffness of RIM and RRIM permit some degree of snapping or peeling the parts out of the mold. On the other hand, the lower stiffness reduces the applicability of these materials to meet many structural requirements, unless the operation of fabricating a preform mat is added. Newer mat- making processes include the use of ultraviolet light-activated powder binder and woven composites with *z*-axis fibers.

Processes for Directed and Oriented Fiber. Specific fiber orientation often is required for structural composites. Other sections of this article describe the need for design optimization and its relation to fiber orientation in primary structural composites. The typical properties of oriented fiber composites are given in Table 5, although more specific properties are given elsewhere in this Volume. Though there are new processes, such as the P4 process described earlier in this article, other processes that have been used for commercial automotive application include filament winding, tape laying, and braiding.

Table 5 Typical properties of oriented fiber composites

Type	Specific gravity	Fiber, wt%	Resin, wt%	Tensile strength		Flexural modulus		Coefficient of linear thermal expansion, 10^{-6}/K
				MPa	**ksi**	**GPa**	**10^6**

Longitudinal	…	…	…	89.7	13.0	15.9	2.31	0.8
Lateral	…	…	…	89.7	13.0	15.9	2.31	0.8

AS, designation for surface-treated fiber

In general, the filament winding and tape laying processes for each technique are similar in that fibers are precoated with resin by the fiber manufacturer or are coated in the fabrication process just before the fiber-placement operation. The parts are then cured, either in a mold or on a supporting surface. The fiber-placement techniques have evolved to high-volume processes. Examples of this include high-volume automated filament winding of composite driveshafts, where several driveshafts can be wound at a time on removable mandrels.

Complex shapes and varying thicknesses can be obtained with these processes. However, the design must be planned so that any supporting surface for the fibers can be removed after curing or can remain as a part of the product.

Resin Transfer Molding and Squeeze Molding. Resin transfer molding and squeeze molding are low-pressure, long cycle time processes that are generally used for low-volume commercial products, such as class eight trucks. They can be thought of as low-productivity, low-pressure versions of the SMC and structural RIM processes. They have the capacity for producing parts that approximate the properties of the higher-productivity processes and, as such, are useful for producing prototype parts for evaluation.

Design Guidelines for Body and Secondary Structural Panels. Although the multitude of composite materials and processes available today for high-volume automotive applications makes design and process decisions difficult, most major automobile companies have developed materials selection and design criteria based on previous experience and through the efforts of the ACC. This section features those points that must be considered when determining which materials are best-suited for automotive body panels.

In general, the structural qualities of panels can be categorized by stiffness and strength requirements. The stiffness requirements provide the rigidity necessary to resist deflection, oil canning, and buckling and to ensure the desired vibration response. The strength requirements provide the needed failure resistance under service loading. In addition, certain panels contribute to crash resistance and energy management when a vehicle is tested under safety loading conditions.

In the case of body panels, the stiffness requirement is selected as the primary performance constraint. This can be justified for preliminary design evaluation, because experience has shown that stiffness requirements are usually the most restrictive. A structural panel can be evaluated for strength after it has been designed for stiffness, and modifications for strength can be added.

Other experience has shown that the secondary structural panels contribute somewhat to the global stiffness of a vehicle, but that local stiffness requirements predominate. The local stiffness is defined as the stiffness of a support-free region of the panel bounded by stiffeners or edge beams. Therefore, a typical body panel assembly could have one or more support-free regions. In the case of uniform-thickness design, the region with the lowest stiffness is used to determine the panel thickness for the entire panel assembly.

Panel stiffness is proportional to the modulus of elasticity (*E*) of the material under consideration and can be approximated as:

$$D \, \alpha \, E \cdot t^{\alpha}$$

where *D* is panel stiffness, *t* is the panel thickness, and α is the stiffness parameter, which is a function of panel curvature and of the loading and boundary conditions imposed on the panel. The value of α for laterally loaded panels can range from α= 1 for closed-box sections and corrugated panels governed by membrane stiffness, to α= 3 for flat panels governed by pure bending stiffness. In general, all secondary structural applications have an α value between 1 and 3, because they have a combination of bending and membrane requirements. Figure 8 depicts the general conditions found in body panels.

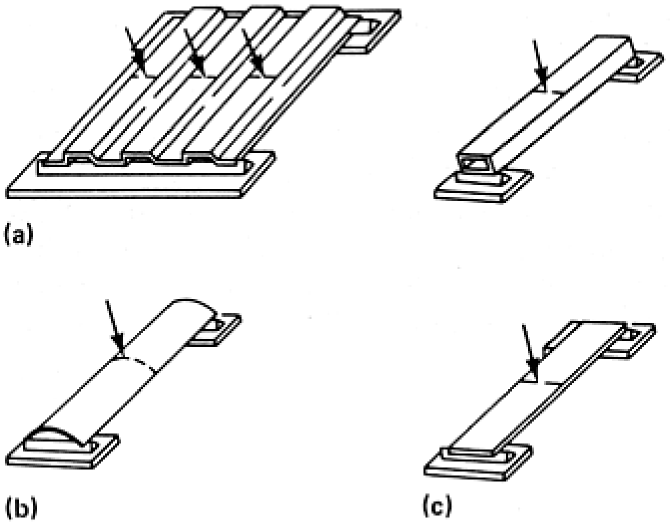

Fig. 8 Panel stiffness criteria. (a) α= 1, pure membrane resistance. (b) α= 2, oil-canning resistance. (c) α= 3, flat panel bending

Table 6 lists the relative thickness, weight, and materials cost for several materials, based on the three general stiffness schemes shown previously. In this example, the thickness and weight calculations have been normalized to SMC. Approximate material costs (not processing costs) and properties are listed in Table 7. Costs and materials properties are approximate and will change with economic, process, and materials developments.

Table 6 Relative thickness, weight, and cost of materials used for automobile body panels

Material	Pure membrane resistance (α= 1, t^1)			Oil-canning resistance (α= 2, t^2)			Flat panel bending (α= 3, t^3)		
	t	**wt**	**Cost**	***t***	**wt**	**Cost**	***t***	**wt**	**Cost**
Appearance SMC	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Structural SMC	0.73	0.77	0.62	0.86	0.91	0.72	0.90	0.95	0.76
RRIM (flake glass)	6.8	4.5	6.0	2.6	1.7	2.3	1.9	1.3	1.8
Structural RRIM	0.94	0.78	0.78	0.97	0.81	0.81	0.98	0.82	0.82
Amorphous nylon	5.6	3.4	9.2	2.4	1.4	3.9	1.8	1.1	2.9

Glass-filled thermoplastic	6.90	1.00	1.4	4.9	1.70	0.771
Steel	207	30.0	7.8	26.5	0.38	0.17
Aluminum	69	10.0	2.7	25.6	1.44	0.653

(a) Modulus (in MPa) divided by specific gravity

To relate the above information to actual applications, Table 8 lists values for typical panel applications. The values can change with size and curvature as well as boundary and loading conditions. It should be noted that using a smaller α value results in a conservative materials substitution design that may be more costly and not take advantage of the composite materials properties in an optimized manner.

Table 8 Typical stiffness parameter (α) values for automotive body panels

Panel	α
Floor pan	1.0
Rear compartment pan	2.5
Motor compartment front panel	3.0
Dash panel	3.0
Roof panel	2.0
Rear end panel	2.0
Quarter inner panel	3.0
Quarter outer panel	2.0
Trunk lid inner panel	1.0
Trunk lid outer panel	2.5
Front fenders	2.5
Hood assembly	2.5

Preliminary evaluation of alternative materials can be made by comparing Table 6 with Table 8. After identifying the most likely materials, an in-depth investigation of processing and tooling costs and assembly alternatives should be conducted before finalizing the design, process, and manufacturing scheme. In this context, manufacturing includes all postprocessing steps as well, including corrosion protection, joining techniques, and final appearance coating.

Footnote

* *Weight percent is used for SMC instead of volume percent because of the traditional practice of the automotive plastics industry, which has served as the main supplier of SMC to the automotive industry. The amount of fiber reinforcement is measured by weight percent to describe the plastics-oriented manufacturing process of SMC. This is in contrast to the customary use of volume percent by manufacturers of primary structural composites. Volume percent is more useful in describing the design and the mechanics of structural composites.

Automotive Applications

Nicholas J. Gianaris, Visteon Corporation

State-of-the-Art and Developing Technologies

Composite-intensive automotive designs have been demonstrated with aerospace design principles as a basis, but have not been shown to be manufacturable for the automotive industry environment. A concentration by the automotive industry on high-volume processes, such as sheet-molded compound PMCs, has shown limited results. Three technologies under development for potential automotive applications are the P4 process, low-cost carbon fiber, and cyclic thermoplastic polymer systems. The P4 process is described earlier and shows the best potential for cost-effective manufacture of structural and optimized automotive PMC systems and components (Fig 6). Derivatives of this process have been implemented for the pick-up box of the General Motors Silverado and Sierra pick-up trucks and for structural systems on the Aston Martin Vanquish 2001 vehicle.

Designs Incorporating Composites. The ACC Partnership for a New Generation of Vehicles (PNGV) has also worked with MultiMatic to design and prototype a hybrid material automotive body that was based on the Chrysler Cirrus body in white. The goal of the project was to see if a vehicle could be designed to save 70% of the mass versus a traditional steel body. It uses woven glass, aramid, and carbon-fiber thermoset-matrix PMC that also achieves class “A” surfaces. Aluminum honeycomb sandwich composites were also used. Basic modeling techniques were used to determine proper composite laminate design for structural and crash safety requirements. (Fig 9). This vehicle was tested recently in a controlled standard crash test with reasonable results (Ref 7). This vehicle did not, however, meet the PNGV goals for high-volume manufacturability and lower cost.

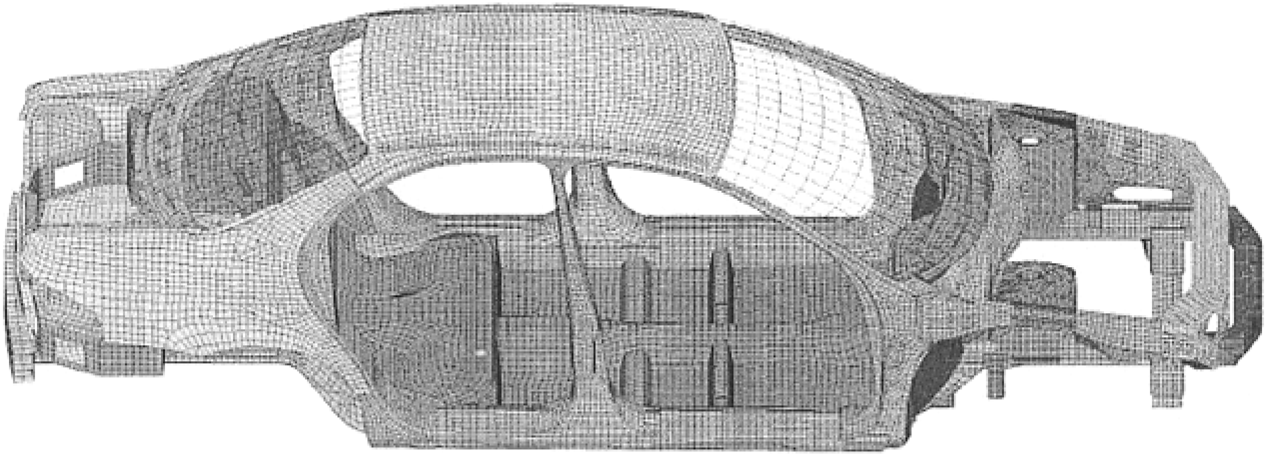

Fig. 9 MultiMatic PNGV hybrid material body in white finite-element model. Source: Ref 7

Similarly, a composite vehicle that takes advantage of optimized design for braided and woven composites is the Solectria Sunrise electric vehicle (Fig. 10). The automobile is manufactured using stitched woven and braided composite fibers. The entire structure for the body and chassis consists of six separate sections and are assembled at a cost that may be comparable to those for high-volume manufacturing of traditional automotive structures.

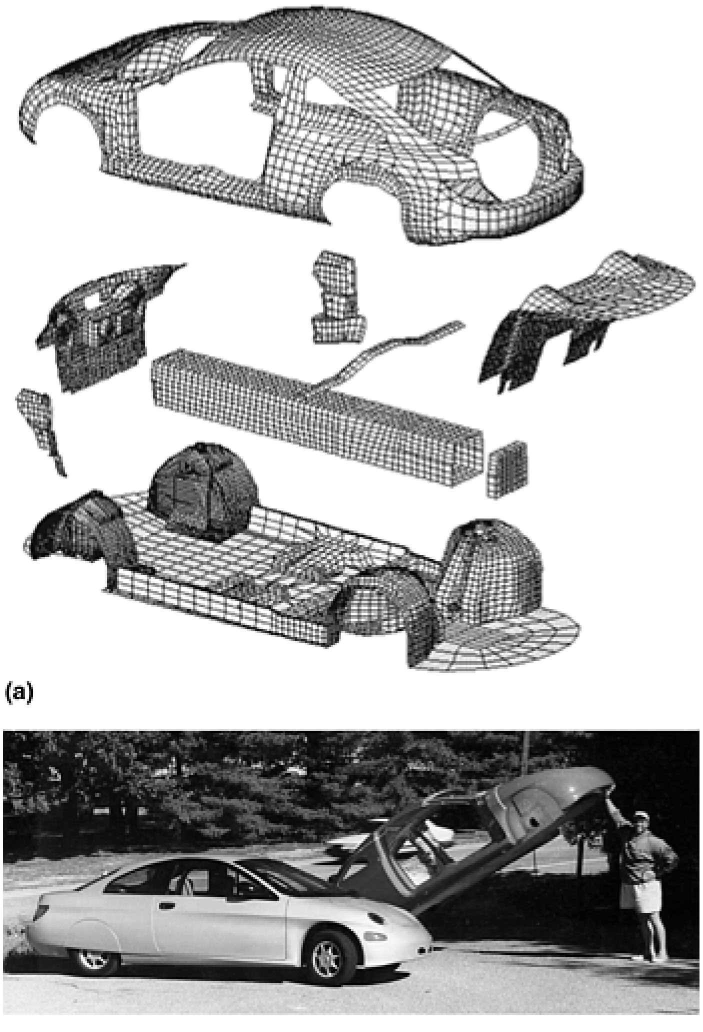

Fig. 10 Solectria Sunrise composite electric vehicle. (a) Assembly view. (b) View showing lightweight body. Source: Ref 8. Courtesy of V. Brachos, Solectria

Composite Fuel Storage Tanks. Another area that has received much attention is the fuel storage tank (Fig. 11). The automotive industry has implemented the use of natural gas-powered vehicles. Composite storage tanks have been shown to be advantageous as a lightweight and durable storage alternative to the more traditional tank storage media (Ref 9, 10). With the further development of hydrogen fuel-based powertrains, the need for hydrogen storage may increase in the future until fuel-cell technology is perfected.

Fig. 11 Composite fuel storage tank. Reprinted by permission from the Society for the Advancement of Material and Process Engineering (SAMPE)

Lower-Cost Carbon Fibers. The composite materials supply base has taken initiatives to produce good-quality carbon fiber at attractive prices, and this has become a catalyst for the automotive design community to further investigate its use. As stated earlier, the need for high stiffness in the automotive structure can be fulfilled by the use of carbon fiber.

Composite driveshafts have enjoyed limited success in the automotive market since the 1980s. In the past, these applications have been driven by the weight savings, natural frequency, and energy management opportunities this technology can provide.

Cost competitiveness with metal (steel, aluminum) and high-temperature performance have impeded broad market penetration. Cost is primarily driven by the cost of carbon fibers, although glass fiber has been used to dilute cost if the application requirements allow. Volume production of standardized low-modulus carbon fibers has had a significant impact on the cost reduction of a carbon composite materials system. Advancements in resin-matrix chemistry have provided much-improved high-temperature strength and stiffness without significant economic penalty.

Automotive OEMs have come under increased market and regulatory pressure to reduce weight and improve NVH characteristics. Many rear-wheel drive and all-wheel drive applications have been driven to two-piece metal driveshaft architectures for improved NVH and vehicle speed requirements. Composite driveshafts can meet many of these application requirements in a one-piece architecture.

There are several performance characteristics that an optimized composite driveshaft can provide. The weight savings and higher natural frequency (critical speed) capability of composite driveshaft technology have been well documented in the industry. The NVH response has generally been acceptable, due to the inherent superior damping qualities of the composite materials system. Design optimization may provide improved NVH response by also tuning the higher-order breathing modes through three-dimensional modeling. The stiffness-to-weight ratio allows smaller shaft diameters to meet application natural frequency requirements, providing increased package space to the OEM. Torsional stiffness may be tuned for drivetrain shock load management. Crush initiators and optimized bias plies may be used to attain an optimal energy management profile. Reduced rotating inertia reduces drivetrain losses in vehicle acceleration.

The reduced pricing of carbon fiber and the increased capability of modeling tools to optimize and enhance other performance characteristics of composite technology has motivated OEM and suppliers to reevaluate composite driveshaft technology. While many challenges remain in system drivetrain simulation and volume composite production methods, the cost- benefit ratio of composite driveshaft technology is stronger than ever.

Natural Fibers. An alternative and ecologically friendly fiber system that has seen use in secondary automotive interior structures is natural fiber. These fibers are found in common organic biological structures, such as flax, leaf, and seeds. These fibers have the advantage of low mass, renewability and recyclability, low cost, and good

thermal and acoustic properties. The disadvantages include lower strength properties, variable quality, moisture absorption, limited processing temperatures, poor fire resistance, and variable prices (Ref 11). Much work is being performed with natural fibers that may result in further use for automotive applications.

Cyclic Thermoplastic Composites. Lastly, the development of cyclic thermoplastic polymer systems for the matrix of structural composites holds promise for high-volume production of automotive composite systems that are recyclable as well. This polymer system has the design and processability attributes of thermoset PMCs. This polymer also has the recyclability attributes of thermoplastic PMCs. Hence, one this polymer system is proven out for its properties for automotive applications, it holds the promise of low- cost structural PMCs that are closed-loop recyclable.

Automotive Applications of Metal-Matrix Composites

Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.; Daniel B. Miracle, Air Force Research Laboratory

Introduction

METAL-MATRIX COMPOSITES (MMCs) have been used commercially in the automotive market for nearly 20 years. Properties of interest to the automotive engineer include increased specific stiffness, wear resistance, and improved high-cycle fatigue resistance (Ref 1). While weight savings is also important in automotive applications, the need for achieving performance improvements with much lower-cost premiums than tolerated by aerospace applications drives attention toward low-cost materials and processes. The raw material cost of cast iron or steel is less than \$0.60/kg (\$0.25/lb), and discontinuously reinforced aluminum (DRA) cast ingot currently costs about \$3.30 to 4.40/kg (\$1.50 to 2.00/lb) for large-scale production, so that the raw material cost of MMCs is higher than that of the material typically replaced. However, the DRA component would weigh 45% less than steel, significantly improving the cost comparison. Nevertheless, wider application of this technology will require performance improvements coupled with novel or innovative process improvements to drastically lower overall cost.

There has been successful application in several automotive applications in which the combination of properties and cost satisfied a particular need. As a result of these successful applications, the 1999 total world market of MMCs for ground transportation (automotive and rail) amounted to 1566 metric tonnes, valued at over \$7 million (Ref 2). Some of these applications are described subsequently, emphasizing the innovations that have led to MMC insertion and the system-level benefits that have been obtained.

Automotive Applications of Metal-Matrix Composites

Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.; Daniel B. Miracle, Air Force Research Laboratory

Engine Applications

Pistons. The piston is subjected to a severe dynamic thermal and mechanical environment. It must support cyclic mechanical loads at frequencies approaching 100 Hz, so excellent fatigue response is a primary requirement. The piston must also maintain a tight tolerance with the cylinder to retain maximum combustion pressure and withstand ring groove pounding. Dynamic strength, excellent wear resistance and a coefficient of thermal expansion (CTE) that matches the cylinder are the desired attributes. The temperature can be as high as 300 °C (570 °F) on the piston dome, so high-temperature properties are important. Finally, thermal gradients and thermal cycling are present, so that a high thermal conductivity is desired to reduce overall temperature and thermal stresses. Prior to 1983, a cast iron insert was often used for the piston top plate and ring groove area for direct-injection diesel engines (Ref 3).

A watershed application for aluminum MMC was the Toyota Motor Manufacturing piston for diesel engines (Ref 4). These pistons were placed into commercial production in Japan in 1983. The part consists of selective reinforcement of the aluminum alloy by a chopped fiber preform in the ring groove area, to provide improved wear and thermal fatigue resistance. The porous ceramic preform is placed in a permanent die mold, and complete infiltration by the molten metal matrix is accomplished by rapid pressurization. This squeeze casting process provides a high-quality component with low cost and very high production rates, as high as 100,000 per month (Ref 3).

The selectively reinforced piston provides significant improvement in wear resistance. As important, the low CTE has allowed redesign of the piston, using tighter tolerances and resulting in higher pressure and improved heat transfer properties (Ref 2). The lower reciprocating mass also adds to improved performance. Finally, the squeeze casting process, which integrates the reinforced top plate and ring groove material with the casting in a single step, resulted in an overall cost reduction compared to the previous design. Thus, although the aluminum MMC is more expensive on a raw material per unit mass basis, the selective reinforcement and simplified process result in a cost reduction at the component level. The performance improvements are added benefits in the use of the MMC.

To date, the selectively reinforced MMC piston has not been strongly considered in the U.S. market, because diesel engines in North America tend to be larger and operate at lower rotational speeds (rotations per minute, or rpm). As a result, the wear and fatigue requirements are not as stringent, and so the benefits are not as compelling. Nonetheless, MMC pistons provide a strong advantage in Asian and Western European designs, and continued growth is expected in this area. For example, Mazda Ford Motor Company introduced a selectively reinforced piston produced by a low-pressure die casting process in 1998 (Ref 2).

Other piston applications have included the use of SiC particulate- and whisker-reinforced aluminum forgings in racing applications. Due to the lower CTE of the MMC, reduced clearances between the piston and cylinder wall are possible. In some cases, an order of magnitude reduction in the specified clearance is possible (Ref 2). Based on trials of MMC pistons in drag racing bikes, improved performance compared to conventional hypereutectic aluminum-silicon alloys can result (Ref. 5).

Cylinder Liners. Widespread use of aluminum engine blocks has led to the need for protective cylinder liners for many of the same reasons discussed previously for pistons. Historically, the first and still the most widespread approach has been to use cast iron inserts as a result of the successful performance of cast iron engine blocks. Good wear resistance has been the primary consideration, even though the cast iron has a high density and relatively poor thermal conductivity.

Aluminum MMC cylinder liners have been in mass production since 1990 in the Honda Prelude 2.3 liter engine (Ref 6). In this case, hybrid preforms consisting of carbon and alumina (Al_2O_3) fibers are infiltrated by molten aluminum to form the cylinder liners during the medium-pressure squeeze casting process for the engine block. This innovative process eliminates the need for separate cast liners to be placed into a die cast machine or pressed into a pre-machined engine block. This reduces the number of parts previously required, and eliminates

the assembly step that was required to place the cast iron liners into the engine block. This engine is shown in Fig. 1.

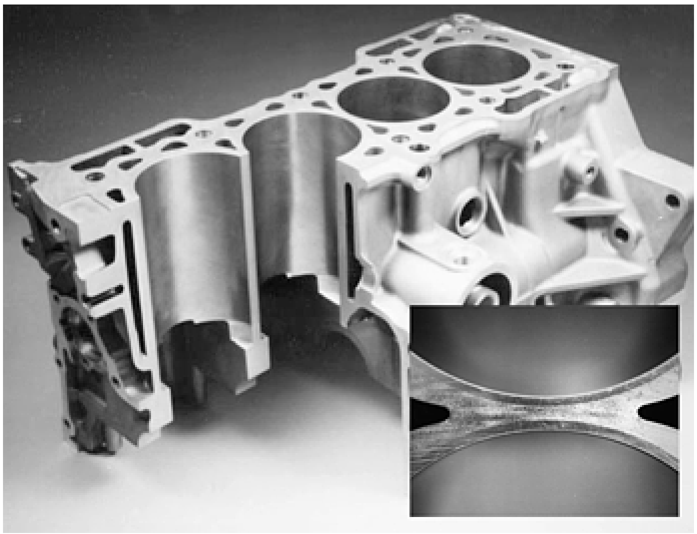

Fig. 1 Engine with integrally cast aluminum MMC cylinder liners

The wear resistance of the aluminum MMC is better than that of cast iron. The overall weight reduction of the aluminum engine block is 20% with the MMC inserts (Ref 3)—a dramatic improvement. In addition, the aluminum MMC has a higher thermal conductivity, so that the operating temperature is lower, thus further extending the life of the engine. Finally, the MMC liner is thinner than the previous cast iron, so that an increase in engine displacement has been achieved without redesign of the engine. Over 300,000 of these engines have now been produced. In addition to the Honda Prelude, MMC cylinder liners are now used in the Honda S2000 sports car, a premium version of the Acura NSX, and in the Porsche Boxter engine (Ref 2). The engine for the 2000 Toyota Celica also incorporates MMC piston liners, and 25,000 units were produced in the first model year. Finally, an aluminum MMC cylinder liner is used in high performance Honda motorcycles, using a powder metallurgy (P/M) process (Ref 3).

Valves. Intake and exhaust valves coordinate the transportation of the air-fuel mixture for combustion and the exhaust gases in automotive engines. Both intake and exhaust valves are subjected to cyclic mechanical loading at frequencies as high as 50 Hz, so fatigue properties are of primary importance. The valves must also possess good resistance to sliding wear in the valve guide. The exhaust valve operates in gas temperatures as high as 900 °C (1650 °F), so good creep resistance is required at the neck, where the maximum stress occurs. The atmosphere of exhaust gases changes, depending on acceleration, but the average gas composition is oxidizing, so that the exhaust valve material must have good oxidation resistance. Finally, the valve is subjected to high-frequency hammering forces, and good resistance to galling adhesion on the valve seat is required. Automotive valves are typically produced from austenitic steel. While the cost is low, these parts have relatively high mass. In addition, high spring forces are required to maintain continuous contact between the valve lifter (follower) and the camshaft lobe at higher rpm, so that a higher spring mass is required. This higher spring force increases frictional forces on the cam, the tensile stress at the neck, and the contact forces with the cylinder head. Finally, the energy required to compress the springs is lost to the cycle and decreases the overall fuel efficiency.

Discontinuously reinforced titanium (DRTi) MMCs have been used as automotive valves since 1998 in the Toyota Altezza 2.0 liter L-4 engine (Ref 7). The DRTi is made by a P/M process using low-cost titanium hydride powder, powders of the appropriate master alloys, and TiB_2 (Ref 8). The powders are mixed in an attritor, then metal-die pressed and sintered. The sintering step provides homogenization, densification, and allows the TiB_2 to react and form the stable titanium monoboride (TiB) reinforcements. Sintered billets can be processed into valves by an intermediate extrusion step followed by upset forging. The matrix alloys for intake valves is Ti-6Al-4V, and for exhaust valves is Ti-6.5Al-4.6Sn-4.6Zr-1Nb-1Mo-0.3Si (Ref 7, 8). Rigorous certification testing included endurance testing at 10,500 rpm (87 Hz).

Since the introduction of the Altezza, over 500,000 DRTi valves have been produced, representing a mass of about 13 metric tonnes. No defective units have been reported. A set of 16 DRTi valves weighs 408 g (14 oz), relative to 677 g (24 oz) for a full steel valveset, for a direct weight savings of 269 g (10 oz) per engine (Ref 7). In addition, the valve spring mass has been reduced by 7 g (0.2 oz) each, so that the total engine weight reduction is 381 g (13 oz). In addition to the reduced mass, the cam contact frictional forces and the energy

required to compress the springs are reduced. The cost of the DRTi valves is currently about twice as high as for steel, due to the relatively low volume of production. However, the cost has been projected to be comparable to steel for full-scale production. Yamaha Motor Corporation, an affiliate company of Toyota Motor Manufacturing, announced that DRTi valves will be used in two of their motorcycles introduced in 2001. An annual production volume of 500,000 units is expected. Figure 2 shows an intake and exhaust valveset used in the Toyota Altezza.

Pushrods. Cylindrical pushrods translate motion from the cam to the valve train in overhead valve (OHV) engines. A typical 8-cylinder OHV engine has 16 ultrahigh-strength steel pushrods. It is vital that the pushrod faithfully reproduces the desired motion from the cam to the valves. Limiting behavior at high engine rpm includes pushrod flexure, “valve toss” or “lofting” caused by loss of contact past the nose of the cam, “valve bounce” associated with lofting, and vibrations induced throughout the valve train caused by exciting a natural frequency of the pushrods. Flexure, lofting, and valve bounce limit engine performance, and excessive vibrations severely limit the lifetime of valvetrain components, especially springs. A high pushrod stiffness is required to control bending, a low mass is needed to reduce lofting, and good damping is essential to limiting vibration.

A fiber-reinforced aluminum MMC is now used in pushrods for high-performance OHV racing engines. The 3M Corporation produces the material by infiltrating 60% of Nextel 610 Al_2O_3 fibers with an aluminum matrix. Hollow pushrods of several diameters are made, where the fibers are axially aligned along the pushrod length. Hardened steel end caps are bonded to the ends of the MMC tubes. The aluminum MMC pushrods provide 25% higher bending stiffness and twice the damping capacity relative to 4340 steel pushrods (Ref 9). The MMC density is less than half that of steel, so that engine speed can be increased by an average of 250 to 400 rpm before valve bounce begins. In addition, it has been projected that the use of aluminum MMC pushrods could provide an extension in spring life of up to 600% as a result of the improved damping characteristics of the MMC (Ref 9). Because valvetrain springsets are generally a significant expense, this benefit provides a value far in excess of the initial acquisition cost. Further benefits of the 3M Corporation MMC pushrods may be achieved through optimization of cam design.

Connecting Rods. Other drivetrain components, and particularly the connecting rod, have been a focus of development (Ref 5). By reducing the mass of the connecting rod/piston assembly, the objectionable secondary shaking forces that can develop, particularly in smaller engines, can be reduced. In addition, lower reciprocating loads should lead to lower loads on the crankshaft and lower friction losses, and increased fuel economy or performance can be realized (Ref 1). In fact, it has been stated that for every 1 kg (2 lb) of weight removed from the connecting rods, 7 kg (15 lb) of weight required by steel connecting rods for support and counterbalance can be removed (Ref 2).

Commercial applications of MMC connecting rods in high-volume vehicles have not yet been achieved, largely because of the difficulty in obtaining a material with the necessary high-cycle fatigue performance and low-cost combination. While prototype connecting rods from hot- forged aluminum MMC have successfully been produced and tested, further cost reduction is required. A prototype connecting rod is shown in Fig. 3.

Automotive Applications of Metal-Matrix Composites

Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.; Daniel B. Miracle, Air Force Research Laboratory

Brake System Applications

Aluminum-based MMCs offer a very useful combination of properties for brake system applications in replacement of cast iron. Specifically, the wear resistance and high thermal conductivity of aluminum MMCs enable substitution in disk brake rotors and brake drums, with an attendant weight savings on the order of 50 to 60%. Because the weight reduction is unsprung, it also reduces inertial forces, providing an additional benefit in fuel economy. In addition, lightweight MMC rotors provide increased acceleration and reduced braking distance. It is reported that, based on brake dynamometer testing, MMC rotors reduce brake noise and wear, and have more uniform friction over the entire testing sequence compared to cast iron rotors (Ref 1).

Metal-matrix composite brake rotors and drums are typically produced by casting processes such as semipermanent gravity casting. Aluminum-magnesium and aluminum-silicon- matrix alloys and both SiC and Al_2O_3 particle reinforcements have been used, typically of at least 20% by volume. A number of automobiles now use MMC brake components. The Lotus Elise used four DRA brake rotors per vehicle from 1996 to 1998, and the specialty Plymouth Prowler has used DRA in the rear wheels since production started in 1997. Discontinuously reinforced aluminum rotors are particularly attractive in lightweight automobiles and are featured in the Volkswagen Lupo 3L and the Audi A2. In addition, a number of electric and hybrid vehicles, such as the Toyota RAV4, Ford Prodigy, and the General Motors Precept, are reported to use MMC brake components (Ref 2). Figure 4 shows a selection of DRA brake rotors.

Fig. 4 Aluminum MMC brake rotors

Discontinuously reinforced aluminum brake rotors are now being used on the InterCity Express (ICE), the German high-speed trains. Metal-matrix composite brake discs are now used on the ICE-1 and ICE-2, representing over 100 trainsets. Application of aluminum MMC in automotive racing applications, where higher- priced material is acceptable for improved performance, has been reported. Brake calipers for Formula 1 racecars produced from a 2124/SiC/ 25p MMC provide less displacement, more leverage, and quicker stops, due to the increased material stiffness (Ref 10). Metal-matrix composites are also reportedly being used as brake pads in conjunction with the Porsche 911 ceramic-matrix composite brake rotors.

Driveshaft Applications

Use of aluminum MMCs in the driveshaft takes advantage of the increased specific stiffness obtained in these materials. Current driveshafts, whether aluminum or steel, are constrained by the speed at which the shaft becomes dynamically unstable. The critical speed of the driveshaft is a function of the length, inner and outer radius, and specific stiffness. In vehicles with packaging constraints that do not allow increased driveshaft diameter, MMCs offer a desirable solution. Use of MMCs enables longer driveshaft lengths at a given diameter, or smaller diameter shafts at a given length. This is important in trucks and large passenger vehicles, where a two-piece driveshaft is sometimes used because of length restrictions. Substitution of a two-piece aluminum or steel driveshaft with a single-piece DRA driveshaft provides a direct weight savings, eliminates the weight and cost associated with the center support structure for the two-piece driveshaft, and reduces the mass required for corrective counterweights and balancing. As much as 9 kg (20 lb) can be saved (Ref 2).

As a result of these benefits, driveshafts comprised of 6061/Al_2O_3 materials produced by stir casting and subsequent extrusion into tube have been applied. In 1996, DRA driveshafts were introduced in the Chevrolet S-10 and GMC Sonomo pickup trucks. The following year, DRA driveshafts became standard equipment on the Chevrolet Corvette. An MMC driveshaft is now also used in the Ford “Police Interceptor” version of the Crown Victoria. Figure 5 shows the driveshaft used in the Chevrolet Corvette.

Automotive Applications of Metal-Matrix Composites

Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.; Daniel B. Miracle, Air Force Research Laboratory

Other Applications

Metal-matrix composites, specifically those based on aluminum matrices, are candidates for application in brake calipers, pump housings, gears, valves, brackets, pulleys, turbocharger and supercharger compressors, and suspension components (Ref 1). In addition, they have been cited for clutch parts, suspension pushrods and rockers, as well as other gearbox and engine parts (Ref 10). Discontinuously reinforced titanium is also under consideration for some of these components.

Snow tire studs have been manufactured from 6061/Al_2O_3 drawn wire. In Finland, where steel tire stud jackets have been outlawed and unreinforced aluminum has insufficient wear resistance, the MMC tire stud jackets have been successfully applied since the mid-1990s (Ref 11), and represent an annual market of about 150 metric tonnes (Ref 2).

Automotive Applications of Metal-Matrix Composites

Warren H. Hunt, Jr., Aluminum Consultants Group, Inc.; Daniel B. Miracle, Air Force Research Laboratory

Conclusions

A growing market has been established for MMCs in the automotive industry. Important applications have resulted when performance and weight benefits overcome the added component cost. Performance benefits have been obtained from reduced weight, improved wear resistance, low coefficient of thermal expansion, and good thermal properties. However, high volume process and material innovations are needed before MMCs are widely applied to the automobile across all product offerings. Continued pressure in the ground transportation industry for lower weight to improve environmental emissons and fuel efficiency is expected to generate growth in the existing application areas, as well as new opportunities for MMCs.

Space Applications

Suraj P. Rawal, Lockheed Martin Astronautics; John W. Goodman, Material Technologies, Inc.

Introduction

TYPICAL SPACE STRUCTURES require high stiffness, low coefficient of thermal expansion, and dimensional stability during the operational lifetime. High-performance composites do satisfy these requirements, and also offer the minimum weight material solution for space applications. Composites have been used in space applications almost from the start of the space program in the 1950s. Building upon the first successful use of composite for solid-fuel rocket motor cases in the 1950s, composites have been continually developed for the aircraft, launch vehicles, missiles, and spacecraft structures.

Elastic response, strength, failure mode, and damage tolerance characteristics of fiber-reinforced laminated composites are quite different from metals. More specifically, polymer-matrix composites are also different from metals in terms of the sensitivity to temperature, moisture, and the space environment. Recognizing these differences, specific design methods, materials, manufacturing processes, and test techniques are used for composite structures. In the last two decades, significant advances have been made in the areas of fibers, matrix materials, design and analysis methods, and composite manufacturing technology. As a result, composite materials have been increasingly used for both structural and nonstructural applications on spacecraft (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, and 15). These applications include truss structure, equipment-panel structure, optical benches, radiators, solar array support structures, antenna reflectors, antenna masts, electronic enclosures, and engine shields. In space launch vehicles and missiles, composites have been increasingly used for rocket motor cases, nozzles, payload fairings, payload support structures, igniters, and the interstage structures.

This article is primarily directed to address composites for unmanned space vehicles. More specifically, a brief overview of the key design drivers, challenges, and environment for use of composites in spacecraft, launch vehicles, and missiles is presented here.

Space Applications

Suraj P. Rawal, Lockheed Martin Astronautics; John W. Goodman, Material Technologies, Inc.

Design Drivers and Challenges

The primary design drivers with respect to selecting composites for space applications typically are reduced weight, reduced part count and structural complexity, improved structural/thermal performance (e.g., specific strength and stiffness, dimensional stability, high thermal conductivity), and potentially lower cost than conventional metallic materials.

When using composites for space applications, major challenges are in the areas of design allowables, cost of manufacturing and test, and perceived risk. For example, there is ongoing need to perform materials characterization testing due to a lack of applicable industry data with respect to mechanical properties of materials, impact resistance, and damage protection. Usually, recurring process control verification testing is expensive. Driven by cost, schedule, and risk- avoidance guidelines, some program managers may not evaluate composites for use despite their benefits in terms of mass/cost savings and significant improvements in performance. While composites do provide the improved performance because of high stiffness, dimensional stability, and low density, they complicate several system-level design issues. These issues include grounding, shielding, handling damage, shelf life, variability in raw materials properties, environmental interactions, adaptability to postbuild design modifications, nondestructive inspection, full-scale test requirements, fracture control, compatible interfaces and attachments, and so on. To address these issues, there is a critical need for interactions among designers, analysts, and materials scientists with extensive composite experience.

Suraj P. Rawal, Lockheed Martin Astronautics; John W. Goodman, Material Technologies, Inc.

Environments

Spacecraft are subjected to various environments during fabrication, transportation, handling, testing, and service life. Design of most structures in a spacecraft is driven by environment on earth, during launch, and in space. In each program, a structural environment definition document is prepared, including specific values of the structural design environment. Key spacecraft environments include transient/steady state, vibration (random and sine), acoustic, pyroshock, pressure, thermal, handling, and transport. In addition, structural design may be affected by other environmental considerations, such as salt-fog, humidity, ambient temperature, and space environment.

The space environment (Ref 14, 15, 17, 18, 19, 20, and 21) includes naturally occurring phenomena such as atomic oxygen (AO), very low-density atmosphere (near vacuum), ionizing radiation, plasma, charged-particle plasma, neutral atomic and molecular particles, micrometeoroids, and man- made debris. Vacuum describing the low pressure in space varies significantly with altitude, being about 10^{-15} torr (1.3×10^{-13} Pa) for geosynchronous spacecraft, compared to atmospheric pressure of 760 torr (101, 325 Pa, exact) at sea level. When exposed to space vacuum, including temperatures experienced, polymer- based composites release substances in the form of gas. This outgassing can lead to two potentially undesirable effects: degradation of key mechanical properties and condensation of gasses on critical surfaces of lenses, mirrors, and sensors, which influences optical performance (Ref 8, 16, 19, and 20).

Design Processes and Trade-Offs

While composites do offer significant performance improvements, one of the key drivers for the use of composites on spacecraft has always been the payoff in terms of reduced mass and, consequently, reduced launch cost. An industry- accepted figure for satellite payload mass savings varies from $20,000 to 100,000 per kilogram (kg). According to these figures, a 25 kg savings in mass reflects a projected cost reduction of at least $500,000. Lack of attention to spacecraft weight might result in a payload too heavy to be boosted into orbit by the launch vehicle originally scheduled for the spacecraft. This would be a calamity in virtually any program. Not only would the use of a larger vehicle cost substantially more due to the increase in unplanned expense, but such vehicles are most often difficult to schedule. Delay in the launch date in turn extends the cost of the development period. For a scientific payload, delay may eliminate the usefulness of the payload altogether. For a government utility satellite such as a weather monitor, the functional loss would be noticeable and embarrassing to the government, and costly to the public relying on accurate prediction of weather patterns.

Reduction in structural mass can also be converted into obtaining greater functionality by using upgraded instruments or electronic components for longer life, higher reliability, or additional capability. Even very late in the program, a weight savings in one area can be used to store additional fuel or compressed gas for longer life with attitude control on orbit.

Design, Analysis, and Tests for Composites. Any design process begins with the mission/system/subsystem requirements as they are reduced to structural design criteria, such as weight, launch acceleration, and minimum acceptable natural vibration frequency. Stiffness and stability constraints are imposed on the structure to minimize distortion and maintain alignment and stability for payload sensors during operational environment. Primary strength and stiffness of the composites are in-plane, and the composite parts are designed, exploiting the anisotropy features and tailorability of materials to satisfy the specific requirements. Basic considerations of fabrication and producibility aspects of composites are also included in the design of each part. Accessibility of components and subsystems is very important, and therefore a modular approach is followed when possible. Scientific instruments must have obstruction- free view angles. Instruments, like magnetometers, may have to be isolated from the satellite with long booms. Some subsystems need quantitatively specified surface areas, while others need 4π steradians of solid-angle field of view. This may necessitate using deployable appendages, such as booms, panels, antennas, and so on. The structure must be electrically conductive to act as a common ground plane for all equipment. The thermal loads typically involve temperatures in the range from–157 to 121 °C (–250 to 250 °F). The structure must provide a minimum mass heat path for the dissipation of excess thermal energy in order to remove all the heat generated inside the spacecraft. For construction and support of optical and antenna components, the acceptable limits on thermal distortion are specified. For unique components, design of the manufacturing tools and fixtures may be a key part of the process. Structural analyses are generally similar to aircraft practice also, but with a stronger reliance on vibration analysis to predict natural frequencies. Additional special analyses include thermal cycling associated with the periodic passage through the earth shadow in orbit, and thermoelastic calculation of the displacements of optical supports.

Structural testing usually does not include building a full-scale structural model for destructive testing; instead, full-scale articles are tested with limited loads and eventually prepared for launch. Subscale or partial components known as “pathfinders” are fabricated and tested to validate new designs and new fabrication procedures. For a typical value, low-production (one to three of a kind) spacecraft, coupons of scraps/ edges cut from production parts are tested routinely to ensure that the materials properties are consistent with the design values. In the large production programs, critical design, production, inspection, and tests are established in the first 4 to 6 units, thus minimizing the testing of subsequent units. Additional information is provided in the articles “Element and Subcomponent Testing” and “Full-Scale Structural Testing” in this Volume.

Materials and Process Trade-Offs. Materials trade-off studies at the beginning of the design phase often involve a design iteration process to arrive at alternative concepts incorporating material capable of meeting design

requirements. Trade-off study parameters include structural configurations, materials (fibers and resin matrices), manufacturing methods, and joining and assembly processes. An accurate and reliable database is needed to obtain a legitimate comparison of materials; typical materials properties used for materials trades can be obtained from the materials manufacturer. Figure 1 shows a typical trade-off study to identify the composite material and attachment methodology for hardware and bus structure. For example, a miniature spacecraft bus (primary support structure) could be a truss structure or a skin frame structure. Usually, if a monocoque structure has to be fabricated, then the selected fiber should exhibit ease of handling and adequate strain to failure. There are several options for an epoxy or cyanate-ester matrix system. A cyanate matrix with a desired cure temperature of 121 or 177 °C (250 or 350 °F) is often used, because it exhibits good microcracking resistance and low outgassing characteristics compared to conventional epoxies. Figure 1 also includes the design criteria for each parameter, thus providing a basis for down- selection of specific composite design. Based on this preliminary evaluation, M55J/cyanate-ester composite is an optimal materials option to satisfy performance requirements and provide a cost-effective honeycomb panel structure for a specific application.

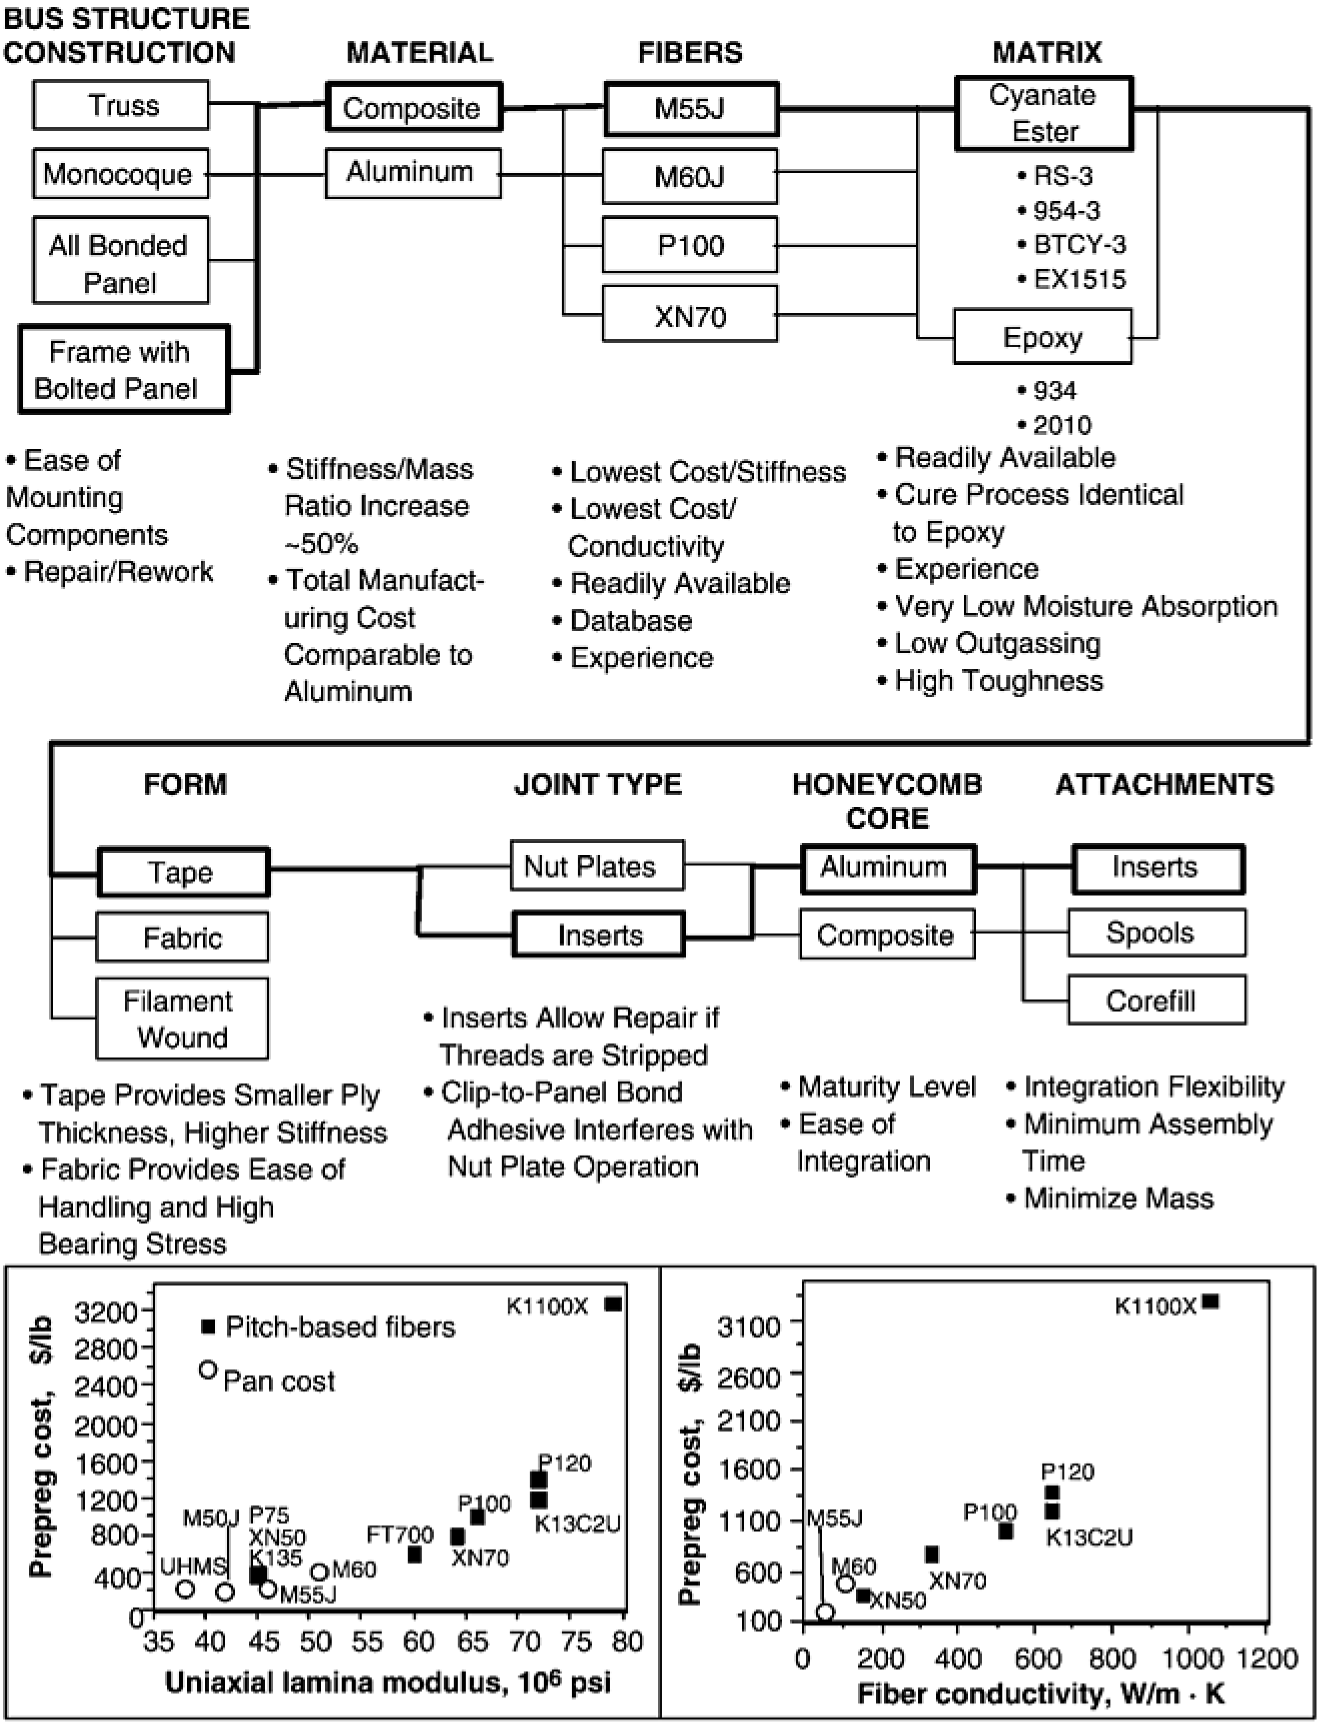

Fig. 1 Example of a design trade-off study used to select optimal composite materials and processes

Lamination theory is often used to predict laminate properties for use in materials selection and the fiber orientation required to meet performance requirements. In general, the fiber directions are oriented parallel to the major loading directions of the component. For components that are stiffness or coefficient of thermal expansion (CTE) driven, the fiber orientation and stacking sequence of each lamina are selected to achieve

composite laminates that meet specific stiffness and dimensional stability requirements. Several lay-up or materials combinations may meet the required performance parameters; selection of the final lay-up and materials combinations finally depends on variables such as cost, availability, fabrication experience, available database, and risk toleration.

If high-heat load components are mounted on the bus walls or deck panels, then the composite facesheet material should have high-conductivity fibers. The high-conductivity composite substrates help to spread heat efficiently, thus keeping the components within acceptable temperature limits.

Joining and assembly of composite hardware is accomplished by adhesive bonding and mechanical fastening methods. The lack of a plastic region in the material stress-strain response makes a joint in a composite part less tolerant of misalignment, fabrication tolerances, and damage from flaws or fatigue than similar joints in metallic materials. Proper consideration of critical composite joints includes basic understanding of load transfer function and detailed analysis that is complemented by elemental and component tests. In general, bonded joints are most suitable for thin members, and mechanical fasteners are used for thicker members. Bonded joints are designed such that the residual stress is minimized at the bond line and adhesive is stressed in the direction of shear, the direction of its maximum strength. Bonded joints are readily used in dimensionally stable composite structures. In recent years, the use of bonded joining techniques, such as mortise and tenon and corner blocks, has increased significantly. Mechanically fastened joints require no surface preparation and offer ease of inspection and disassembly, compared to bonded joints. Mechanically fastened joints are designed so that bearing is the critical failure mode. Typical quasi-isotropic composite laminate provides optimal bearing strength.

Fabrication and Acceptance of Composite Components for Spacecraft. Spacecraft laminates are usually thin, and most components are, in fact, sandwich structures with composite facesheets. Some sandwich panels consist of precured facesheets adhesively bonded to the aluminum honeycomb core. The “cocured” sandwich, in which the facesheet and the adhesive are cured simultaneously, is becoming common. The cure temperature varies from 121 to 177 °C (250 to 350 °F), depending on the laminating resin and adhesive selected. The pressure during cure is typically 207 kPa (30 psi), rather than the 689 kPa (100 psi) employed for solid laminates.

A general principle of manufacturing composite components holds that costs are reduced by reducing the number of individual operations and the number of individual parts. Cocuring of large components achieves such savings. Other methods to reduce fabrication cost include processing resin-transfer-molded composite shapes, which superficially resemble the metal extrusions in aircraft. Such parts can be processed for significantly less cost than the cost of hand lay- up of complex shapes. Some bolted joints must be provided to permit separation (or rework and repair) during assembly and test to permit equipment installation. Composite fasteners are becoming available but are not yet widespread.

Typical design verification testing of composite components for spacecraft includes the following four types of tests: (a) development, (b) qualification, (c) protoflight, and (d) acceptance. Development tests are conducted as necessary (on simulated components) to provide engineering design and test information to validate analytical techniques, evaluate optimal designs, and test procedures. Qualification tests are performed to provide verification that the flight-quality component, subsystem, or an entire vehicle has met its full performance/design requirements. Test levels and duration normally exceed the expected flight limits to ensure that the specified design safety margins are available. Often, prototype hardware, a nonflight hardware, is built to flight hardware requirements and then subjected to qualification-level test environments. In the protoflight-level tests, the test article (flight hardware) is subjected to the qualification environment-reduced (acceptance) duration. Protoflight testing of the first flight unit qualifies the flight hardware so that subsequent flight hardware need undergo acceptance-level testing only. Acceptance tests are conducted primarily to detect latent material and workmanship defects by performing tests at levels equal to or greater than the limit levels predicted for flight.

Composite Materials Properties

Design allowable properties are the numerical values of mechanical and physical properties used in structural analysis for preliminary design and subsequent design verification. These properties are generally based on tests of unidirectional [0], simple cross-plied $[0/90]_s$, or quasi- isotropic $[0/+45°/–45°/90°]_s$ laminates. In contrast, aircraft and automotive industries generate design allowables by testing a statistically significant number of specimens of every laminate lay-up and local structural configuration. Design allowable properties for actual spacecraft laminates, however, are implicitly calculated by anisotropic computer laminate analysis programs for stiffness and failure criteria for strength in the prescribed stress state. With so many potential combinations of fibers and lay- ups, it is impractical and cost-prohibitive to test the hundreds of specimens to rigorously establish A-basis allowables for all spacecraft composites. More specifically, MIL-HDBK-17 recommends that five prepreg batches of the composite material need to be tested so that materials properties data can be included in the handbook. Based on this recommendation, thirty tests per data point (six tests per batch) provide the basis to determine the B-basis properties.

Tests for both the physical and mechanical properties of cured lamina are performed in accordance with the American Society for Testing and Materials (ASTM) recommended test methods. Physical property tests include density, fiber, volume, resin volume, ply thickness, and glass transition temperature. The mechanical property tests include 0° and 90° tension, 0° and 90° compression, and in-plane shear tests. Short beam shear tests are required for determining process control test minimum values. Most often, a limited number (average ten) of coupon specimens are tested to generate a limited database, and small sample statistical analysis is employed to estimate minimum design allowables for strength and average values for stiffness and other parameters. The designers use structural allowables that are a combination of vendor and test data, with appropriate knockdown factor, if needed.

Manufacturers of composite structures for spacecraft generate materials property databases, often proprietary, on composite materials. The MIL-HDBK-17 committee on spacecraft composites has documented the available data from open literature, vendors, and spacecraft manufacturers. For preliminary design use, typical property data are available for nearly all spacecraft composite materials from the fiber and prepreg manufacturers. Typical fibers used in the spacecraft composite structures include a variety of fibers, such as S-glass, high silica, quartz, aramid, boron, and carbon. Carbon fibers are dominant for spacecraft bus structure, including, in the manufacturer's nomenclature, T300, M46J, M55J, XN50, M60J, P75, XN70, P120, K13C2U, and K1100. While a significant amount of test data is available in MIL-HDBK- 17 and other sources, Tables 1 to 3 list the typical properties (Ref 22, 23, 24, 25, and 26) of different carbon-fiber- reinforced organic-matrix composites used in spacecraft applications. Tables 1 to 3 include the test data of unidirectional carbon-fiber/cyanate- resin laminates, carbon-fiber/epoxy-resin laminates, and high-thermal conductivity carbon-fiber laminates.

Effect of the Space Environment on Composite Materials. Many materials used on spacecraft surfaces are susceptible to attack by nascent atomic oxygen (AO), a major atmospheric constituent in the low earth orbit (LEO) region (Ref 16, 17, 18, 19, and 26). The harsh environment of LEO includes not only AO erosion, but also solar ultraviolet radiation, temperature cycling in orbit, vacuum, condensates of volatile organic substances evaporated from spacecraft surfaces, micrometeoroid and man-made debris impacts, and high-energy radiation. The combined effects of the space environment can lead to serious deterioration of mechanical, optical, and thermal properties of some material surfaces. Optical properties (solar absorptivity and thermal emissivity) may change due to AO bleaching or ultraviolet (UV) radiation darkening. Polymeric films may peel due to thermal cycling. In turn, this opens new surfaces that can be attacked by AO or AO and UV. The electrical conductivity of a material may be affected by AO, resulting in spacecraft charging. The strength and stiffness of composite structures may degrade due to AO erosion of resin binders, although the strength is rarely needed after reaching orbit and completing deployment. However, degradation of stiffness of an optical bench or main support structure for a typical optical system will compromise system performance. Temperature cycling, as experienced by any orbiting system, must be controlled or compensated to maintain optical alignment. Based on the testing of composite specimens exposed to LEO environment, there is very limited degradation in the fiber-dominated properties. Also, the measured CTE values exhibit no substantial degradation other than that associated with outgassing. Careful selection of materials can ensure satisfactory performance over the design life of the system. Absolute protection from AO erosion is not realistic, but specific spacecraft are provided with AO protection optimized for the planned mission life, plus an operating margin to allow for variations in orbital conditions or for reasonable mission extensions. Spacecraft operating for short periods in LEO and spacecraft bound for high orbits or interplanetary trajectories require far less AO protection than spacecraft designed to operate for several years at intermediate Earth orbits. Geostationary, deep-space, and planetary spacecraft structures do not require AO protection, because the oxygen population in those environments is negligible.

State-of-the-Art Applications

General discussion of specific applications of composites is often limited by the information available in the open literature. Tables 4 and 5 provide brief lists of composite applications in spacecraft and rocket-motor cases, respectively. In each of the structural and non-structural applications, composites do offer unique performance characteristics and the ability to realize weight savings. The following sections describe the specific state-of-the-art applications of composite materials for spacecraft missiles and launch vehicles.

Table 4 Application of advanced composites on spacecraft

Spacecraft (S/C)	Launch year	Composite hardware
Intelsat IV (10 S/C)	1971–1979	Hybrid boron and fiberglass-epoxy aluminum foil waveguide; carbon-epoxy (C-epoxy) stiffeners on supporting structure for Earth coverage horn antennas
Apollo (3 S/C)	1971–1972	Boron-epoxy lunar surface drill
Anik B 1, 2, 3	1972, 1973, 1974	C-epoxy mesh grid offset parabolic antenna reflector
Explorer 49	1973	Boron-epoxy booms
ATS-6 (F/G)	1974	C-epoxy antenna feeds support truss
SATCOM	1974–1975	Aramid/epoxy antenna reflector assemblies
HEAO 2	1978	C-epoxy x-ray telescope optical bench
FLTSATCOM 1–7	1978–	C-epoxy tubular boom for helical receiver antenna deployment; aramid

	1986	ground plane support
Intelsat V (8 S/C)	1980–1985	Aramid/epoxy and GY-70/epoxy on Nomex H/C for 4 and 6 GHz reflectors; 51 and 25 mm (2.0 and 1.0 in.) diam GY-70/epoxy tube truss for antenna feed structure; copper-coated T300/epoxy waveguides; T300/epoxy feed arrays (copper clad); P75/epoxy Al honeycomb solar panel; T300/epoxy solar array yoke

Spacecraft Applications

A spacecraft consists of a “payload,” which is the mission-specific equipment, and a “bus” structure, which includes components of different subsystems. Table 6 lists the spacecraft subsystems, functions, and its major components.

Table 6 Spacecraft systems

Subsystem	Functions	Key components
Attitude control subsystem	Determines and controls the spacecraft's attitude (orientation) and orbital position	Sensors for determination; actuators for control (components that introduce forces or moments)
Propulsion subsystem	Changes the spacecraft's orbit	Propellant, storage tanks, pipes, and thrusters
Communications subsystems	Communicates directly or indirectly with ground control personnel and enables spacecraft tracking	Receiver, transmitter, and antenna
Command and data handling subsystem	Processes and distributes commands; stores, encrypts, and decrypts data	Data recorder and computer
Electrical power subsystem	Generates, stores, regulates, and distributes electrical power	Solar arrays, batteries, electronics, and cables
Thermal control subsystem	Monitors and controls temperatures	Heaters, radiators, heat pipes, louvers, insulation, and coatings
Structures and mechanisms subsystem	Physically supports spacecraft components, moves them as necessary, and protects them from dynamic loading	Primary, secondary, and tertiary structures; mechanisms

Subsystem makeup varies from one spacecraft to the next. Some spacecraft may not need all of these subsystems.

Source: Ref. 8

The bus is the body of the spacecraft that attaches to the expendable booster vehicle at an interface, including a separation device. The bus, as the primary structure, is the major load path between the spacecraft components and the launch vehicle. Electrical, optical, and other instruments are mounted within the bus. While primary structure is loaded mainly by steady state and transient loads, secondary and tertiary structures are loaded mainly by vibroacoustic loads. Secondary structures, such as antennas and solar arrays, are folded up and stowed during launch and deployed from the bus after orbit is reached. The electronic boxes and brackets that support cables are tertiary structures.

Antennas may be parabolic shells or more (electrically and geometrically) complex components. Solar arrays include interconnected solar cells on composite sandwich panels, or sometimes planar frames supporting membranes that in turn support the solar cells. The propulsion system on some spacecraft has included carbon-carbon composite nozzle/exit cone parts. Carbon-fiber wrapping of high-pressure gas storage tanks is becoming more and more the norm. The bus also provides attachment points that allow handling of spacecraft during assembly, testing, transportation, and launch.

Minimum weight is achieved with composites if the (compressive) strength-to-density ratio and the modulus-to-density ratio are tailored for specific applications. Composites with the highest stiffness currently available contain carbon/ graphite fibers derived from pitch, with elastic modulus about 900 GPa (130×10^6 psi). For components that require moderate strength to withstand the launch acceleration and vibration, slightly lower

modulus fibers, about 500 GPa (73 × 10^6 psi), are appropriate. For small clips and brackets, stiffness properties are not critical, and lower modulus carbon fibers about 225 GPa (33 × 10^6 psi) in fabric form are sufficient. Fibers with very high thermal conductivity, which are also very stiff and exhibit relatively low compressive strength and low strain to failure, are used in both structural and nonstructural thermal management applications. Glass and aramid fibers are rarely used on spacecraft, but quartz fibers are sometimes employed for their dielectric properties.

The structural components of spacecraft are in the forms of trusses, platforms, pressure vessels, and shells. A brief description of the key applications, such as spacecraft bus module, optical bench, solar array, and reflector structure, is presented here.

Spacecraft Bus Module. Composites provide low mass, high stiffness, and thermal stability for the spacecraft bus modules. The platform structures use the two most common forms of construction: sandwich construction and isogrid. Both of these constructions offer high stiffness and high buckling strength relative to their mass. A sandwich structure consists of two thin facesheets separated by and adhesively bonded to a lightweight aluminum honeycomb core. Most often, the facesheets are composite laminates with quasi-isotropic lay-up (e.g., $[0/\pm45/90]_s$ or $[0/\pm60]_s$). The facesheets carry the axial loads, bending moments, and in-plane shear loads acting on the panel, and the core carries out-of- plane flexure shear loads. Bus modules using panel structure have been used in several spacecraft, including Mars Global Surveyor (Fig. 2). Composite grid (including isogrid) stiffened structures have also been fabricated using a mortise-and-tenon-based flat laminate fabrication technology (Fig. 3). Using simple molded tubes, angles, and cylinders, the composite bus structures would ideally be designed such that the bonds are not in the load paths. Lay-ups are tailored to increase the structure stiffness without adding weight. While most spacecraft bus structure panels are fabricated using graphite/epoxy or graphite/cyanate composite, carbon-carbon (C-C) composite has also been used to fabricate some structural panels for high-temperature applications. A flat C-C composite panel, using aluminum honeycomb core, provided higher stiffness and thermal conductivity than a baseline aluminum panel. This C-C panel was successfully flown as a structural radiator on an operational spacecraft (Ref 27).

Fig. 3 Composite grid structure for the fast orbit-recording transient events spacecraft. Courtesy of Composite Optics Inc./Los Alamos National Laboratory

Truss structures usually consist of an assemblage of tubes. The tubes are designed to have high axial and bending stiffness and low CTE. Tube-to-end fitting (generally titanium) joints are designed to withstand thermal stresses caused by temperature cycling, and also to provide stiffness compatibility to minimize the stresses caused by any imposed loads. The application technology satellite was one of the first satellites (in 1974) to use composite truss structure that provided 50% weight savings over a similar metallic design.

Small spacecraft bus structures (octagon or hexagon shapes) usually have separation interfaces with launch vehicles that also provide the main supports for the bus structures. It is desirable to have load paths directly connected to the supports, such as the corners of the bus frame. The frames are assembled from pieces that are cut from quasi-isotropic flat laminates. Frames and panels may be fabricated in parallel and then integrated together using simple assembly fixtures.

Conventional aluminum structures inherently satisfy other system-level concerns, such as grounding and shielding requirements of the spacecraft bus module, but for composite laminates, a thin aluminum or copper foil is co-cured with the laminates to satisfy electron-magnetic interference shielding requirements. If needed, nickel powder is added to the adhesive to meet the electrical conductivity requirement. Furthermore, to minimize thermal stresses at the composite/metallic fitting interface, titanium is usually used for fittings due to its low CTE, low density, and high strength.

Optical benches are structural platforms with mounting interfaces for the attachment of optics, telescopes, interferometers, and other precision instruments. Key requirements for optical bench structures are high stiffness, thermal and mechanical stability, high strength, and light weight. Critical design considerations for an optical bench are near-zero CTE and coefficient of moisture expansion (CME) for the final assembly (Ref 28, 29, and 30). Sandwich panels and trusses are conventionally employed. High- or ultrahigh-modulus graphite

fibers impregnated with epoxy or cyanate-ester resin are normally used to fabricate the laminates or tubes. In a quasi- isotropic laminate configuration with a 60% fiber volume fraction, these materials systems can offer: a near-zero CTE (~0.0±0.1 ppm/°C), a low coefficient of moisture expansion (80–160 ppm/ %M), an in-plane tensile modulus of up to 147 GPa (21×10^6 psi), tensile strength as high as 450 MPa (65 ksi), and densities of approximately 1.7 g/cm^3. For example, the optical bench structure for the Hubble space telescope (Fig. 4) satisfies the CTE requirement of 0.0±0.1 ppm/ °C. Figure 5 shows a composite truss-type optical bench structure, consisting of tubes with plates and a thick honeycomb sandwich panel. Optical benches have also been designed with facesheets and internal egg-crated ribs. Ribs are made from thin laminates and slotted half-height to allow crossing through. The slots cause change of CTE from one side of the rib to the other; counter slots sometimes are required to balance the CTE. Ribs may also have tabs to engage with the slots in the facesheets. This configuration can include mortise-and-tenon joints in which the bond line is in shear and therefore able to take higher load than a tensile bond. Average bond-line thickness needs to be uniform, because inconsistent thickness may cause unpredictable thermal distortions due to varying CTE. Most fittings used in optical bench assemblies are Invar, possessing both low CTE and high modulus.

Solar arrays are usually categorized as rigid or flexible structures. Flexible arrays demonstrate their best performance advantages for large applications and unique launch envelope requirements. The rigid solar arrays are predominately used in the small-to-medium size applications and even into the large applications. The state-of-the-art rigid solar array substrate (SAS) that supports the solar cell population is a relatively large panel that is required to be flat, lightweight, thermally conductive through the panel, electrically nonconductive in-plane at the cell interface, and structurally capable of surviving launch conditions.

The rigid SAS is manufactured from the smallest sizes up to approximately 4 × 3 m (13 × 10 ft). Overall panel flatness usually is maintained at 1 mm/m (0.01 in./ft), but can be tightened up to approximately 30 to 50% of that value if required. The state-of-the-art SAS is a honeycomb sandwich construction with discrete hinge and/or snubber attachment fittings around the perimeter, and shear tie fittings nested in the interior of the panel. Usually, aluminum honeycomb core is used because of cost and thermal conductivity considerations. Often, the reticulated adhesive film (which cures at 122 or 177 °C, or 250 or 350 °F) is used to bond the skin to the core. Local doublers are incorporated in high shear areas and as strongbacks to maintain overall panel stiffness and local skin strength. These doublers can be embedded within the panel skins or bonded to the panel skin exterior.

Candidate materials for rigid SAS panels can be aluminum, aramid (unidirectional tape or woven fabric), high-modulus graphite/epoxy or cyanate ester (350 to 525 GPa, or 50 to 75 × 10^6 psi, unidirectional tape), ultrahigh-modulus graphite/epoxy or cyanate ester (560 to 910 GPa, or 80 to 130 × 10^6 psi, unidirectional tape), or conductive K1100 graphite/epoxy or cyanate ester unidirectional tape. Hybrid combinations of these materials for skins and doublers are common. Composite skins offer 30 to 40% mass savings and ease of bonding surface preparation compared to the aluminum skins. Because the composite-graphite fibers in the skins are electrically conductive in-plane, the panel skins are insulated from the solar cell population by using a nonconductive film, such as aramid/epoxy skin, which can be co-cured with the composite skin or secondarily bonded.

Reflectors. Two common reflector designs include composite honeycomb sandwich and isogrid structure. Most reflectors with a surface accuracy requirement of 0.100 mm (0.004 in.) root mean square (rms) or greater are honeycomb sandwich designs. The isogrid ribbed design requires more labor than the sandwich design, but it

has been fabricated to satisfy the requirements of a few micron RMS surface roughness. Composite materials used to manufacture some reflectors are aramid and graphite/cyanate ester. These materials offer high stiffness-to-weight ratio and nearly zero CTE. Figure 6 shows an antenna reflector assembly, consisting of a 1 m (3 ft) dish fabricated by using advanced co-cured sandwich structure. However, laminates and sandwiches made from these materials have high CTE through the thickness and high CME. Determination of the CTE and CME is very crucial in order to predict and control the surface accuracy during manufacturing as well as on orbit.

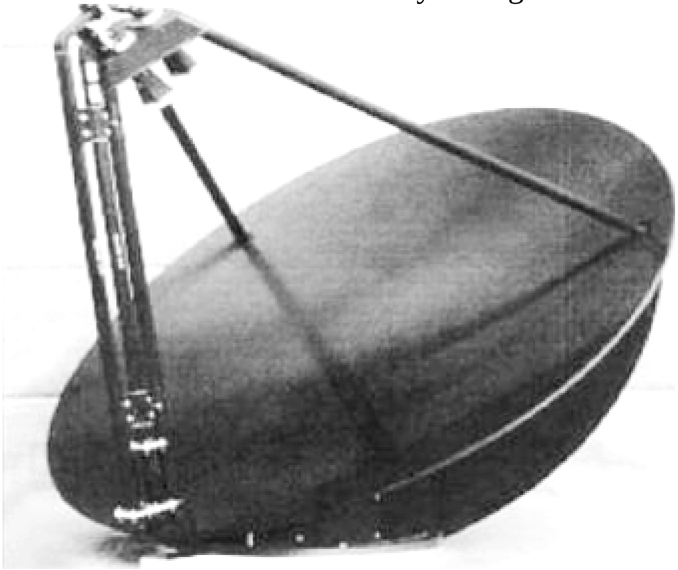

Fig. 6 Antenna assembly for the Seawinds spacecraft. Courtesy of Composite Optics, Inc./JPL

In addition to reflector and solar array support structures, polymer-matrix composites have been used to fabricate attachment fittings, avionics boxes/enclosures, thermal planes (i.e., heat sinks for circuit cards), thermal doublers (i.e., heat sinks under high-heat-generating components), radiator fins, and antenna elements (including waveguides, feed horns, and integrated feed towers).

Metal-Matrix Composite Parts. While polymer-matrix composites have been used for most of the primary and secondary structure applications, there have been a few applications where metal-matrix composites and C-C composites have also been successfully used. The space shuttle is one of the first production applications of metal-matrix composites. Unidirectional boron-aluminum structural tubular struts have been used as the frame and rib truss members in the midfuselage section and as the landing gear drag link of the space shuttle orbiter. The 242 boron- aluminum tubes construction weighing 150 kg (330 lb) resulted in nearly 44% weight savings over baseline aluminum extrusions design. Driven by the high stiffness and low CTE requirements, diffusion-bonded graphite-fiber-reinforced aluminum composite has been used as the high-gain antenna boom for the Hubble space telescope. The structure is 3–6 m (10–20 ft) long, with internal dimensional tolerances of 0±0.15 mm (0±0.006 in.) along the entire length so that the tube can act as a wave guide.

Carbon-Carbon Composite Parts. Carbon- carbon composites have also been used in spacecraft applications for both structural (e.g., radiator [Ref 25]) and nonstructural (e.g., engine shield, thermal planes, and thermal doublers [Ref 29]) applications. For example, if the thermal management needs of the electronic box necessitates the use of a thermal doubler, then the spacecraft designer needs a composite material that has high thermal conductivity, low CTE (equivalent to the facesheet), and low elastic modulus (compared to the facesheet). Conventional aluminum thermal doublers do not satisfy these requirements, because the combination of its high CTE and stiffness nearly equivalent to the facesheet could induce structural damage in the composite facesheet. A low-modulus two-dimensional and three-dimensional C-C for thermal doublers for composite structures provides the best combination of low density, low elastic modulus, low CTE, and high thermal conductivity (*K*). More specifically, a two-dimensional C- C doubler, processed at high graphitization temperatures, exhibits in-plane thermal conductivity of 130 to 160 W/m · K, and through-the-thickness conductivity of ≈40 W/m · K, whereas a three-dimensional C-C thermal doubler, heat treated at high temperature, exhibits in-plane conductivity ≥200 W/m · K, and through-the- thickness conductivity of 170 W/m · K, nearly equivalent to the thermal properties of an aluminum thermal doubler at lower weight.

Space Launch Vehicle and Missile Applications

Composites are used in a large number of space launch vehicle and missile components, such as rocket motor cases, nozzles, control surfaces, aerodynamic fairings, and launch canisters. Since the early days of lunar missions, filament-wound composite tanks have been used for the storage of fuels and pressurized gases on launch vehicle upper stages and satellites. A brief description of key applications, including solid rocket motor casings, payload fairings, and payload support (adapter) structures, is presented subsequently.

Solid Rocket Motors. Space motor components must be highly reliable and lightweight structures. Building upon the early successful use of composites for Altair, Antares, and BE-3 motor cases (in the 1950s) for the Vanguard and Scout launch vehicle programs, composites have been used in solid rocket motors of nearly all expendable launch vehicles. In the solid-propellant-type motor, fuel burns inside the case, generating moderately high pressures, which are contained by the large case wall. Composites with high tensile strength and low density offer an excellent materials solution. These families of expendable launch vehicles include Delta, Titan IV, Pegasus, and Ariane, each designed with capability to launch payloads of different weights to the desired altitude. For example, Delta II comprises a large family of expendable rockets that can be configured as two- or three-stage vehicles, depending on mission needs. The first stage of Delta II is powered by Boeing Rocketdyne-built RS-27A main engine, and by solid rocket strap-on graphite/epoxy motors (GEMs) (Fig. 7) for added boost during lift-off. The use of solid rocket motor upgrade system provided 25% increased performance and heavier lift capability than the boosters of the previous design of Titan IV launch vehicles. In particular, Titan IV-B rocket motor cases use high-strength IM7 fiber and durable HBRF-55B epoxy-resin composites. These cases are filament wound and produced by state-of-the-art automation, robotics, and process controls.

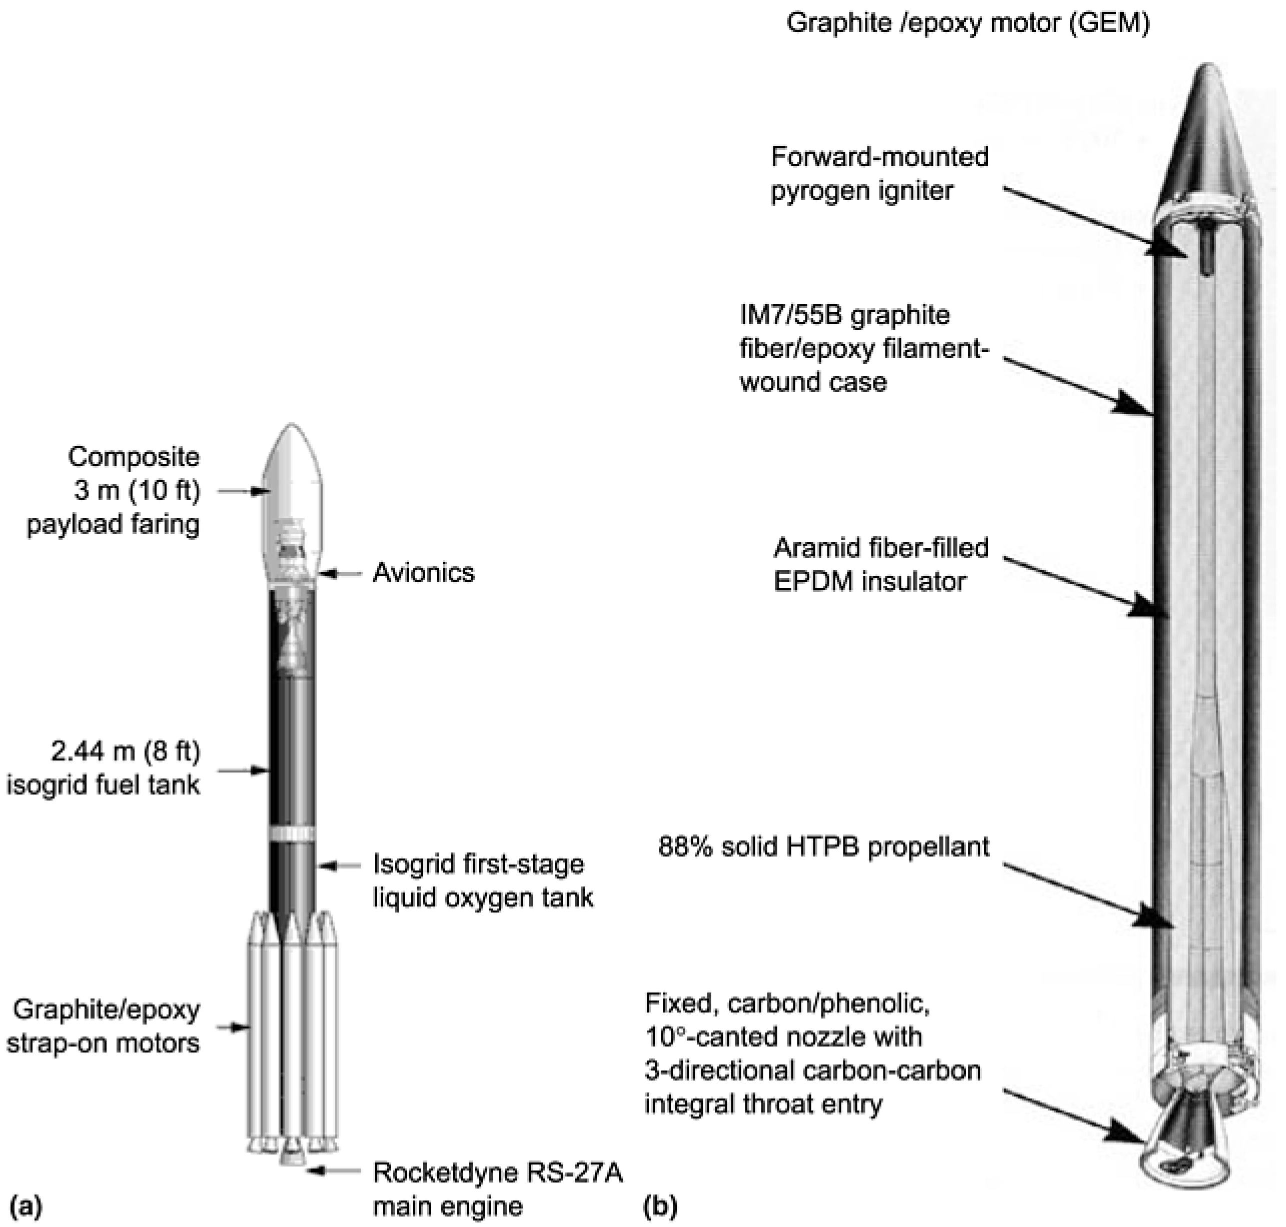

Fig. 7 Delta II launch vehicle. (a) View showing solid rocket strap-on graphite/epoxy motors (GEMS). (b) 3 m (10 ft) composite payload fairing

Filament-wound solid rocket motor casings have been extensively used in almost all missile systems, including strategic ballistic and defensive missile systems. For example, three filament-wound composite motor cases form the primary structure of the Trident I solid propellant missile system. These cases use Kevlar-49 (DuPont) aramid-fiber/epoxy composite in the pressure vessel section of the case and standard- modulus carbon-fiber/epoxy composite in the highly loaded, integrally wound thrust skirts. The Trident II (D5) missile is a three-stage, solid propellant missile that makes extensive use of composite structures. Major composite components of the missile include first-, second-, and third-stage rocket motors, igniters, the interstage structure, and equipment section. For example, the first-stage motor structure consists of a 2.1 m (6.9 ft) diameter by 7.3 m (24.0 ft) long standard-modulus carbon/epoxy filament-wound motor case (Fig. 8) with integral forward and aft skirts, aluminum attach rings, and aluminum port adapters that are integrally wound into the dome sections of the composite case.

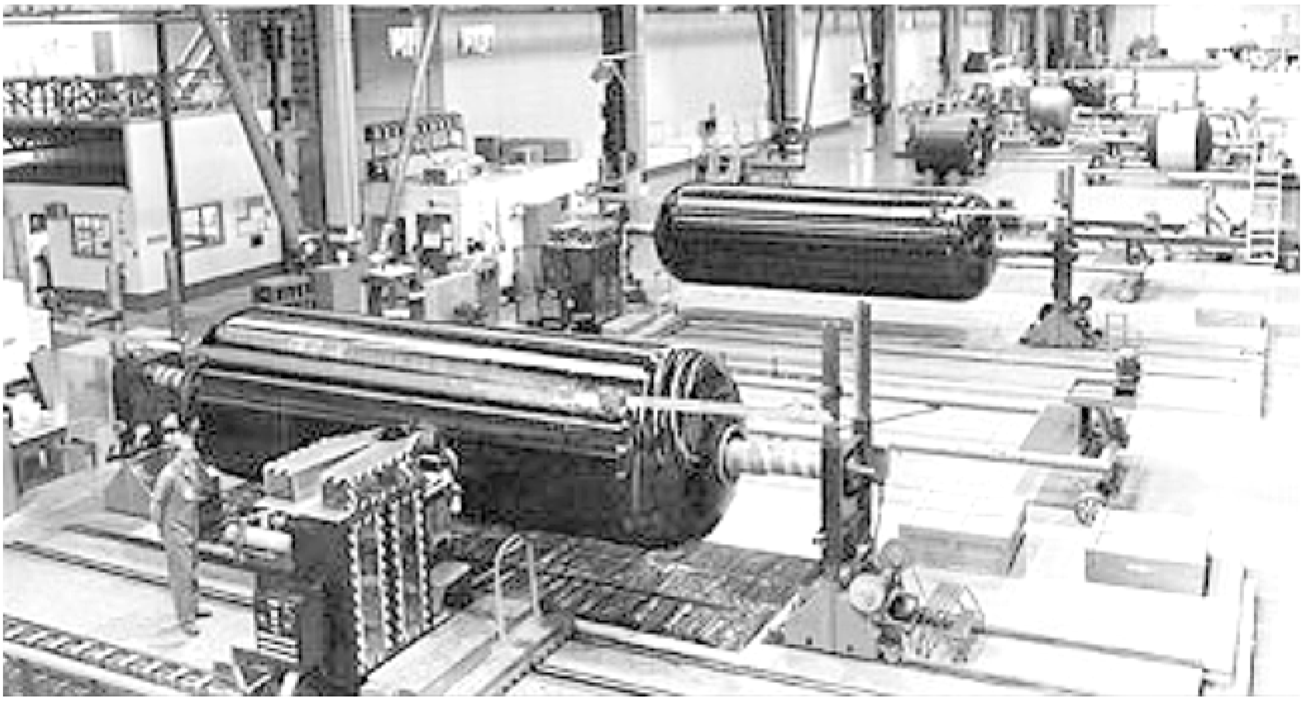

Fig. 8 High-performance graphite/epoxy motor chambers fabricated using computerized filament winding. Courtesy of Alliant Aerospace Company

Payload Fairings and Adapters. The payload fairings constitute a critical element of payload accommodation, because they protect the spacecraft/payload during the launch and ascent phases of flight. With respect to payload fairings, composite structures, and adapters, the current state-of-the-art is exemplified by the products being used by the European Space Agency and on the Atlas V program. For example, Arian 5 and Atlas V launch vehicles typically use 5.4 m (17.7 ft) diameter composite payload fairings. The payload fairings are constructed using vented aluminum honeycomb core co-cured to self-adhesive graphite/epoxy facesheets and cork thermal protection. They are fabricated in sections using hand lay-up of the facesheets. The Delta II and Delta III use 3 and 4 m (10 and 13 ft) diameter composite fairings, respectively, that separate into halves in flight to permit payload deployment. These composite fairing designs also incorporate acoustic blankets to protect payloads from noise and vibration at lift-off. In addition to honeycomb sandwich structures, composite payload shrouds have also been constructed using an advanced grid-stiffened (AGS) structure, a rib-skin configuration. A conical AGS shroud fabricated by Air Force Research Laboratory, New Mexico, was successfully flown in 1997. Advanced grid-stiffened structures are composed of composite shells supported by a “grid pattern” of composite stiffeners (Fig. 9). These structures are of interest due to their structural efficiency, high damage tolerance, suitability for propensity toward automated manufacture, and environmental robustness.

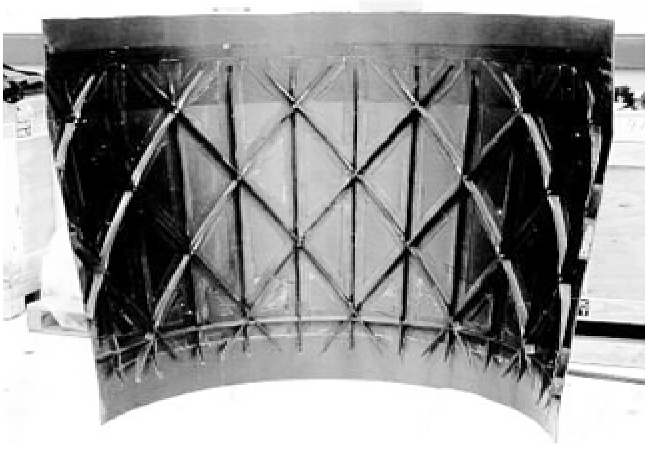

Fig. 9 Advanced grid-stiffened structure for launch veicle systems. Courtesy of Air Force Research Laboratory, Kirtland Air Force Base

The interstate adapters used on the Atlas V program are constructed with similar materials, but are fabricated using automated fiber placement, which reduces touch labor, minimizes material scrap, and improves process control and repeatability. Graphite/epoxy facesheets are used based upon exhibiting good strength and stiffness, reasonable cost, good elevated temperature (i.e., up to about 150 °C, or 300 °F) capability, and fairly extensive heritage in space applications. Aluminum honeycomb is preferred over structural foam and on metallic cores due to its superior compression and shear strength properties, lighter weight, and reduced cost. Cork is still generally less expensive and more effective than spray-on insulations and ablatives for exterior thermal protection. Spray-ons are used, and do work, but they rarely fully deliver on their promises. Bismaleimides and polyimides are frequently studied and sometimes used to improve facesheet performance at higher temperatures. With the proper postcure processing, the materials can be used at temperatures up to 188 and 233 °C (370 and 450 °F), respectively, without the need for ancillary thermal treatments. However, they are quite expensive, generally more difficult to process, and sometimes exhibit problems resisting launch vehicle environments, such as moisture absorption.

New Developments and Future Needs

For several years, the trend in composite materials for spacecraft has been regular introduction of new fibers and new composite product forms; it is likely to continue. In particular, fibers with still-higher thermal conductivity are anticipated, and the use of carbon-carbon for thermal conductance will increase. In the long

run, a locally leak-free (nonpermeable) composite will be developed, capable of containing a fluid and leading to wholly composite heat pipes embedded in composite laminates and sandwich panels.

For low-cost small satellites, such as those produced by the dozens for LEO telephone communications, composite designs and procedures will evolve to still-simpler shapes and methods. For these satellites, redundancy of systems on orbit will permit acceptance of risk of structural/ functional failure of composite components. The motivation, of course, is cost reduction by eliminating expensive inspection and quality control procedures.

For unique high-value spacecraft, such as the next-generation (optical) space telescope, more and more adaptive structures with embedded piezoelectric or magnetostrictive elements will be employed to obtain precise dimensional control.

In processing, resin transfer molded and pultruded parts will be available in sufficient variety to replace most hand lay-up long, straight shapes for frames and stiffeners in bus structure.

In design of solar arrays and other secondary structures, the trend will continue to lighter composite sheets. Already, honeycomb core sandwich structure employs ultralight carbon-fiber facesheets that may be a single ply of a triaxial weave fabric, a single ply of conventional square weave fabric, or even two crossed plies of unidirectional prepreg tape. An additional weight reduction is likely from ultrathin prepregs, thinner than 0.1mm (0.004 in.). Composite truss tubes will routinely contain integrally formed composite end fittings.

The impact of composite advances on evolving ultrasmall micro- (10 kg, or 22 lb) and nano- (1 kg, or 2 lb) satellites is still unclear; if huge weight savings are accomplished with the functional components, the savings available from structural composite materials may be less attractive. On the other hand, advances in carbon nanotube based composites should offer multifunctional structure design solutions for the fabrication of micro- and nano-satellites.

Composite users for reusable launch vehicles require an extensive database containing mechanical properties of common graphite/epoxy systems, which would be most useful. These data should be based on lamina, common laminates, and honeycomb sandwich specimens tested in sufficient quantities to yield A-basis allowables at room temperature dry and wet, elevated-temperature dry and wet, and reduced temperature (cryogenic) dry and wet. More work needs to be done to characterize the effects of compression after barely visible impact and standard repair techniques. Lower-cost materials and processes and more-consistent process repeatability will also help the future of composites. Also, more work needs to be performed to improve cost and weight effectiveness of acoustic transmission loss characteristics without the need for heavy ancillary treatments. The inherent advantages of graphite/epoxy honeycomb sandwich structures in terms of improved specific stiffness make them ideal transmitters of acoustic noise. Frequently, the treatments applied to mitigate acoustic transmission severely penalize the performance of composite structures.

Aeronautical Applications of Metal-Matrix Composites

Daniel B. Miracle, Air Force Research Laboratory

Introduction

METAL-MATRIX COMPOSITES (MMCs) could claim only a few significant applications as recently as the 1980s. None of these were aeronautical applications. Since that time, however, dramatic advancements have been made in the areas of material and process development, design, manufacturing scale-up, and certification of MMCs. As a result, a number of significant MMC applications are now in service in the aeronautical field. Metal-matrix composites are used in both military and commercial aeronautical systems. Major applications exist for aerostructural components and parts in aeropropulsion systems, and a growing number of uses in aeronautical subsystems is evident. The current generation of MMC applications largely includes structural components and applications for thermal management, but important applications for wear resistance have also been considered.

The primary motivation for the insertion of MMCs into aeronautical systems is the excellent balance of specific strength and stiffness offered by MMCs relative to competing structural materials. As shown in Fig. 1, fiber-reinforced MMCs offer specific strengths and stiffnesses significantly higher than those of aerospace metal alloys. However, their properties are highly anisotropic, limiting potential applications, as discussed in more detail subsequently. Further, their specific properties are still inferior to those of organic-matrix composites, such as graphite/epoxy, in the uniaxial orientation. Discontinuously reinforced aluminum (DRA) MMCs have isotropic properties and provide specific stiffness values that are higher than those of aerospace metal alloys by

as much as 100%. While the highest levels of specific stiffness are obtained by using higher volume fractions of particulate reinforcement, good fracture properties (ductility, toughness, and fatigue) can only be obtained with current technology for volume fractions of 25% or less.

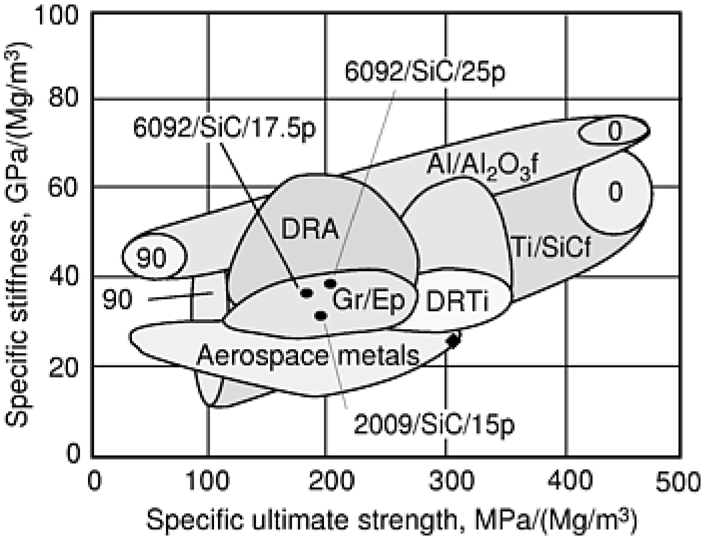

Fig. 1 Specific strength and specific stiffness of existing aerospace structural materials with isotropic properties, including metal alloys, discontinuously reinforced aluminum (DRA), discontinuously reinforced titanium (DRTi), and cross-plied graphite/epoxy (Gr/Ep). Graphite/epoxy/overlaps the lower-stiffness region of DRA. Three data points for particular aerospace-qualified DRA materials are labeled. Fiber-reinforced MMCs (Al/Al_2O_3f and Ti/SiCf, or TMC) are also shown. Data for DRTi are available only for reinforcement volume fractions of ≤20%, as represented by the labeled oval, and the larger oval suggests the potential properties that may be achieved with higher volume fractions of reinforcement. The diamond represents data for high strength specialty steel.

Data points for the most widely used DRA aerospace materials are labeled in Fig. 1 and have volume fractions that range from 15 to 25% of SiC particles. These materials have isotropic specific stiffnesses up to 50% higher than those of metal alloys and isotropic specific strengths that are equivalent to those of the best commonly-used aerospace metal alloys, such as Ti- 6Al-4V and 7075-T6 aluminum. These MMCs also provide specific stiffnesses equivalent to those of the best graphite/epoxy cross-plied material and have specific strengths in the midrange of cross-plied organic composites. The structural properties of discontinuously reinforced titanium (DRTi) are shown in Fig. 1 to illustrate the potential of this class of MMCs. Although less mature than DRA, these materials already have important applications, including intake and exhaust valves in production automobiles (see the article “Automotive Applications of Metal-Matrix Composites” in this Section). The labeled bubble illustrates the current range of specific properties of DRTi for reinforcement volume fractions to 20%, and the larger bubble outlines the projected range of properties that may be achieved with higher volume fractions.

A great deal of effort has been undertaken to develop fiber-reinforced MMCs for aerospace applications. Early success was achieved with aluminum alloys reinforced with boron monofilaments or graphite fibers, resulting in spacecraft applications (see the article “Space Applications” in this Section). However, no applications in aeronautical systems resulted from fiber-reinforced aluminum MMCs. Additional matrix alloys based on copper, magnesium, nickel, and niobium have been studied, but by far the largest effort has focused on fiber-reinforced titanium alloys. The motivation for this research and development activity was to obtain exceptional specific strength and stiffness for high-temperature applications in systems such as the National Aerospace Plane (NASP) in the United States and in advanced gas turbine engines. Candidate matrix alloys included α-titanium alloys, α+β- titanium alloys, β-titanium alloys, and titanium- aluminide alloys. Alumina was sometimes considered as a reinforcing fiber, but SiC monofilaments were most commonly used. A number of innovative processes were explored and developed. Although the required material properties goals were largely achieved in these research and development efforts, the high raw material cost associated with the SiC monofilament and difficulty in processing and machining provided critical barriers to insertion.

Significant resources have been applied to develop these materials for critical components in gas turbine compressors of advanced gas turbine engines. In one case, such efforts are still underway, and it is not certain whether a successful insertion will result. Nonetheless, fiber-reinforced titanium has been specified as bill of material in an actuator piston rod for a nozzle actuator in the F119 engine for the F-22 aircraft and for use as an actuator linkage in the F110 engine for the F-16 aircraft. These parts provide a simple component shape, easing manufacturing concerns. The loading is purely axial, which takes best advantage of material properties. Finally, the part is not fracture-critical, providing a low-risk component for first insertion. These components are discussed later in this article.

An equally large, though more diffuse, activity on discontinuously reinforced metals has been undertaken in the past 20 years. Many international efforts have explored MMCs based on alloys of magnesium, copper, iron, and titanium. A number of important applications have been developed for discontinuously reinforced Fe, including hard, wear-resistant parts such as industrial rollers and extrusion dies. Discontinuously reinforced titanium has been successfully developed for a few significant applications, including intake and exhaust valves in the automotive industry (Ref 1). Clearly, however, the most significant success over this time period has been the development and commercialization of DRA. Self-sustaining industries are now established in Great Britain, Canada, and the United States, satisfying demands from the automotive, aerospace, thermal management, tribology, and recreation industries. Applications of DRA range from sophisticated, high-technology components such as net shape, integrally processed multifunctional parts to simple commodities such as automotive-cylinder liners and snow tire studs. By far the widest range of applications exists in the automotive, space, thermal management, and aeronautical fields. The current aerospace powder metallurgy (P/M) market in the United States alone amounts to 50 tonnes per year, and the automotive market represents a volume over an order of magnitude larger.

The DRA materials constitute an extremely broad and flexible material system. Matrix alloys can be based on either cast or wrought compositions, and a full range of microstructural modifications from thermal and mechanical treatment is available. SiC, Al_2O_3, B_4C, and graphite are commonly used as reinforcements. Reinforcements may be particulate or whiskers and may comprise a volume fraction from 10 to 70% by volume. A significant degree of control can be exercised over the size and distribution of reinforcing particles. A number of commercial primary and secondary processes have been established for DRA, and the interested reader is referred to other articles within this Volume for a detailed description.

A convenient standardized nomenclature, ANSI H35.5-1997, has been established for aluminum MMCs and is illustrated here: 2009/SiC/ 15p-T4. The four-digit Aluminum Association alloy designation, which specifies the matrix alloy composition, is followed by the reinforcement composition. This is followed by the reinforcement volume fraction (in volume percent), and a single letter that signifies the morphology of the reinforcements (p = particle, w = whisker, and f = fiber). The standard Aluminum Association temper designation (T4 in the example) is used at the end of the MMC designation, as appropriate.

The following briefly describes the most significant aeronautical applications of MMCs. With only one exception (the hydraulic manifold for the V-22), the components described are now in production—the remaining component had been selected as bill of material and was awaiting certification testing at the time of publication. Each description includes discussion of the main features and requirements of the particular application, including service requirements and deficiencies of previous materials. Design considerations and trade-off studies that led to the selection of the MMC are highlighted. The MMC material and process as it applies to the specific component is then described. Finally, the benefits that have resulted from the use of MMCs are highlighted. In this article, a distinction is drawn between applications for aeronautical systems, which are covered here, and space systems, which are covered elsewhere in this Section. Many important applications of DRA are established in aeronautical systems for thermal management and electronic packaging, but these are covered elsewhere in this Section (in the article “Thermal Management and Electronic Packaging Applications”). Automotive uses of MMCs are described in the article “Automotive Applications of Metal-Matrix Composites” in this Section.

Aeronautical Applications of Metal-Matrix Composites

Daniel B. Miracle, Air Force Research Laboratory

Aerostructural Applications

Ventral Fin. The F-16 aircraft has two ventral fins on the lower half of the fuselage just aft of (behind) the wings (Fig. 2). In a number of operational regimes, including those with high angles of attack, the horizontal stabilizers become less effective due to turbulence from the wings. The purpose of the ventral fins is to provide additional flight stability to the aircraft under such conditions. The ventral fins are subjected to aerodynamic loading and require high strength and stiffness. The ventral fins, however, were experiencing a higher than expected rate of failure. The failure mode was dramatic and resulted in complete destruction of the component. The cause of these failures was identified as unanticipated loading from aerodynamic turbulence (that occurred during certain flight maneuvers), such as a rapid decrease in power to the engines (a "throttle chop"). This causes a wave of highly turbulent air, originating at the front of the engine intake, to propagate along the fuselage. The ventral fins were subjected to a rolling moment and a first mode torsion, which twisted the fin along the fuselage axis. Measurements on operational aircraft during such maneuvers showed that the peak-to-peak amplitude of the ventral fin oscillation at the tip, resulting from the rolling moment, was as much as 10 cm (4 in.). These bending moments produced elongation of the bolt holes and eventual failure. While pilot and aircraft were not seriously endangered, the frequent failures led to high downtime and significant repair costs.

Fig. 2 An F-16 aircraft, illustrating the ventral fins, which are located on the bottom of the fuselage just aft of (behind) the wings. The ventral fins are now assembled from 6092/SiC/17.5p discontinuously-reinforced aluminum sheet material produced via a powder metallurgy process.

The original ventral fins were made of a built- up structure consisting of a 2024-T4 aluminum alloy sheet over an internal structure. This internal structure consists of a central root rib that projects normal to the fuselage skin, and a front and rear spar, which are parallel to the fuselage skin. The sheet is attached to these structures, and a honeycomb core completes the assembly. The assembly is attached to an engine access panel, which is, in turn, attached to the fuselage. Design trade studies were conducted to identify the best solution to the ventral fin

failure problem described. Critical design properties included high stiffness and good high cycle fatigue strength. Preferred solutions that would provide the same form, fit, and function of the original design were sought, so that additional certification of significantly different materials or component configurations would not be required. As an example, a preferred solution would allow stripping, painting, and repair of battle damage (bullet holes) by techniques that had already been specified and standardized for the existing aluminum part. In addition, the preferred solution should be affordable. Candidate solutions included a graphite/epoxy skin over the existing spar structure, regions of increased thickness of the original 2024-T4 aluminum alloy, and a DRA sheet over the aluminum alloy spar. Graphite/epoxy was eliminated because of the difficulties of support and cost, and the modified aluminum alloy and DRA approaches underwent testing.

The DRA material selected for study was 6092/SiC/17.5p. The 6092 aluminum matrix alloy is a modified 6*xxx* age-hardenable aluminum alloy that was optimized to be used as a matrix alloy for DRA. This alloy has been approved by the Aluminum Association and is the DRA matrix analog to 6013. Design trade studies and material and process development were undertaken as a collaborative effort between Lockheed-Martin, the U.S. Air Force Air Logistics Center at Ogden, UT, DWA Aluminum Composites, and the U.S. Air Force Materials and Manufacturing Directorate. Material and process development and process scale-up were conducted by DWA Aluminum Composites Specialties, Inc. under a contract with the U.S. Air Force. In this work, powder handling, mixing, outgassing, and consolidation were established. Sheet rolling of consolidated powder was also established. Initial billets 51 cm (20 in.) in diameter were extruded to 7.5 × 36 cm (3 × 14 in.) rolling stock. This was cut to 66 cm (26 in.) lengths, then cross- rolled from 36 cm to 76 cm. The material was then rotated 90° and rolled to final thickness (3.18 and 1.02 mm, or 0.125 and 0.040 in.). The material was sheared to length, heat treated, and quenched. Flatness was obtained by stretching (3.18 mm) or offset rolling (1.02 mm). The DRA sheet was then inserted into the existing repair line established for the original aluminum fins. The only modifications required were the use of polycrystalline diamond tooling and a new chemical masking agent. The standard chemical milling process established for the original aluminum component was used for surface activation required for adhesive bonding to the honeycomb core.

In addition to establishing the commercial processes required to produce the DRA material in sufficient quantity and of quality, the DRA material satisfactorily completed the rigorous testing schedule required for MIL-HDBK-5 certification testing, providing design-allowables properties for the 6092/SiC/17.5p material. Data obtained from this study are shown in Table 1. The design trade studies showed DRA to be the preferred solution. Extensive flight testing was conducted in collaboration between the U.S. Air Force, Lockheed Martin, the Royal Netherlands Air Force, and the National Aerospace Laboratory of the Netherlands (NLR). The flight testing was fully successful, and the DRA ventral fin has been established as the preferred spare.

Table 1 Properties of 6092/SiC/17.5p and 2009/SiC/15p-T4 MMCs

Property	6092/SiC/17.5p	2009/SiC/15p-T4
Tensile yield strength, MPa (ksi)	434 (63)	343 (54)
Ultimate tensile strength ± 1 standard deviation, MPa (ksi)	490 (71)	498 ± 4.5 (72 ± 0.7)
Tensile modulus, GPa (10^6 psi)	107 (15.5)	93 (13.5)
Strain to failure, %	6	6.2
Fracture toughness, MPa $\sqrt{m}$(ksi $\sqrt{in.}$)	Not measured	25 (23)
High cycle fatigue strength at 10^7 cycles	Not measured	270 (39)
Bearing ultimate strength (*e*/*D* = 2.0), MPa (ksi)	924 (134)	Not measured
Shear strength (longitudinal), MPa (ksi)	296 (43)	Not measured
Density, g/cm^3 (lb/in.^{3})	2.80 (0.101)	2.83 (0.102)

The DRA sheet provided a 40% increase in specific stiffness over the baseline design. This increased stiffness nearly eliminated the first mode torsional loads on the fin, providing a solution to the bolt hole elongation. Instrumented flight testing showed that the peak tip deflections of the ventral fin were reduced by 50%. As a result of this effort, replacement of the original ventral fins is now in progress with the 6092/ SiC/17.5p DRA ventral fins. A projected improvement in service life of 400% is expected for the new ventral fins, and flight experience over the past several years now bears this number out. The reduced maintenance, inspection, and downtime costs associated with the DRA ventral fins have resulted in a life-cycle cost savings to the Air Force of over $26 million.

Fuel Access Door Covers. During high-G maneuvers, the fuselage of the F-16 aircraft is subjected to bending stresses, which produce significant axial stresses in the skin. The upper fuselage skin is perforated by many fuel access doors (Fig. 3). In the original aircraft design, these doors did not carry any of the load in the fuselage skin, and so the corners of the door openings act as stress concentrators. As a result, the F-16 fuselage skin was cracking near the vertical tail root. As a solution to this problem, special door fasteners were designed that allowed the doors to carry some of the load, thus reducing the stress at the door openings. These new fasteners required a redesign of the doors, since the original doors were not designed to support a load. Several design options were considered, including 2024 Al doors of double thickness and 6092/SiC/17.5p DRA doors. Critical design properties for the new doors included high strength and stiffness, high bearing strength, good high-cycle fatigue resistance, and compatibility with jet fuel equivalent to aluminum alloys.

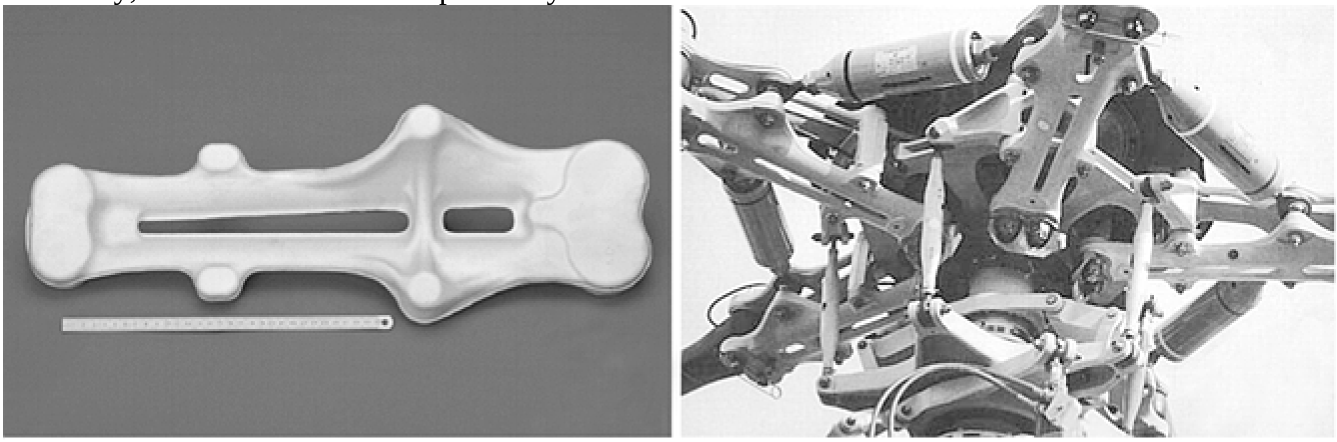
Fig. 3 An F-16 center fuselage, illustrating the size and location of fuel access door covers, which are located between the wings. Of the 26 doors on each F-16, 23 are now made from 6092/SiC/17.5p discontinuously- reinforced aluminum.

The doors are made of 6092/SiC/17.5p wrought P/M material in sheet form. The process is identical to that described for the F-16 ventral fins, with the exception that the final sheet thickness is 2.54 mm (0.10 in.) for most doors, with a few at 2.03 mm (0.08 in.). After producing the sheet, the doors are shipped to the fabricator. The final dimensions are obtained with a high-speed routing operation followed by finish machining. Holes are pre-punched and then drilled. Routing and drilling are done with diamond tooling, and the punching operation is done using standard equipment. The DRA punches much better than standard aluminum alloys do, due to the higher modulus. The punched surface is much cleaner, with no edge rollover. The door is roll-formed to the final contour and given the final aging heat treatment. Since the upper fuselage skin is a fuel- cell wall, the door material must be compatible with JP-4 jet fuel. Exposure studies established that the DRA response is equivalent to that of the unreinforced metal alloy. The part is cleaned and painted in a final operation.

In combination with the improved door fasteners, the 6092/SiC/17.5p DRA doors provided the best solution to the cracking problem because of the combination of higher specific strength and stiffness compared to that of 2024 aluminum. The DRA was also able to satisfy a higher bearing allowable, which was required by the new door fasteners. Doors of DRA have been inserted in 23 of the 26 fuel access doors on the F-16 aircraft in an active retrofitting program called Falcon Up. This is the first military retrofit application for a MMC. As a result of the new doors and fasteners, the peak skin stresses have been reduced by 38% and the average skin stresses have been lowered by 10%. This has fully eliminated the cracking previously observed in the F-16 upper fuselage skins and has extended the durability life calculation for the F- 16 fuselage to over 8000 flight hours.

Helicopter Blade Sleeve. The Eurocopter France EC120 and N4 helicopters are used for civilian law enforcement and search and rescue in Europe, the United States, and in many other countries. The large centrifugal loads of each rotor blade (the N4 has five blades) are supported by a blade sleeve, which holds the rotor blade to the drive shaft (Fig. 4). This component requires an infinite fatigue life, excellent fretting fatigue resistance, high specific strength, and good fracture toughness. The blade sleeve is designated as a Class I vital critical rotating part, since component failure results in total loss of the craft and its inhabitants. Helicopter

performance and durability are linked very strongly to rotating mass, and the principle motivation for consideration of DRA in this application is the reduction in rotating mass and the high cost associated with titanium alloy, which has now been replaced by DRA.



(a) (b)

Fig. 4 EC-120 helicopter rotor application. (a) Rotor blade sleeve. The part is made of forged 2009/SiC/15p discontinuously reinforced aluminum (DRA). The scale below the part is 30 cm long. (b) Rotor assembly showing the DRA blade sleeves. Photos courtesy of DWA Aluminum Composites, Inc.

Forged 2009/SiC/15p-T4 DRA has replaced the wrought titanium alloy component originally specified. Extrusion of a 36 cm (14 in.) P/M billet, which weighs 95 kg (210 lb), provides a 95 mm (3.7 in.) diameter preform. After cutting to length, each piece is blocker forged, followed by closed-die forging to a sonic inspection envelope. The sonic envelope is also the final component shape, and less than 1% of material is discarded as scrap after drilling and final machining. As a result of the criticality of this component, extensive testing and certification are conducted. Twenty-five-year traceability is provided for raw materials and finished goods via archived documentation of processing and inspection. In addition to measuring minimum mechanical properties in the transverse orientation on each billet, the electrical conductivity (as a quality check for microstructural uniformity), chemistry, reinforcement volume fraction, and density are also documented for each billet. Inspection is performed via a macroetch and ultrasonic inspection using MIL-STD 2154 Class AA (no defect ≥1.2 mm, or $\frac{3}{64}$in., is allowed). The primary requirement is for infinite fatigue life. The 2009/SiC/15p-T4 material has a fatigue strength of 270 MPa (39 ksi) at 10^7 cycles, compared to 155 and 180 MPa (22 and 26 ksi) for 2024-T4 and 7075-T6, respectively. This excellent fatigue performance allows DRA to compete successfully with wrought titanium. The fracture toughness of this DRA material is 25 MPa $\sqrt{m}$(23 ksi $\sqrt{in.}$), and the specific strength is comparable to the displaced titanium alloy. Other properties for the 2009/SiC/15p-T4 DRA material are provided in Table 1.

Nearly 14 kg (over 30 lb) of rotating mass have been saved by the use of 2009/SiC/15p-T4 DRA, which is a dramatic reduction for helicopter rotors. In addition to reduced weight, the DRA blade sleeves are less costly to produce, providing a saving in acquisition cost. This is the first aerospace application of DRA in a fracture-critical component.

Aeronautical Applications of Metal-Matrix Composites

Daniel B. Miracle, Air Force Research Laboratory

Aeropropulsion Applications

Fan Exit Guide Vane. The fan exit guide vane (FEGV) of high-bypass gas turbine engines removes the “swirl” component of bypass air, so that maximum thrust can be obtained from the redirected air flow. In commercial engines, primary design requirements include high specific stiffness, excellent erosion and ballistic response,

and low acquisition and support costs. Recent engines have specified graphite/epoxy for this application. However, poor ballistic performance and susceptibility to erosion from airborne particulates and rain have led to high in- service costs and concerns regarding flight safety. An interim solution, bonding a titanium- alloy foil over the graphite/epoxy leading edge, provided improvement in the erosion response (but no improvement in ballistic performance) and increased the cost significantly.

Between 1996 and 1998, 6092/SiC/17.5p DRA has entered service in the Pratt & Whitney 4084, 4090 and 4098 engines, replacing graphite/epoxy. The DRA material is a P/M product that is consolidated into billets. A large reduction ratio during extrusion provides improved particulate distribution, which enhances the fracture properties of the material. A high-tolerance extrusion produces the net shape airfoil contour of the component, and a double-hollow internal configuration is produced to remove unnecessary mass (Fig. 5). The bridge between the two hollow cavities is both formed and joined during the extrusion process, and this bridge improves the structural performance of the airfoil. The resulting DRA component weight is equivalent to the solid graphite/epoxy unit initially specified. Extrusion of this part utilizes existing metalworking infrastructure with only minor modifications. The extrusion die is a standard tool steel die, with a Ferro-TiC die insert. (Ferro-TiC, a trademark of Alloy Technology International Inc., is a discontinuously reinforced iron alloy that uses TiC particulates as reinforcement; it is used in the tool and die industry, and for high wear applications such as industrial rollers.) Current FEGV dimensions include a chord width of 14 cm (5.5 in.) or 19 cm (7.5 in.) and a length of 61 cm (24 in.). After cutting to length, each part is coined to provide a slight camber and is then embedded in thermoplastic end fittings with an elastomeric coupling agent. Over 10,000 piece parts have been manufactured to date.

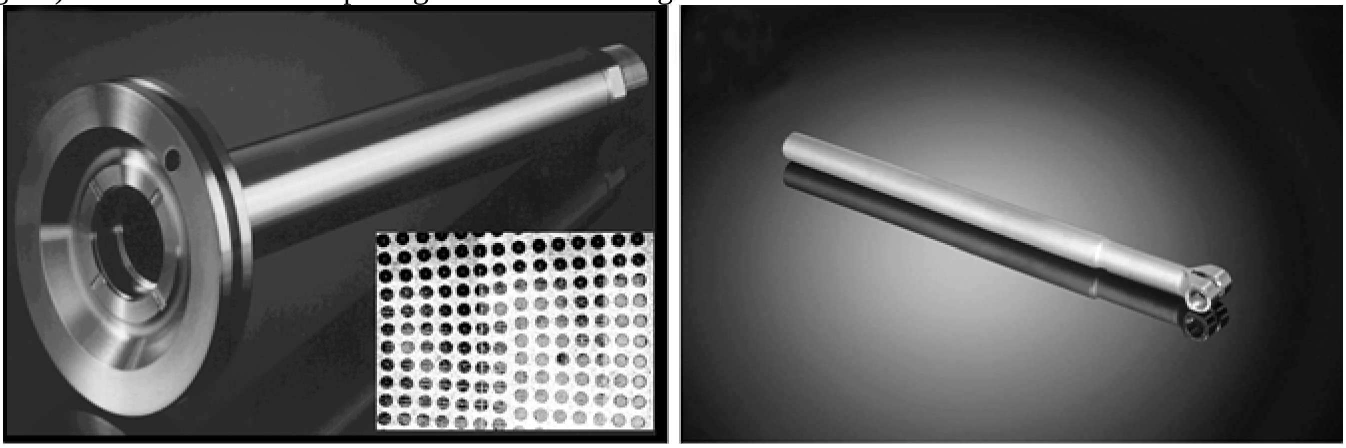
Fig. 5 Fan exit guide vane blank (top), showing the high quality of the as-extruded product and the double-hollow construction. Below is an assembled fan exit guide vane mounted in the endcap. This component is used in Pratt & Whitney 4084, 4090, and 4098 gas turbine engines. Component dimensions are provided in the text. Courtesy of DWA Aluminum Composites, Inc.

This component, used in engines that power the Boeing 777 aircraft, was the first commercial aerospace production application of DRA. The DRA components have demonstrated a seven- fold reduction in erosion rate and significant increase in resistance to ballistic damage from foreign objects, such as hailstones. A dramatic reduction in the unit acquisition cost was realized at the time of introduction. In addition, an overall increase in service life of 300% and reduced maintenance and repair costs also increase the life-cycle cost savings. The total realized savings since introduction has been well in excess of $100 million.

TMC Nozzle Actuator Piston Rod. Turbine- engine nozzle flaps increase the efficiency of gas turbine engines by controlling the velocity and, in some cases, the direction of the exhaust gas. This is accomplished by controlling the nozzle flap position via actuator and linkage devices. A pair of divergent nozzle flaps are used on each of the two Pratt & Whitney F119 engines used on the F-22 aircraft. Each divergent nozzle flap is driven

by an actuator assembly consisting of a hydraulic cylinder and a metallic piston, which is connected, in turn, to a linkage mechanism. The piston must support large axial loads and must also possess high stiffness. Weight is a primary concern in the F-22 aircraft, so specific strength and stiffness are the primary selection criteria. The piston rod is subjected to fatigue loading, and the maximum operating temperature is 450 °C (850 °F). The initial material specified for the piston actuator was a solid rod of 13-8 Cr-Ni precipitation hardened stainless steel, which has now been replaced by a SiC fiber- reinforced titanium alloy MMC. This MMC is often referred to as a titanium-matrix composite (TMC), and it is inferred that the reinforcement is continuous when this acronym is used.

The TMC actuator piston rod is manufactured by a novel metal wire process. A Ti-6Al-2Sn- 4Zr-2Mo (Ti-6242) alloy is hot-drawn in a conventional wire drawing process to a diameter of 178 μm (0.007 in.). The Trimarc-1 SiC monofilament reinforcement is 129 μm (5.07 × 10–3 in.) in diameter, and is produced by a chemical vapor deposition process on a tungsten wire core. An outer C-based coating protects the fiber from chemical interaction with the matrix during consolidation and service. The Ti-6242 metal wire is combined with 34 vol% of the SiC monofilament by wrapping on a rotating drum. The wires are held together with an organic binder and are then cut and removed from the drum to make a preform "cloth." This cloth is wrapped around a solid titanium mandrel, so that the SiC and Ti-6242 wires are parallel to the long axis of the mandrel. A short Ti-6242 cylinder, with an outer diameter of 10 cm (4 in.) and 5 cm (2 in.) high, is placed around one end of the cloth- wrapped mandrel, from which the piston head will be formed. After hot isostatic pressing consolidation, the piston head is machined from the stocky cylinder at one end of the piston, and a threaded connection is machined from the titanium mandrel at the other end. The remainder of the mandrel is removed by gun drilling. The final component is 30.5 cm (12 in.) long, and the shaft is 3.79 cm (1.49 in.) in diameter (Fig. 6a). The excellent fiber spacing is shown in the figure inset.



(a) (b)

Fig. 6 Jet engine applications of titanium-matrix composites. (a) A nozzle actuator piston rod used on the Pratt & Whitney F119 engine for F-22 aircraft. The part is made of a Ti-6Al-2Sn-4Zr-2Mo alloy reinforced with SiC monofilaments that are 129 μm in diameter. The inset shows the typical distribution of the SiC reinforcements (inside diameter of the rod is to the left in this inset micrograph). (b) A nozzle actuator link from the General Electric F110 engine, made of a similar metal-matrix composite, used for F-16 aircraft. Component dimensions are provided in the text. Courtesy of Atlantic Research Corporation.

The use of a TMC in the actuator piston is a landmark application and represents the first aerospace application of TMCs. In addition to providing significant improvement in the specific strength and stiffness over steel (compare steel properties, indicated by the diamond data point, with Ti/SiCf in Fig. 1), the TMC material passed fatigue properties certification by a very wide margin. Certification of the TMC actuator piston rods has resulted in a direct weight savings of 3.4 kg (7.4 lb) per aircraft. The F-22 is an extremely weight-sensitive aircraft, so this weight savings is considered significant. Further, since the weight removed is in the aft end of the aircraft, counterweights added in the fore section of the aircraft to shift the aircraft center of gravity forward can also be removed, providing additional weight savings. At the time of publication, the first orders of the TMC actuator pistons had been shipped for the initial production phase of F-22 aircraft.

TMC Nozzle Actuator Links. Based on the experience gained from the success of the TMC actuator piston rod, TMCs have now been certified as nozzle links on the General Electric F110 engine, used for F-16 aircraft. The nozzle of the F110 engine consists of 24 nozzle flaps arranged symmetrically around the exhaust periphery in a "turkey feather" configuration. Every second nozzle flap is driven by an actuator via a nozzle link, so that 12 TMC nozzle link actuators are now specified for each engine. The original link was produced from a square tube of Inconel 718, which was formed from sheet and welded along its length.

The manufacturing process begins by winding Trimarc-2 SiC monofilament, which is similar to Trimarc-1 but is produced on a carbon core, on a drum as for the piston rod. Rather than using metal wire, Ti-6242 powder is sprayed with an organic binder over the wound SiC fibers to produce a preform cloth. This cloth is then cut and removed from the drum as before, and wrapped around a mandrel. Added at each end are Ti-6242 fittings for a clevis attachment and a threaded end, and the entire assembly is consolidated via HIP. After machining the clevis and the threaded end, the mandrel is removed. A finished part is shown in Fig. 6(b).

The new TMC links have been certified for F110 engine rebuilds in the F-16. The TMC links provide a 50% increase in buckling resistance relative to the Inconel 718 component. Insertion of the TMC links have provided a direct weight savings of over 2 kg (4.5 lb) per shipset. This application provides a low-risk first insertion of TMCs for the F110 engine. From this, the end- user will gain critical field experience in the application and support of TMCs, and the manufacturer (Atlantic Research Corporation) will be able to identify and implement important process improvements anticipated to improve material quality and reduce costs.

Aeronautical Applications of Metal-Matrix Composites

Daniel B. Miracle, Air Force Research Laboratory

Aeronautical Subsystem Applications

T-1 Racks. The first flight application of DRA in a military aircraft occurred as avionics support racks for the Lockheed-Martin U2/TR-1 Spy Plane. The material used was 6091/SiC/25p DRA. The matrix alloy is the DRA analog to 6061. The principal requirements for the racks are isotropic stiffness, good bearing strength, and high electrical conductivity, necessary for a high-quality grounding plane for the avionics. The original structure was an aluminum alloy, but this was replaced by graphite/epoxy in order to save weight. However, the need for isotropic stiffness required a quasi-isotropic lay-up, which produced section channels that were thicker than necessary to support the primary loads. The poor bearing strength of the graphite/epoxy also added weight to the structure, since local reinforcement was required. Finally, the high-quality grounding plane was provided by bonding aluminum foil to the structure. This added both weight and cost, and introduced significant support issues when the aluminum foil was damaged as avionics racks were slid across the surface.

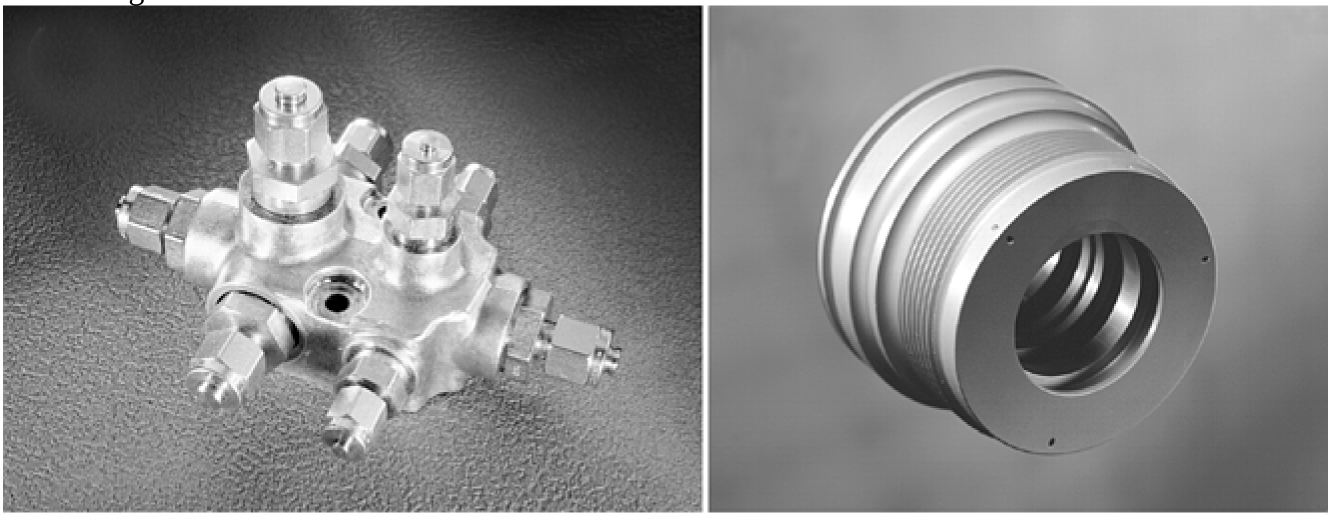
The rack section channels were the first successful attempt to produce precision mill shapes of DRA from multiple-holed extrusion dies. Straight tubing was produced with a minimum gage thickness. The reduced mass allowed by the minimum gage, along with the high intrinsic electrical conductivity and good bearing strength, allowed the DRA rack to save 20% in weight over the graphite/epoxy design and 34% relative to the original aluminum design. Reduced material costs improved manufacturability, and improved supportability led to reduced component cost. This part was first introduced in 1988.

Hydraulic Manifold in V-22 Osprey Tiltrotor and F-18 E/F. Materials of DRA are being used to produce hydraulic manifolds for the Navy Osprey V-22 Tiltrotor aircraft. The manifolds redistribute high-pressure hydraulic fluid (up to 70 MPa) to flight control surfaces. In addition to high mean pressures, the manifold is subjected to impulse loading during flight. The operating temperature is up to 100 °C (210 °F). Selection criteria include affordable near net shape processing, high specific strength to support the high hydraulic pressures, and good resistance to high-cycle fatigue from the impulse loading. Two manifolds are used for each V-22 aircraft.

The initial design specified 7050 aluminum, but the hydraulic manifold failed in burst tests, so a whisker-reinforced 2009/SiC/15w DRA is now being used. Components are manufactured by a P/M process, whereby a solid block is produced, and the manifold is machined from this solid block of DRA. This material satisfies the

service requirements, but the material cost is high due to the whisker reinforcements used. The component cost is high due to the significant machining required.

An alternate DRA material, A206/SiC/40p DRA, produced by pressure infiltration casting of a molten aluminum alloy into a particulate ceramic preform, is now being pursued. Preform manufacture is simplified by a unique castable process, providing a preform that is near net shape. Controlled reinforcement volume fractions from 30 to 70% can be achieved. A clean preform that is free of organic material is produced, and a uniform particle distribution is achieved. This process uses low-cost SiC particulates, which significantly reduces the cost of producing a manifold. The near net shape processing requires only finish machining, further reducing component cost. Full-scale components have passed proof, impulse, and burst testing. This component was awaiting certification testing by Bell Helicopter at the time of publication. An image of this component is provided in Fig. 7.



(a) (b)

Fig. 7 Manifold applications. (a) A manifold used to redistribute high-pressure hydraulic fluid to flight control surfaces in V-22 Osprey Tiltrotor aircraft. This component is made by infiltration casting of A206/SiC/40p discontinuously reinforced aluminum. Courtesy of Triton Systems, Inc. (b) A fluid manifold end gland currently used in F-18 E/F aircraft as part of the subsystem that controls the rudder and aileron. The material is a powder metallurgy discontinuously reinforced aluminum, 2009/SiC/15p. Dimensions for the end gland are provided in the text. Courtesy of DWA Aluminum Composites, Inc.

A DRA fluid manifold end gland is currently in production for the F-18 E/F. This component is part of the subsystem that controls the rudder and aileron. The end gland is 7.5 cm (3 in.) in diameter and is less than 7.5 cm (3 in.) in length. There are two fittings per aircraft. The operational conditions are similar to those described for the V-22 manifold. In addition, this component requires good wear resistance. The original component was made from an aluminum bronze. While this performed well, the high density of this material led to an excessive part weight. The DRA component is made from 2009/SiC/15p, which is machined from an extrusion. This is precisely the same material and process as described above for the helicopter blade sleeve, and so certification requirements were minimal. The DRA component provides reduced weight, and has a lower coefficient of thermal expansion, a higher wear resistance, and a fatigue limit that is twice that of the initial component. This last property is notable, since standard high-strength aluminum alloys typically possess poor fatigue response in hydraulic fluid when the pressure is greater than about 34 MPa (5 ksi). As a result, titanium is often specified for these applications. However, the DRA component performed very well in fatigue testing in high-pressure hydraulic fluid, so that DRA can now be considered a replacement for titanium alloys in similar applications.

Implementation Strategy

Critical evaluation of the case histories above provide useful guidance for future successful efforts to apply MMCs in new applications. Since technical considerations for the selection of an MMC are reviewed earlier in this article and elsewhere in this Volume, discussion here emphasizes nontechnical approaches. Experience has shown that the nontechnical factors are often at least as important as are the technical details in selecting materials to meet specific application requirements.

In every single component described above, the MMC displaced some other material that had been initially specified. This reflects the embryonic familiarity and confidence with which the design community views MMCs. This poor familiarity is manifested as a perceived high initial cost, concern about availability and depth of supply chain, lack of field experience, questions on reparability, and knowledge base and analysis tools available to design engineers that address MMCs. It is therefore essential that an internal advocate exists within the organization considering the use of an MMC. This advocacy function must be knowledgeable in MMC capabilities and limitations and should also possess some contact within the design function for the organization. Previous examples described herein also strongly support the importance of a close collaboration between the system manufacturer, the materials and component suppliers, and the end-use customer. The customer (or user) provides system requirements and constraints. When a solution to an existing problem is sought, the customer can provide information relating to causes and modes of failure; the customer establishes the value of the proposed improvement and also may provide insights into possible solutions. The manufacturer typically provides the design function. Internal testing and certification by the manufacturer is also critical, since data generated in house is often considered more relevant and reliable. Finally, the supply chain provides detailed information regarding the material capability and processing options and limitations. Such partnerships divide the risk and combine expertise to achieve an optimum solution. Many of the successes described resulted from such teamwork.

Another important point is that MMCs nearly always solved an existing operational problem or deficiency in the previous examples. Very infrequently are new materials such as MMCs selected simply because they provide a benefit over an existing system if that system is not currently deficient in some operational consideration. This follows from the high cost of certifying a new material and from the conservative design philosophy typically followed in the aeronautical industry.

The approach of developing a single MMC material that can satisfy the requirements for a range of applications is an effective strategy for reducing certification costs. Thus, certification costs for a particular material can be shared by several business units within a given company. Multiple applications provide an expanded payoff, thus providing a better return on investment for certification costs. In two cases above, a second application of an MMC within an organization followed a successful first insertion. A related approach is to form cross-industry teams (such as aeropropulsion and rocket propulsion, or aerostructures and automotive), which can share ideas and resources while minimizing issues of competition. Thus, a useful materials development strategy is to achieve a balance of properties that are acceptable for several requirements, rather than tailoring an MMC to achieve an optimum set of properties for a single application. Again, this approach shares the risk and expands the impact.

With regard to fiber-reinforced MMCs, the conservative approach of focusing on applications with simple geometric shapes and relatively low risk for failure is proposed until the technology matures and designer familiarity and confidence increases. Components with nearly axial loading are also suggested, since the technology for producing isotropy via cross-plied architectures is expected to remain difficult in the coming years.

View of the Future

While the emphasis of this Volume is as a practical guide for existing technologies, a brief look forward may be helpful to anticipate and benefit from major advancements as they develop.

The use of DRA is almost certain to continue the current trend of increasing application. The existing stable, production-oriented supplier base has brought costs down significantly, so that cast DRA can compete on a cost basis in some applications even with steel, and P/M DRA competes very favorably with titanium alloys. Subsystem uses provide the lowest risk of insertion, but aerostructural applications are expected to provide a strong market. Cast DRA is the standard MMC material and process for the automotive industry, and steady progress in this technology, especially infiltration casting, for high-quality aerospace applications is expected to produce initial applications in coming years. This near net shape process will improve the overall affordability of this material. Efforts to produce uniform ceramic preforms at reinforcement volume fractions below 30% is important to ensure that infiltration cast DRA components retain adequate fracture properties.

A great deal of progress has been achieved in producing affordable aluminum MMCs reinforced with alumina fiber tows. This is now a commercial product, and markets include high- performance automotive and mechanical subsystems. Power transmission cables are likely to enter first service within a few years. Many aerospace applications have largely axial loading and simple component shape, and so are candidates for this material. Candidate components include cases, shrouds, struts, rods, and shafts. In many cases these have requirements that eliminate organic-matrix composites from consideration, and so significant benefit over existing metal materials are expected. The processing technology has been well established for a simple unit product shape.

Two remaining MMC technologies with significant potential in the next ten years include DRA for application at temperatures up to about 200 °C (400 °F), and DRTi. High-temperature DRA is a prime candidate for replacing many titanium components that are specified because the use temperature is just a little higher than the full-life capability of aluminum alloys (about 150 °C, or 300 °F). Examples include engine pylon structures for transport aircraft and aft fuselage structure for fighter aircraft where the engine is embedded in the fuselage. In both cases, conduction and radiation from the engine heats the surrounding structures. Titanium provides a significant cost and weight penalty, and so is an important target for these applications. The DRTi materials may provide the highest level of isotropic strength and stiffness of any common structural material and so have a very broad range of possible applications. The DRTi materials may be produced by cast, wrought, or P/M technology, providing flexible processing and forming options.

High-Temperature Applications

Tito T. Serafini; Stephen C. Mitchell, General Electric Aircraft Engines

Introduction

HIGH-TEMPERATURE-RESISTANT POLYMERS are used in aerospace, electronic, and other applications that demand outstanding elevated-temperature physical and mechanical properties. Major product forms of these polymers include adhesives, coatings, fibers, film, foam, insulation paper laminating resin solutions, molding powders, and wire enamels. A wide range of literature is available on their chemistry, processing characteristics, properties, and applications.

Early applications of high-temperature polymers as matrix resins in fiber-reinforced composites were limited to nonstructural (nonload- bearing) components. However, following the development of in situ polymerization of monomer reactants (PMR) polyimides at the National Aeronautics and Space Administration (NASA) Lewis (now NASA Glenn) Research Center (Ref 1, 2, and 3) and their commercialization by prepreg suppliers, the fiber-reinforced PMR polyimide based on PMR-15 has found increased acceptance as an engineering material for high-performance structural applications. Because it has become the most widely used high-temperature polymer, most of the applications discussed in this article are representative examples of the use of fiber-reinforced PMR-15 polyimide. In addition, resin systems that compete with and, in some cases, extend the temperature range of PMR-15 are BMI, AFR700C, Avimid RB, PETI, PMR-II, Avimid N, AFR700B, and phthalonitriles. Other resins that have found use in composites for high-temperature applications include phenolics and bismaleimides; applications for these materials are described in the articles “Phenolic Resins” and “Bismaleimide Resins” in this Volume.

General Characteristics

For a material to function as a viable matrix in a fiber-reinforced composite, the matrix must bind the constituents, transfer loads, provide environmental stability, and perhaps most important, provide processibility. Most organic polymers soften or melt below 204 °C (400 °F). The key to preparing high-temperature polymers is to incorporate highly stable structural units in the polymer chain, such as aromatic and/or heterocyclic rings. These structural units are able to absorb thermal energy and contain a minimum of oxidizable hydrogen atoms.

In addition to being resistant to elevated temperatures, many high-temperature polymers are also resistant to being processed into useful structural components. The poor processing characteristics of early high-temperature polymers prevented them from performing the necessary functions of a matrix material.

Composites fabricated with these polymers exhibited high void contents, poor fiber translation efficiencies, inferior elevated-temperature mechanical properties, and inferior thermooxidative stabilities. Little progress was made in developing polymers with improved processibility, because the major thrust of polymer synthesis research up until 1970 was in the area of improved thermal stability, without any concern for processibility.

Condensation-Type Polyimides

High-temperature laminating resins of the class known as condensation-type polyimides were first commercialized in 1962 and 1965 and emerged as the sole contenders for resin-matrix applications. Although these materials presented processing difficulties, they had good high-temperature properties along with cost and availability advantages. Because polyimide laminating resins generally used the same monomers as those used in versions for other product forms, such as film and wire enamels, it was a relatively easy matter to make the laminating resins commercially available at a reasonable cost.

The major problems in processing condensation-type polyimide prepreg materials can be attributed both to the inherent nature of condensation reactions (by-product evolution) and to the use of high boiling point aprotic solvents, leading to void content problems. During thermal processing of the prepreg to effect chain growth and solvent/by-product removal, appreciable imidization also occurs, converting the resin to an intractable state. Reduced resin flow prevents the removal of the last traces of solvent and by-products. The entrapment of these volatile materials results in composites having void contents in the range of 5 to 10 vol%, particularly for thick sections (>1 mm, or 0.04 in.). The presence of these voids adversely affects mechanical and thermooxidative stabilities of the composite.

Applications of Condensation-Type Polyimides. The earliest applications for fiber-reinforced condensation-type polyimides, in 1972, were for radomes on advanced aircraft (Ref 4) and for sound-suppression panels in the engine nacelles of subsonic commercial transports. Both applications can be considered secondary structural applications. In fact, the high void content of condensation polyimides is desirable for the sound-suppression panels. The formidable processing problems of these materials were solved by using dynamic dielectric analysis. More than 200 fiberglass-polyimide radomes measuring 4.6 × 0.5 × 0.6 m (15 × 1.6 × 2.0 ft) have been produced for EA-6B aircraft.

PMR Polyimides

A major advance in high-temperature resins was the development of polyimides that cured by an addition reaction (Ref 5 and 6). Low-molecular-weight amide-acid prepolymers whose chain ends were terminated, or end-capped, were synthesized. In the early 1970s, attempts to commercialize a resin, designated P13N, met

with limited success because of several shortcomings. It was to circumvent the shortcomings of condensation-type and addition-type prepolymer polyimides that investigators at NASA Lewis developed the novel PMR polyimides. In the PMR approach, the reinforcing fibers are impregnated with a monomer reactant mixture dissolved in a low-boiling-point alkyl alcohol, such as methanol or ethanol. In situ polymerization of the monomer reactants occurs when the impregnated fibers are heated, followed by final polymerization to a void-free composite. Further details on the polymer reactions are available in Ref 1 and 7, 8, 9, and 10. Prepreg materials based on PMR-15 are commercially available in the United States from the major prepreg suppliers. The structures of the monomers used in PMR- 15 are shown in Fig. 1. Additional information on resin chemistry is provided in the article “Polyimide Resins” in this Volume.

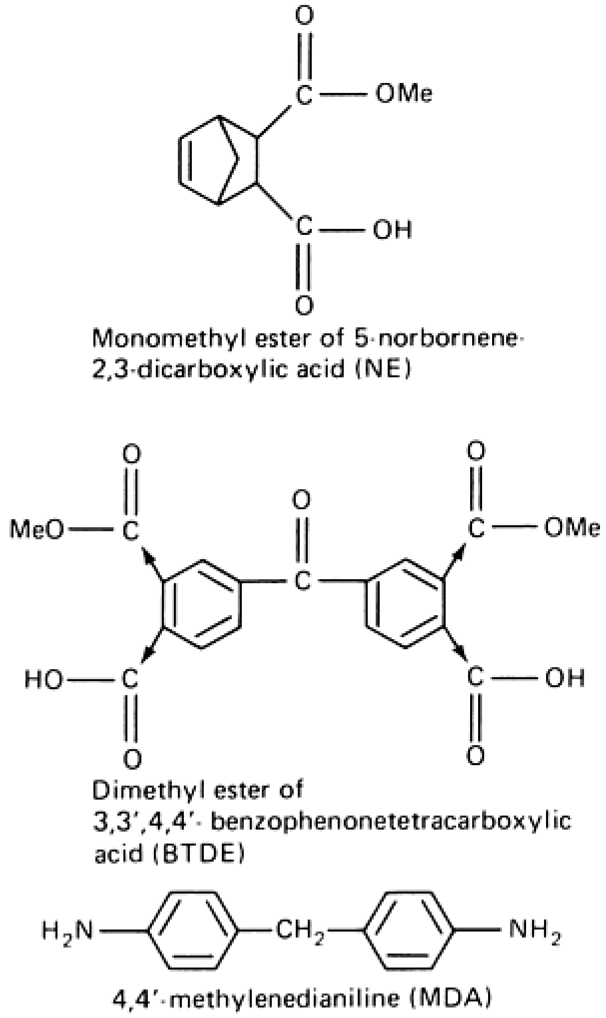

Fig. 1 Structures of monomers used in PMR-15

The early studies (Ref 1, 7) conducted at NASA Lewis also clearly demonstrated the efficacy and versatility of the PMR approach. By varying the chemical nature of either the dialkyl ester acid or the aromatic diamine, or both, and the monomer reactant stoichiometry, PMR matrices having a broad range of processing characteristics and properties could easily be synthesized. Figure 2 shows that significantly higher resin flow for high tensile strength (HTS) graphite-PMR composites can be achieved by reducing the formulated molecular weight. However, the PMR compositions that exhibited increased resin flow were found to be less thermooxidatively stable at 288 °C (550 °F). The lower resin flow and increased thermooxidative stability in going from PMR-10 to PMR-15 clearly show the sensitivity of these properties to imide ring and alicyclic contents. The reduction in resin flow with increased formulated molecular weight also serves to account qualitatively for the intractable nature of condensation-type polyimides at an early stage of their process cycle.

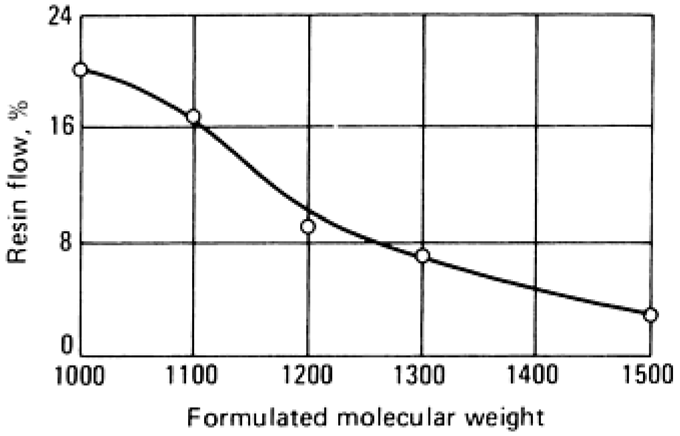

Fig. 2 Effect of formulated molecular weight on resin flow of HTS graphite fiber-PMR

High-pressure (compression) and low-pressure (autoclave) molding cycles have been developed for fabrication of fiber-reinforced PMR composites. Although the thermally induced addition cure reaction of the norbornenyl group occurs at temperatures in the range of 275 to 350 °C (527 to 662 °F), nearly all the processes developed use a maximum cure temperature of 316 °C (600 °F). Cure times of 1 to 2 h followed by a free-standing postcure in air at 316 °C (600 °F) for 4 to 16 h are also normally used. Compression molding cycles generally use high heating rates (5 to 10 °C/min, or 9 to 18 °F/min) and pressures in the range of 3.5 to 6.9 MPa (0.5 to 1.0 ksi). Vacuum bag autoclave processes at low heating rates (2 to 4 °C/min, or 3.6 to 7.2 °F/ min) and pressures of 1.38 MPa (0.200 ksi) or less have been used successfully to fabricate void-free composites. Autoclave processing methodology can be successfully applied to PMR polyimides, because of the presence of a thermal transition, termed melt flow, which occurs over a fairly broad temperature range (Ref 11). The lower limit of the melt-flow temperature range depends on a number of factors, including the chemical nature and stoichiometry of the monomer reactant mixture and the thermal history of the PMR prepreg.

Differential scanning calorimetry analysis has shown that four thermal transitions occur during the overall cure of a PMR polyimide. During the first and second thermal transitions, solvent and condensation by-products can be volatilized without converting the polymer to an intractable state. During the third thermal transition, and with the application of pressure, fusion occurs. At still higher temperatures, and while maintaining the applied pressure, the addition cure reaction occurs. The high-temperature postcure mentioned previously must be used to obtain optimal thermooxidative stability and mechanical properties retention at elevated temperatures. The cure temperature requirements of PMR polyimides exceed the capabilities of many existing autoclave facilities and impose a severe strain on the temperature capabilities of current bagging and sealant materials (Ref 12, 13, and 14). It should be noted that the increase in production applications of high-temperature composites has increased the availability of appropriate high-temperature autoclaves and the ruggedness of bagging materials.

Many investigations have been conducted to determine the effects of various hostile environments on the physical and mechanical properties of PMR-15 composites. The thermooxidative stability and retention of mechanical properties at elevated temperatures have been found to be far in excess of what would be predicted on the basis of polymer molecular structure criteria for polymer thermal stability. Graphite-PMR-15 composites have been reported (Ref 15) to be suitable for use in air at 288 °C (550 °F) for at least 5000 h. At 316 °C (600 °F), the useful life of graphite-PMR-15 composites is in the range of 1200 to 1400 h.

Fiber-reinforced PMR-15 polyimide composites are finding increased acceptance as engineering materials for the design and fabrication of aerospace structural components, particularly in aeropropulsion. Components being fabricated range from small, compression-molded bearings to large, autoclave-molded aircraft engine cowls and ducts. Processing technology and baseline materials data are also being developed for the application of PMR-15 composites in weapon systems. Firms involved in manufacturing small, compression-molded bearings made from particulate or chopped-fiber PMR molding compounds have found it convenient to become captive producers of PMR-15 resin. In contrast, firms involved in fabricating larger components made from tape or fabric materials rely on traditional sources of composite materials for PMR-15 prepreg. Materials based on PMR-15 are commercially available from the major suppliers of composite materials in the form of solutions, molding compounds, prepregs, and adhesives.

The presence of methylene dianiline (MDA) in the PMR-15 polyimide resin requires individuals to comply with the Occupational Safety and Health Administration (OSHA) Standard 29 CFR 1910.1050 document

entitled “Occupational Exposure to 4,4′methylenedianiline (MDA).” This document applies when a material contains greater than 0.1% MDA by weight or volume. Because MDA is a suspected carcinogen, much effort has been put into developing alternatives to PMR-15. Other high-temperature polyimides, such as PMR-II, Avimid N, and AFR700B, do not use MDA. Additional information is provided in the article “Polyimide Resins” in this Volume.

High-Temperature Applications

Tito T. Serafini; Stephen C. Mitchell, General Electric Aircraft Engines

---

Applications of PMR-15

The development of PMR-15 resin as a viable, high-temperature composite system had a profound effect on increasing the number of applications of composite components. Prior resin systems placed significant size and thickness constraints on potential applications; however, the advent of PMR-15 allowed engineers to design large, complex components with thick sections. PMR-15 produced significant interest within the military propulsion community, due to the high operating temperatures within the low-pressure system. In addition, the

high weight savings of composite rotor components saw the initial PMR-15 applications occur in both rotors (blades) and stators (vanes).

The blade illustrated in Fig. 3 was the first structural airfoil component fabricated with a PMR-15 resin and reinforced with HTS graphite fiber. The blade was designed and fabricated for an ultrahigh-speed fan stage (Ref 16, 17). The blade span is 28 cm (11 in.), the chord is 20 cm (8 in.), and the thickness ranges from about 13 mm (0.5 in.) in the dovetail to about 0.5 mm (0.020 in.) at the leading edge. At the thickest section, the composite structure consists of 77 plies of material arranged in varying fiber orientations. The airfoil surface line visible at approximately one-third the height from the blade tip resulted from a change in fiber orientation from 40° in the lower region to 75° in the upper region, in order to meet torsional stiffness requirements. Although some minor internal defects were induced in the blade during low-cycle and high-cycle fatigue testing, the successful fabrication of these highly complex blades established PMR-15 as a processible matrix resin.

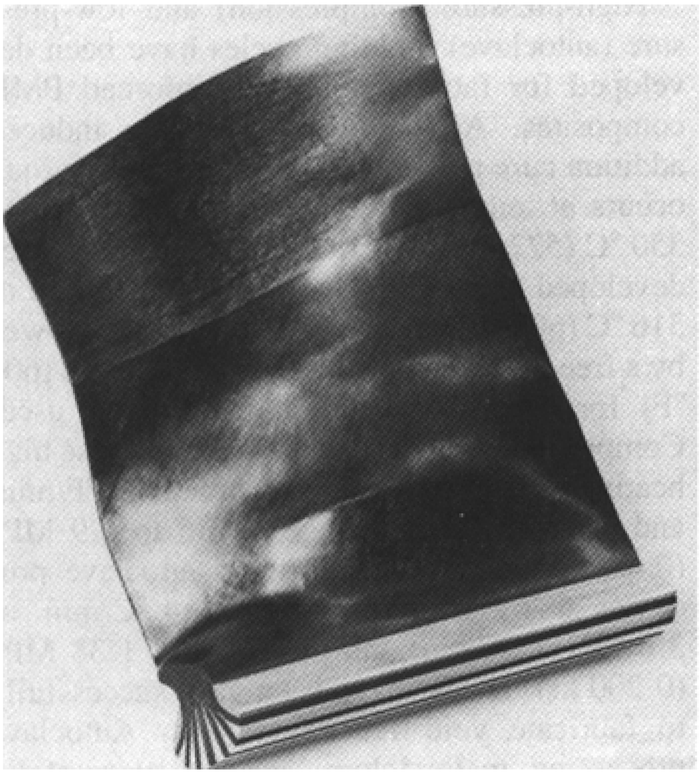

Fig. 3 Graphite fiber-PMR-15 fan blade

Another early application of PMR-15 composites in rotating components was the fourth- stage compressor blade shells and spacers (Fig. 4) in a supersonic wind tunnel. More than 24,000 pounds of fiberglass-PMR-15 were processed for this application (Ref 18). The total quantity of material was equally divided between 360 blade shells and 600 blade spacers.

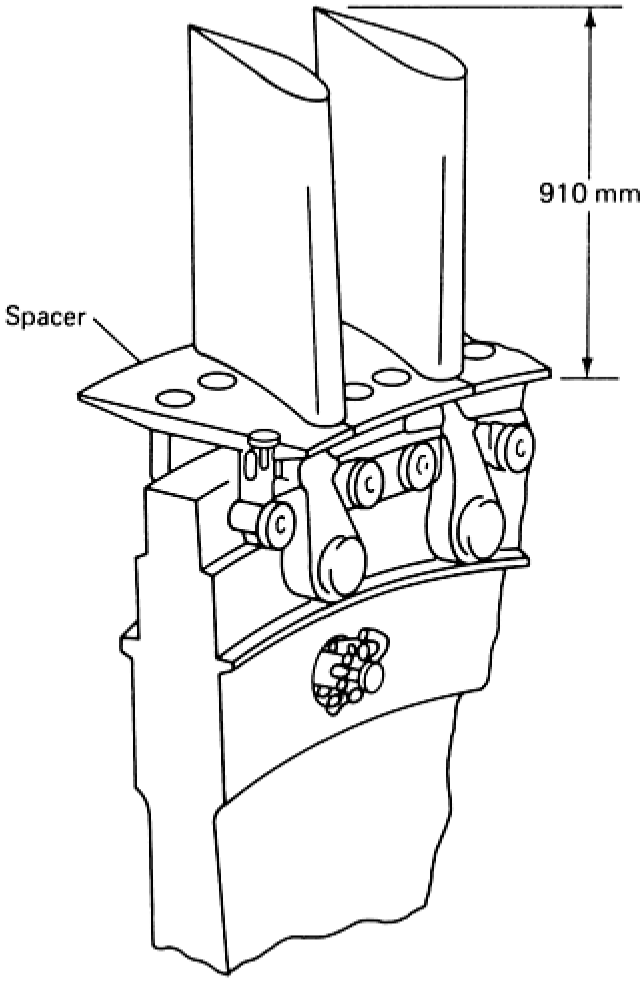

Fig. 4 Application of PMR-15 in supersonic wind tunnel

The success with small airfoil components developed the interest in applying PMR-15 to large static structures. In 1975, NASA and General Electric Aircraft Engines (GEAE) launched the most aggressive use of composite components in a propulsion system. Figure 5 shows a cross section of this quiet, clean, short-haul experimental engine commonly known as the quiet, clean, short-haul, experimental engine (QCSEE) propulsion system. To meet the program goals for low weight, low noise, clean emissions, and improved efficiency, composites were used extensively in the fan blades, vane frame, containment, integrated nacelle, inlet, external flaps, and inner core cowl (Ref 19). The blades, frame, and nacelle components were fabricated with carbon- epoxy tape and fabric; the containment was fabricated with aramid fabric; and the inner core cowl was fabricated with graphite-PMR-15 fabric. The high-temperature environment of the core cowl was not the result of any operating condition, but rather the product of radiant heating at shutdown. The absence of any airflow at shutdown raised the temperature of the core cowl to approximately 315 °C (600 °F).

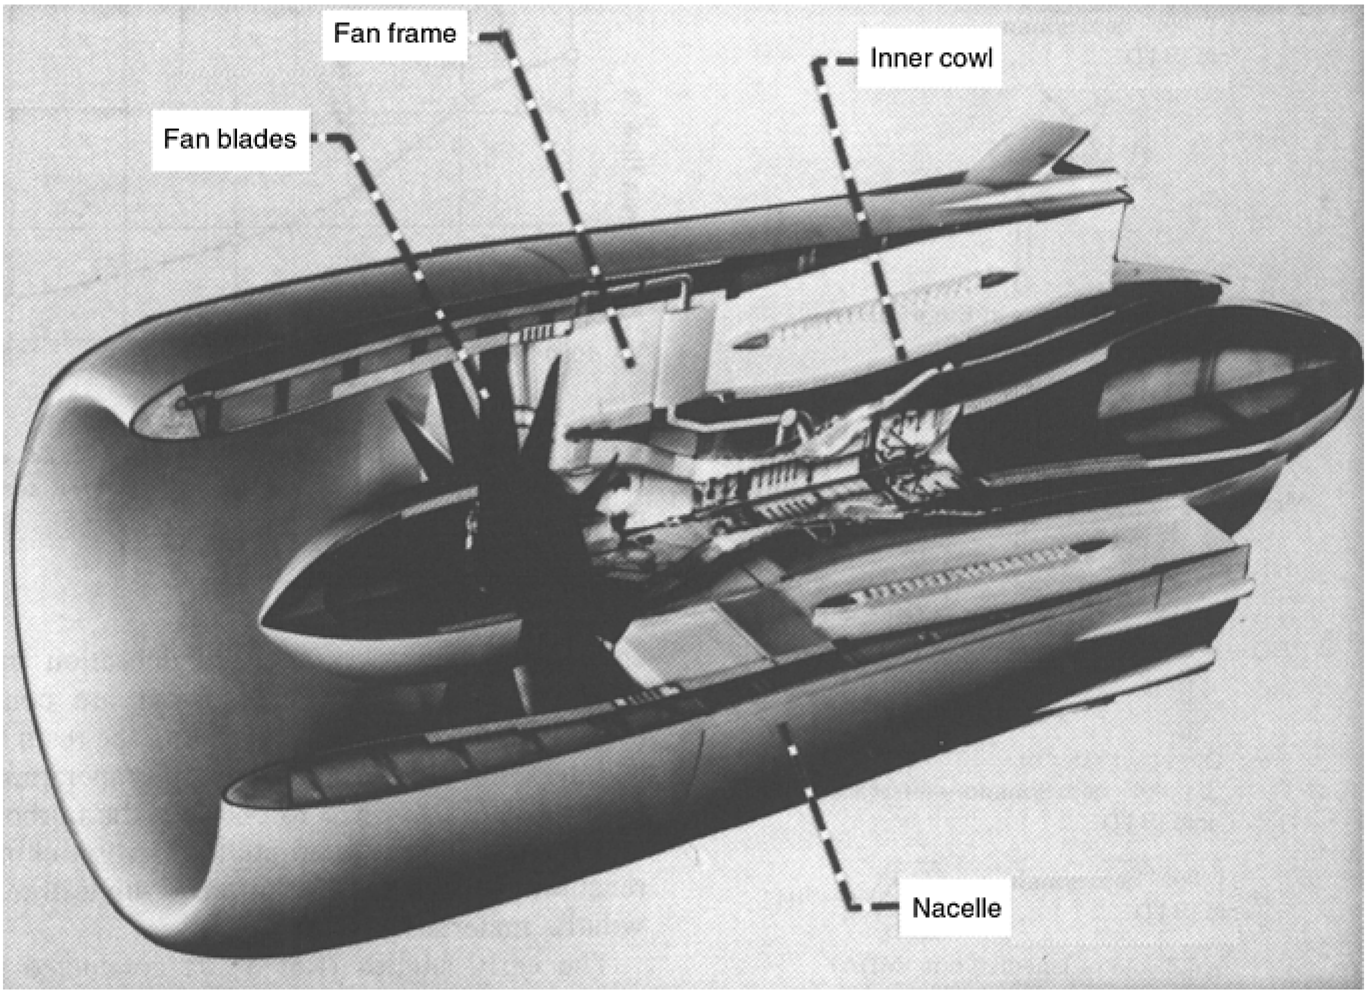

Fig. 5 Application of composites on QCSEE

Figure 6 shows the inner core cowl installed on the QCSEE occupying the region below the pylon and aft of the vane frame. The core cowl was a honeycomb sandwich structure with a maximum diameter of 90 cm (35 in.) and a length of 165 cm (65 in.). Fiberglass-polyimide honeycomb was used as the core material that was bonded to the inner surface of the premolded, perforated outer skin. The inner skin was then cocured to the honeycomb core. In an effort to reduce acoustic emissions, the entire flowpath surface of the core cowl was perforated with 0.5 mm (0.020 in.) holes to a 10% porosity level. In addition, the size limitations of the autoclave forced the core cowl to be a bonded assembly of four sectors. Today's large autoclaves would allow the fabrication of a unitized cowl without any bonded sectors. Complete details of the core cowl fabrication are provided in Ref 20. The cowl did not exhibit any degradation after 300 hours of engine ground testing (Ref 21). The successful autoclave fabrication and ground engine testing of the QCSEE core cowl established the feasibility of using graphite-PMR-15 composite materials for large static structures.

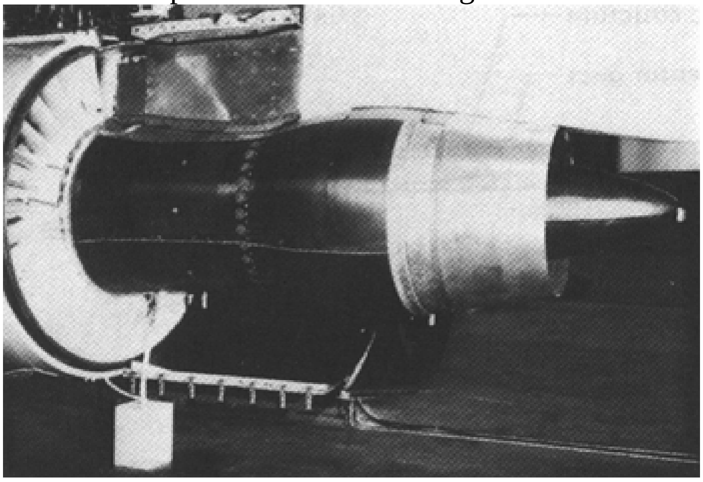

Fig. 6 Carbon fiber-PMR-15 polyimide QCSEE inner cowl

In the late 1970s, the U.S. Navy and NASA jointly sponsored a program (NAS3-21854) to replace the F404 titanium bypass duct with the world's first, large primary production engine structure fabricated with graphite-PMR-15. Studies conducted by GEAE indicated weight savings in excess of 4.5 kg (10 lb) (Ref 22). The duct shown in Fig. 7 is about 75 cm (30 in.) in diameter, 100 cm (40 in.) long, 2.3 mm (0.090 in.) thick, and sized from large loads attempting to compress and buckle the shell. The titanium outer bypass duct is a sophisticated casing located between the engine mounts and fabricated by forming, welding, machining, and chemical milling. Difficulties in the bonding and inspection operations of the QCSEE core cowl dictated that the F404 bypass duct would be a solid monolithic shell. The initial prototype F404 composite ducts contained titanium flanges bonded and riveted to a composite shell; however, within six months, the production duct of the F404 contained integral composite flanges. Another feature of the duct was the use of metal grommets needed for the attachment of approximately 100 configuration components. The top and bottom duct halves are fabricated by hand lay-up of T300 carbon-PMR-15 preimidized fabric into external molds. The parts are then bagged and autoclave cured. Prior to production, the duct successfully underwent 2500 hours of ground testing and 700 hours of flight testing. By 2000, over 1000 composite ducts had accumulated over 1.4 million flight hours on F-18 aircraft.

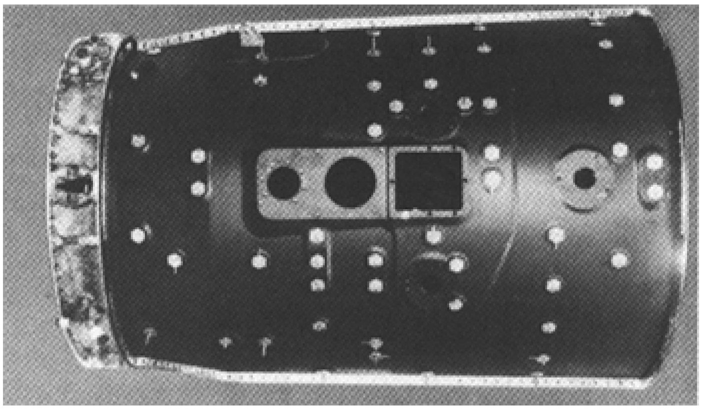

Fig. 7 Carbon fiber-PMR-15 polyimide F404 outer duct

The success of the F404 carbon-PMR-15 bypass duct resulted in a carbon-PMR duct as the prime production “bill of materials” for the F414 in the early 1990s. The F414 duct shown in Fig. 8 became a second-generation component by incorporating several significant improvements in material, manufacturing, and design. To improve thermal oxidation resistance, the carbon-fiber fabric was changed from T300 to T650-35. The lay-up fabrication was improved by changing from two external molds for the top and bottom to one single internal mandrel. The axial flange design was improved by replacing the upright bolted flange used in the F404 with a bolted double-splice joint. These three changes significantly improved the quality and producibility of the F414 duct. The duct was introduced into production in 1997.

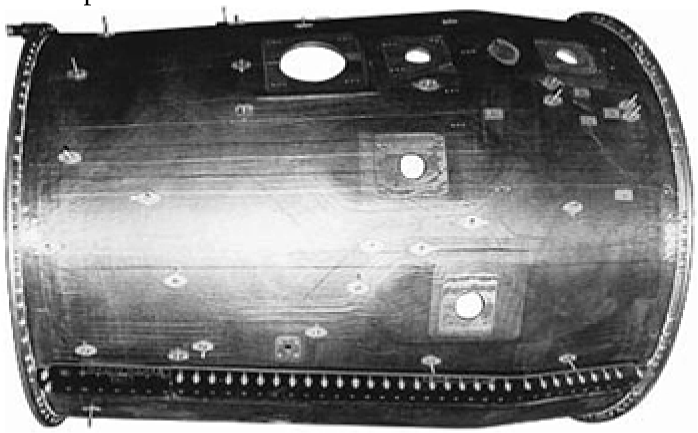

Fig. 8 Carbon-PMR-15 F414 outer duct

The success of the F404 bypass duct led to the 1984 production introduction of the carbon- PMR F110 fan frame splitter panels and forward inner duct shown in Fig. 9. Although these components are secondary

structures, they provide important flowpath performance benefits. The inner duct has a 100 cm (40 in.) diameter, 40 cm (15 in.) length, and 1.5 mm (0.060 in.) thick shell, and is fabricated with T300-PMR-15 fabric. The frame splitter panels (Ref 23) are eight separate curved panels approximately 25 cm (10 in.) long and 15 cm (6 in.) wide. In 1986, the metal outer exhaust nozzle flap on the F110-400 was replaced with the hand lay-up carbon-PMR fabric design shown in Fig. 10. This 1.4 kg (3 lb) rib-stiffened part is 70 cm (27 in.) long, 30 cm (12 in.) wide, and varies in thickness from 1.8 to 13 mm (0.07 to 0.50 in.) at the stiffeners.

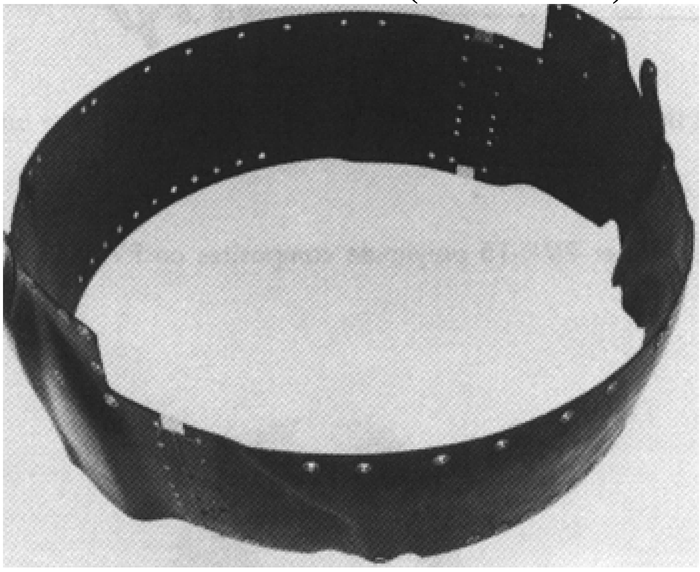

Fig. 9 Carbon fiber-PMR-15 polyimide F110 inner duct

Fig. 10 Carbon-PMR General Electric (GE) F110-400 exhaust nozzle flap

The success of the F404 carbon-PMR bypass duct also generated interest in swirl frame structures. In late 1978, GEAE conducted design studies that indicated a 30% cost and weight savings of a hybrid composite swirl frame versus a brazed metal frame. In 1979, GEAE was awarded an Army contract (DDAK51-79- C0018) to fabricate and test three composite metal hybrid swirl frames for the T700 engine (Ref 24). The frames had an outside diameter of 50 cm (20 in.) and an axial length of 20 cm (8 in.). Figure 11 shows a section of the hybrid frame fabricated from a brazed cage of 410 stainless steel hollow struts and rings and bonded with various types of PMR-15 materials. The low transverse thermal conductivity of carbon- PMR material forced the struts to be steel. The antiiced hub and outer flowpath were fabricated from aluminized glass-PMR-15, due to improved thermal conductivity and superior erosion resistance. The structural flanged aft portion of the outer case was fabricated as a manifold from carbon-PMR fabric with laser-drilled holes on the inside surface. The manifold was used to distribute water for washing the inside of the swirl frame. The forward portion of the outer case contained an air manifold used to distribute hot air into struts for antiicing. Hot air exited the bottom of the struts and entered the hub flowpath. After bonding, the entire inside flowpath was coated with an aluminum oxide coating to provide erosion resistance. All three frames were subjected to a series of tests. The first and

second frames successfully passed all iceball impact, sand erosion, static load, and fire tests. The third frame successfully ran on the T700 engine for over 100 hours. This program proved the structural viability of a hybrid frame, and in 1985 the GE27 engine (Fig. 12) incorporated a hybrid carbon-PMR composite inlet particle separator.

Fig. 11 Composite PMR hybrid swirl frame

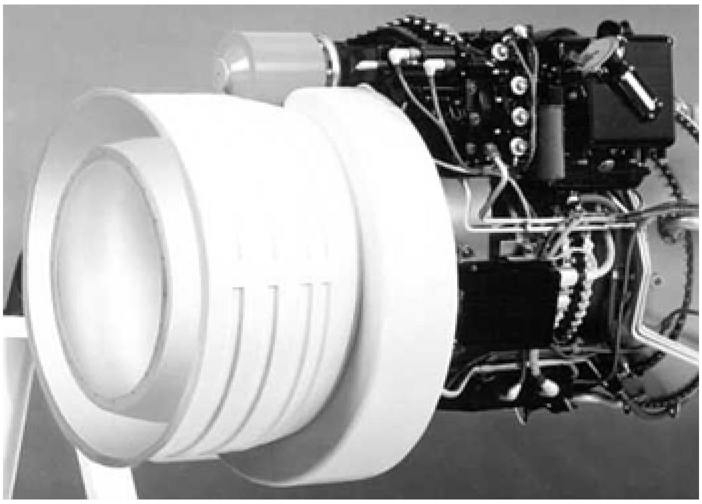

Fig. 12 GE27 engine with carbon-PMR inlet particle separator

The GE27 engine provided an opportunity to explore another carbon-PMR composite component, but with a molding compound form of material. In 1983, GEAE was awarded an Army contract to fabricate an engine accessory gearbox. A considerable series of trial fabrications were conducted to identify the proper fiber length needed to successfully fill the complicated press mold, plus provide adequate strength. The final design, shown in Fig. 13, was a press-molded shell with rib-stiffened integral flanges and separately bonded metal tubes for bearing lubrication. After two years, four forward portions of the accessory gearbox were fabricated and successfully tested. Testing consisted of static, bench, ballistic, and fire tests. The final design demonstrated a 10% weight savings over the metal baseline.

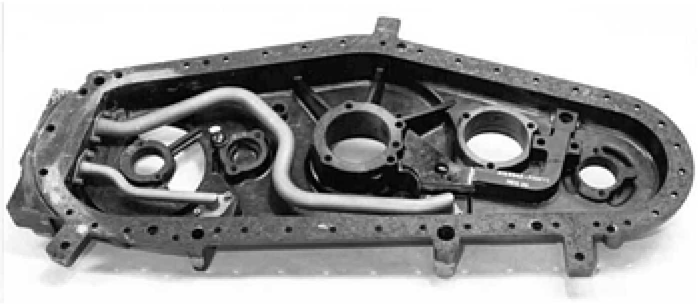

Fig. 13 GE27 carbon-PMR accessory gearbox

Perhaps the largest single application of carbon-PMR structures occurred in the 1982 to 1989 time frame when the General Electric (GE) YF120 engine, shown in Fig. 14, incorporated a carbon-PMR front frame, fan case, stator vanes, and bypass ducts. All of these components were successfully static, engine, and flight tested. The front frame struts were hollow for air antiicing requirements, and the frame casing supported the variable flaps. The fan case bolted to the front and fan frames and supported the outer ends of the fan stator vanes. The bypass duct consisted of two structures. The forward duct was split into a top and bottom half, whereas the aft duct was a complete continuous casing.

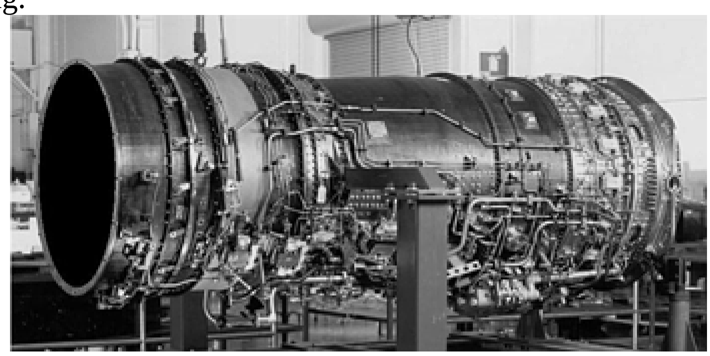

Fig. 14 GE YF120 engine with carbon-PMR parts

Figure 15 shows "committed" and "potential" applications of graphite-PMR-15 composite materials on the PW1120 turbojet under development. A committed application is one for which a metal backup component is not being developed. The only committed applications for graphite-PMR-15 composites are the external nozzle flaps and the airframe interface ring. Graphite-PMR-15 external nozzle flaps are on the PW1130 turbofan engine. Figure 16 shows different components fabricated from graphite- PMR-15 for both the PW1120 and PW1130 engines (Ref 25).

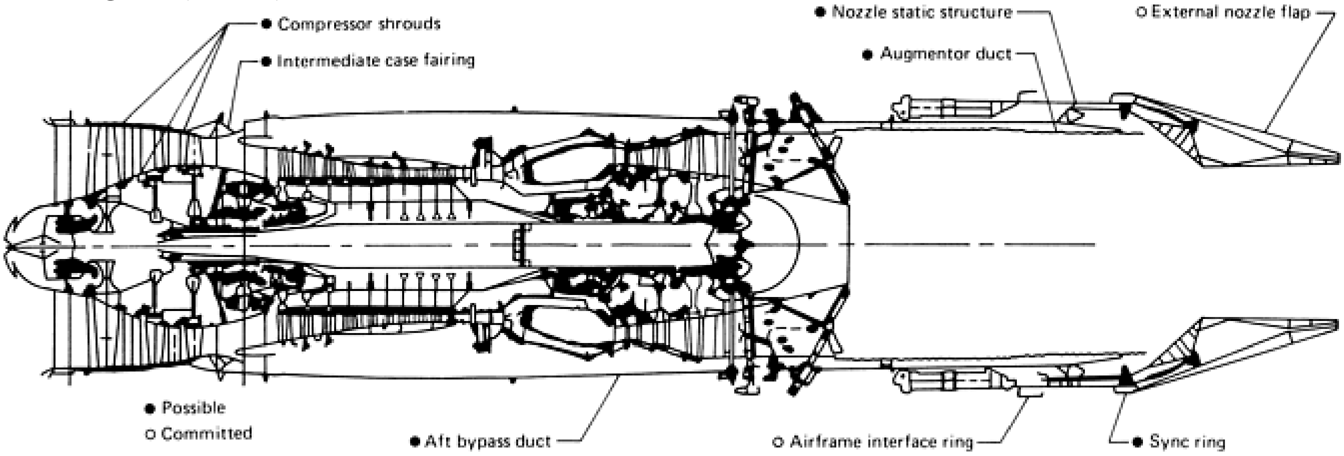

Fig. 15 Possible and committed applications of graphite fiber-PMR-15 polyimide components on PW1120 engine

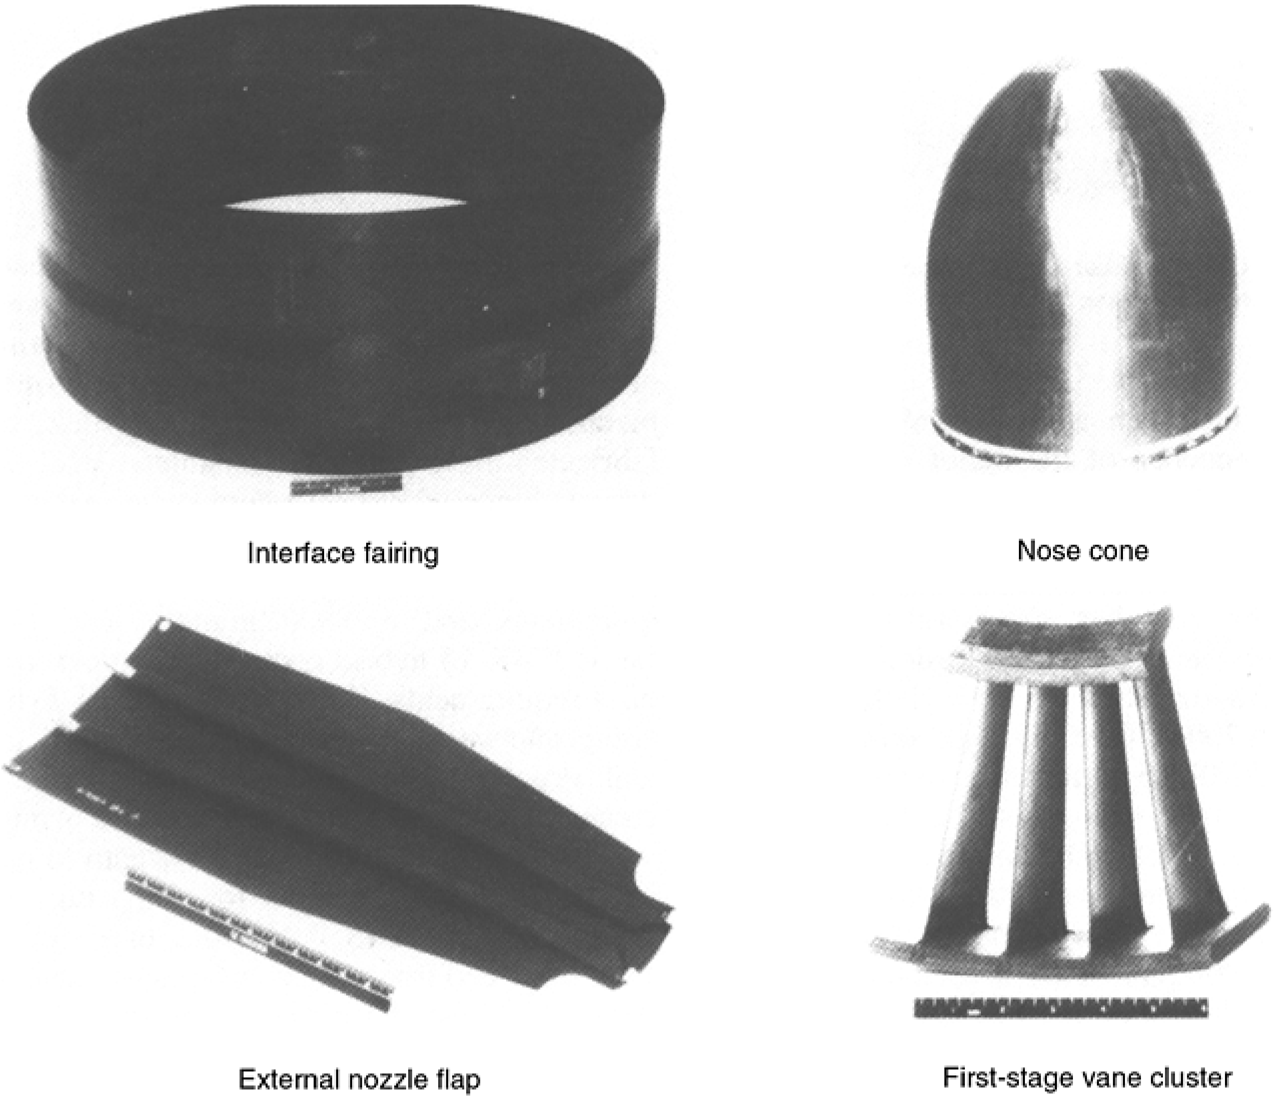

Fig. 16 Graphite fiber-PMR-15 composites on PW1120 and 1130 engines

Figure 17 shows a PMR-15 sandwich structure for which the skins were procured and then bonded to a glass-polyimide honeycomb using a commercially available adhesive based on PMR- 15 (Ref 26). Interest has also been shown in applying PMR-15 composites to filament-wound structures. In 1985, a small, integrally flanged carbon-PMR conical shell was wet wound on a filament winder by Brunswick Corporation. Although this component lacked numerous details, it showed promise for future filament winding.

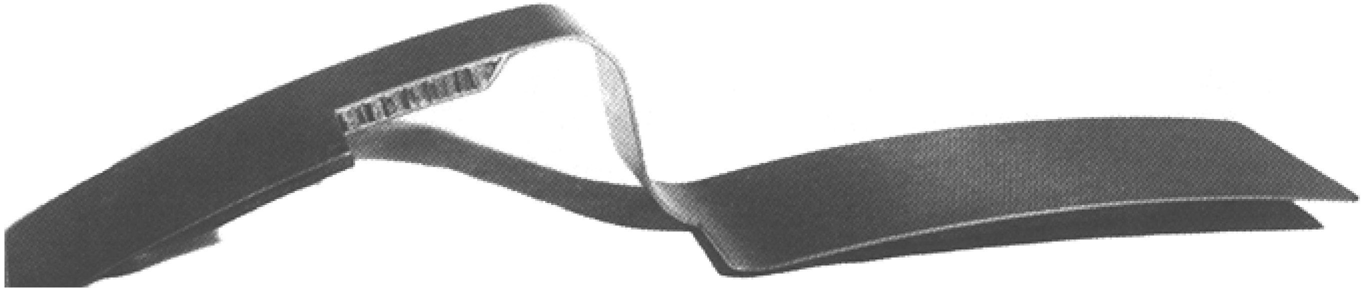

Fig. 17 Graphite fiber-PMR-15 sandwich structure

In 1990, GEAE was awarded an Air Force Manufacturing Technology program (F33615- 91-C-5719) to significantly reduce the cost of high-temperature engine structures. The goal of the Design and Manufacturing of Low-Cost Composites for Engines (DMLCC,E) program was to reduce the cost of hand lay-up carbon- PMR bypass ducts by 50%. The program examined every aspect of duct design and incorporated numerous changes to reduce cost. The basic changes involved a new form of carbon- PMR material, automation, and a new axial flange design. In order to incorporate automation, the prepreg fabric had to be replaced with a new form of tow

material. A preimidized tow was developed that allowed the material to be used on filament winders, braiders and tape placement machines. In order to satisfy all of the equipment requirements, 3 K, 6 K, and 12 K prepreg tows were manufactured and evaluated. The evaluation consisted of fabricating by filament winding, braiding, and tape placement on both cylindrical shells and integrally flanged subscale ducts, shown in Fig. 18. The shells were 50 cm (20 in.) in diameter and 90 cm (36 in.) long, and the subscale ducts were 50 cm (20 in.) in diameter and 75 cm (30 in.) long. Over 50 subcomponent shells and ducts were fabricated and tested. Testing consisted of buckling tests, flange subelement tests, and material property tests. Results of a down selection showed filament winding and braiding as viable alternatives. Tape placement results indicated continued development needs in manufacturing methods. In 1996, an Industry and Government team was formed to move the technology from subscale to a full-scale F110 production design. General Electric Aircraft Engines and Lincoln Composites teamed with the U.S. Air Force Manufacturing and Propulsion Directorates to design, fabricate, and test a full-scale bypass duct. Numerous towpreg production adjustments and filament-winding trials were conducted on subscale ducts and full-scale prototype tools. In late 2000, the first filament-wound, carbon-PMR, integrally flanged duct was fabricated, as shown in Fig. 19. In a parallel effort, GE also developed the hand lay-up carbon-PMR bypass duct, shown in Fig. 20. Both ducts are approximately 15% lighter than the current titanium duct. Structural and engine testing is ongoing for planned production in 2002. Results of this program can be found in Ref 27.

Fig. 19 F110 carbon-PMR filament-wound duct

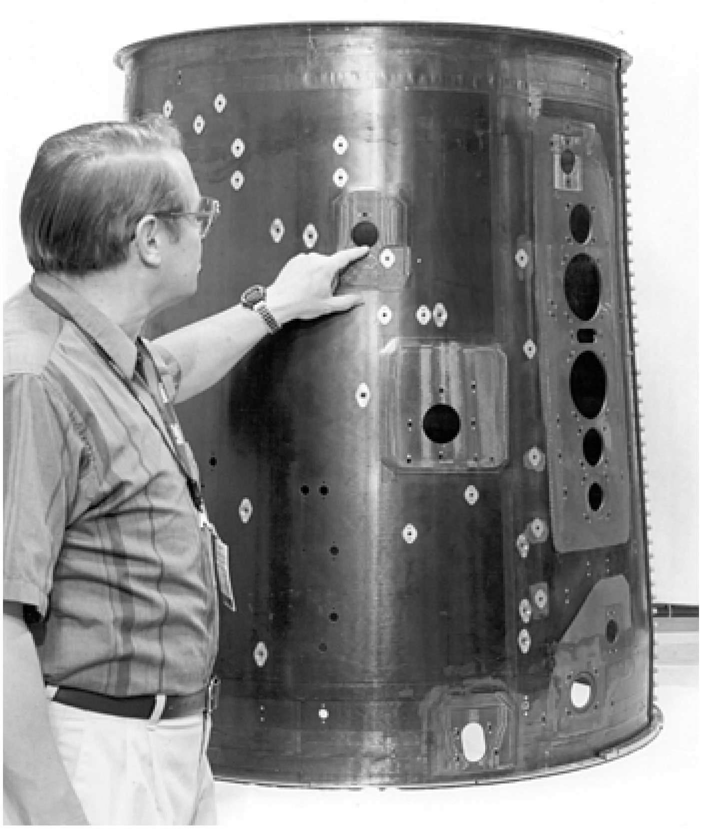

Fig. 20 F110 carbon-PMR hand lay-up fabric duct

In 1996, the DMLCC,E program also explored solvent-assisted resin transfer molding (SaRTM) of braided preforms as a low-cost manufacturing method for carbon-PMR. Subcomponent frame struts shown in Fig. 21 were fabricated to assess manufacturability and structural viability. These struts demonstrated braided-SaRTM of carbon-PMR as a viable system for low-cost manufacturing. This success prompted a NASA Glenn-funded development program for an engine thrust link using the braided-SaRTM process. Under an internally funded program, GE investigated replacing the production hand lay-up GE90 center vent tube with the braided carbon-PMR tube, shown in Fig. 22.

Aircraft Applications

Mark Wilhelm, Boeing Commercial Airplane Company

Introduction

FIBER-REINFORCED COMPOSITES have become an increasingly attractive alternative to metal for many aircraft components. Composites are strong, fatigue resistant, damage tolerant, and have been shown to be very durable when the design of the component includes proper consideration for the operating environment common to the component. They meet design and certification requirements and offer significant weight advantages. Composites also can provide significant cost reductions, especially when viewed in terms of aircraft life-cycle costs.

The composite materials used in the aircraft industry are generally reinforcing fibers or filaments embedded in a resin matrix. The most common fibers are carbon, aramid, and fiberglass, used alone or in hybrid combinations. Carbon fiber is replacing fiberglass as the most widely used reinforcement. The resin matrix is usually an epoxy-based system requiring curing temperatures between 120 and 180 °C (250 and 350 °F). Both past and current applications of fiber-reinforced composites in commercial and military aircraft are described in this article.

Mark Wilhelm, Boeing Commercial Airplane Company

Early Commercial Applications

Contracts awarded in the early 1970s by the U.S. Air Force and the National Aeronautics and Space Administration (NASA) to investigate and encourage the use of composites resulted in the design, test, certification, and in-service use of a large number of composite components on commercial aircraft. Building on the contract and military experience, composites were incorporated into civil aircraft, such as the 757, 767, and 777. Table 1 summarizes these applications.

Table 1 Composite components in various types of aircraft

One example of these government-sponsored programs, the composite spoiler for the Boeing 737, was funded by the NASA Langley Research Center. Its design featured carbon-fiber-reinforced skins and end-closure ribs made of fiberglass. The other components of the spoiler, including the center hinge fitting, front spar sections, and honeycomb core, were existing aluminum parts. The composite spoiler was completely interchangeable with the standard aluminum version. By July 1973, the Boeing Commercial Airplane Company had placed 111 composite spoilers in regular airline service for evaluation; these were periodically removed and tested in laboratories. Construction details of the part are illuminated in Fig. 1.

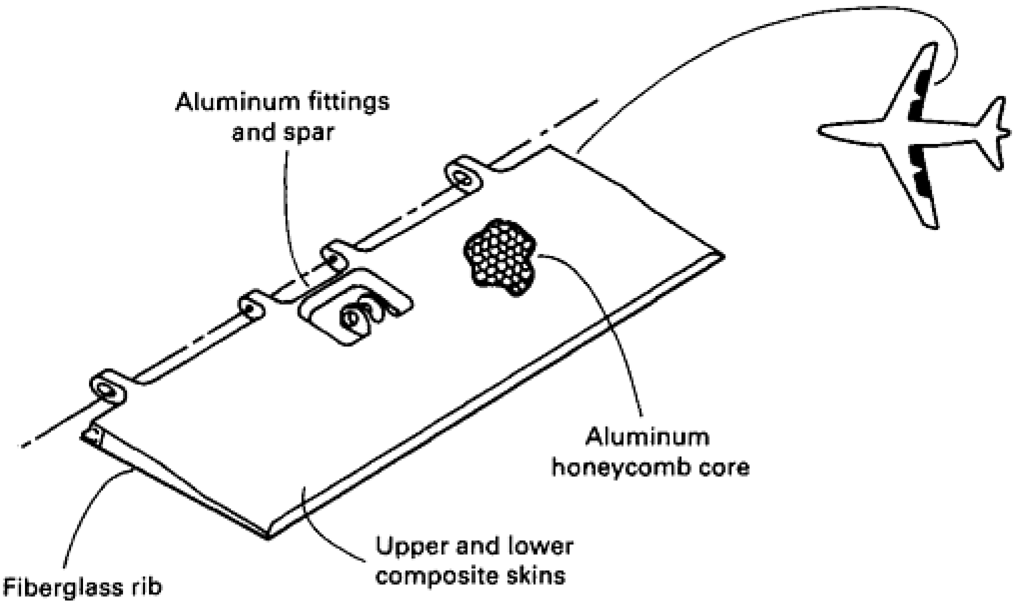

Fig. 1 Construction of Boeing 737/NASA composite spoiler. Length, 130 cm (52 in.); width, 56 cm (22 in.); surface area, 1.5 m^2 (15.8 ft^2); weight, 5 kg (12 lb)

Under a NASA contract, Lockheed-California Company manufactured three advanced composite fins for the L-1011 airliner. Shown in Fig. 2, the fin box configuration had a span of 760 cm (300 in.), a root chord of 270 cm (107 in.), and a tip chord of 120 cm (46 in.), for a surface area of 15 m^2 (l50 ft^2). The box had 2 covers, 2 spars, and 11 ribs. The skins were co-cured in a single piece from a 180 °C (350 °F) curing tape material.

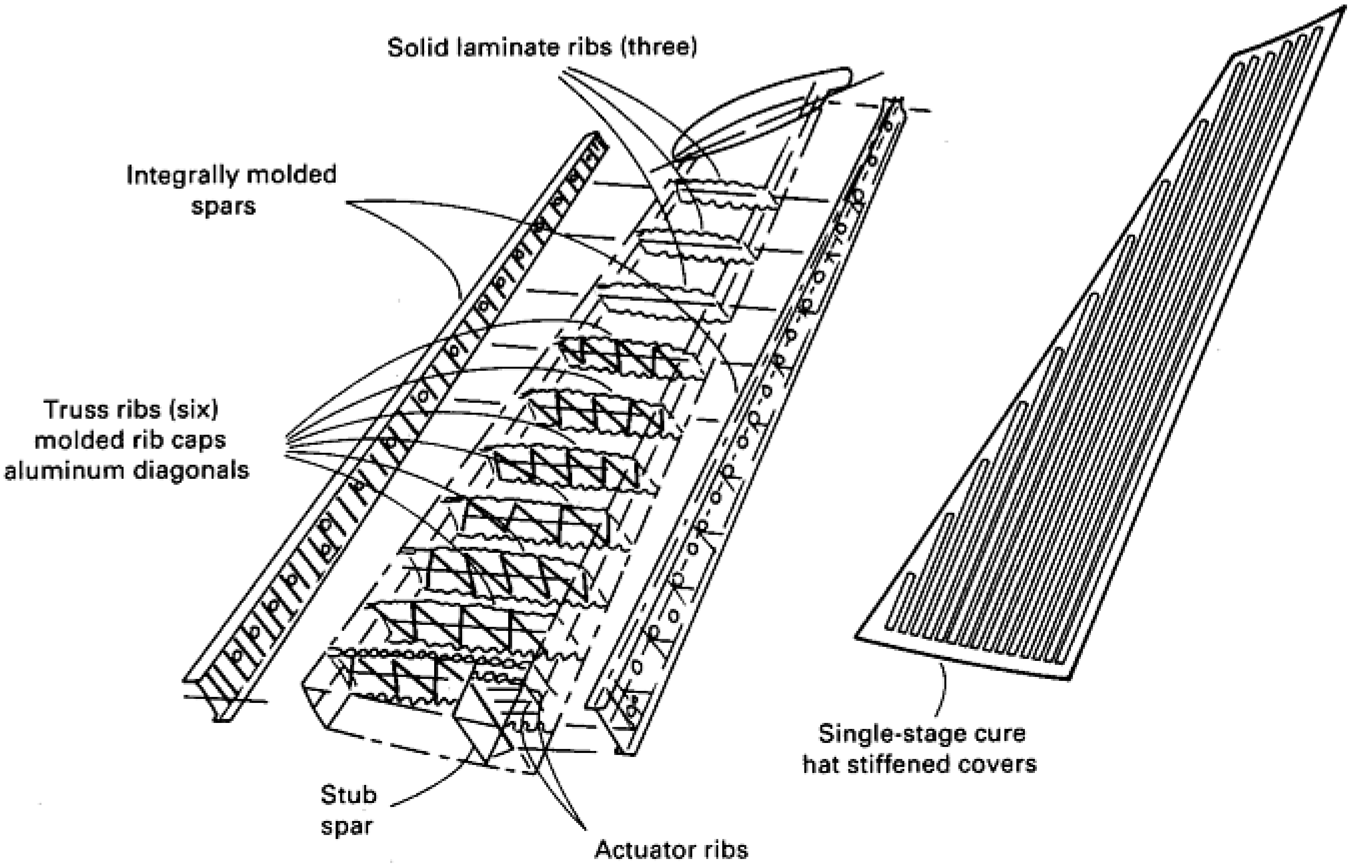

Fig. 2 L-1011 advanced composite vertical fin configuration

In the late 1970s, in reaction to the oil crisis, NASA created the Aircraft Energy Efficiency (ACEE) program. The NASA-ACEE funded a program for the McDonnell Douglas DC-10 upper aft rudder that resulted in the fabrication of 20 carbon-fiber-reinforced components for flight service evaluation. Furthermore, NASA-ACEE sponsored the design and fabrication of elevators and horizontal stabilizer boxes for the empennage of Boeing 727 and 737 jetliners. The 727 elevator shown in Fig. 3 is composed of one- piece upper and lower honeycomb skin panels, laminated front and rear spars, and honeycomb ribs. The program provided for fabrication of five slip sets for flight service evaluation, all of which were certified December 1979 and continue to be deployed on commercial aircraft. The composite components resulted in a weight reduction of 68 kg (150 lb), or 26%. The 737 horizontal stabilizer box shown in Fig. 4 was the first application of a composite primary structure on a Boeing commercial airplane. Five and one- half ship sets of stabilizer boxes were fabricated. All components were certified May 1981 and are still in commercial service. The stabilizer box shown in Fig. 5 consists of I-stiffened, laminated lower and upper skins mechanically fastened to laminated front and rear spin. The ribs are of a honeycomb sandwich-type construction and are very similar to those fabricated for the 727 carbon-fiber-reinforced epoxy elevator. A 22% weight savings (55 kg, or 116 lb) was achieved on the stabilizer box.

Aircraft Applications

Mark Wilhelm, Boeing Commercial Airplane Company

Current Production Aircraft

Composite components are used extensively on current commercial production aircraft such as the Boeing 757 and 767 and the Airbus A310, which employ about 1500 kg (3300 lb) each, while smaller planes such as the 737-300 use approximately 680 kg (1500 lb). Composite utilization on selected Boeing aircraft is listed in Table 2. While composite primary structure for the 737 horizontal stabilizer was certified in 1982, a follow-on production commitment was not made. In contrast, the vertical fin of the Airbus A310 was produced from carbon-reinforced epoxy as a production commitment and certified in 1985. In fact, the empennage primary structure for all Airbus models beginning with the A320 have been made from carbon/epoxy materials. Boeing's reentry into primary composite structure occurred on the 777 empennage (Fig. 6 and 7). To support the certification process, a total of 8059 material coupon and element tests were conducted. The 777-200 was certified jointly by United States and European regulatory agencies in April 1995. This aircraft was the first to enter commercial service with approval for extended range twin engine operations. The composite utilization for the 777-200 is shown in Fig. 8. Excluding the payload (interiors), each aircraft contains approximately 7450 kg (16,400 lb) of carbon- and fiberglass-composite material; 71% of this amount is carbon reinforced. The majority of the carbon/epoxy quantity is an intermediate modulus fiber impregnated with a toughened epoxy-based matrix used in floor beams, the horizontal stabilizer, and the vertical fin.

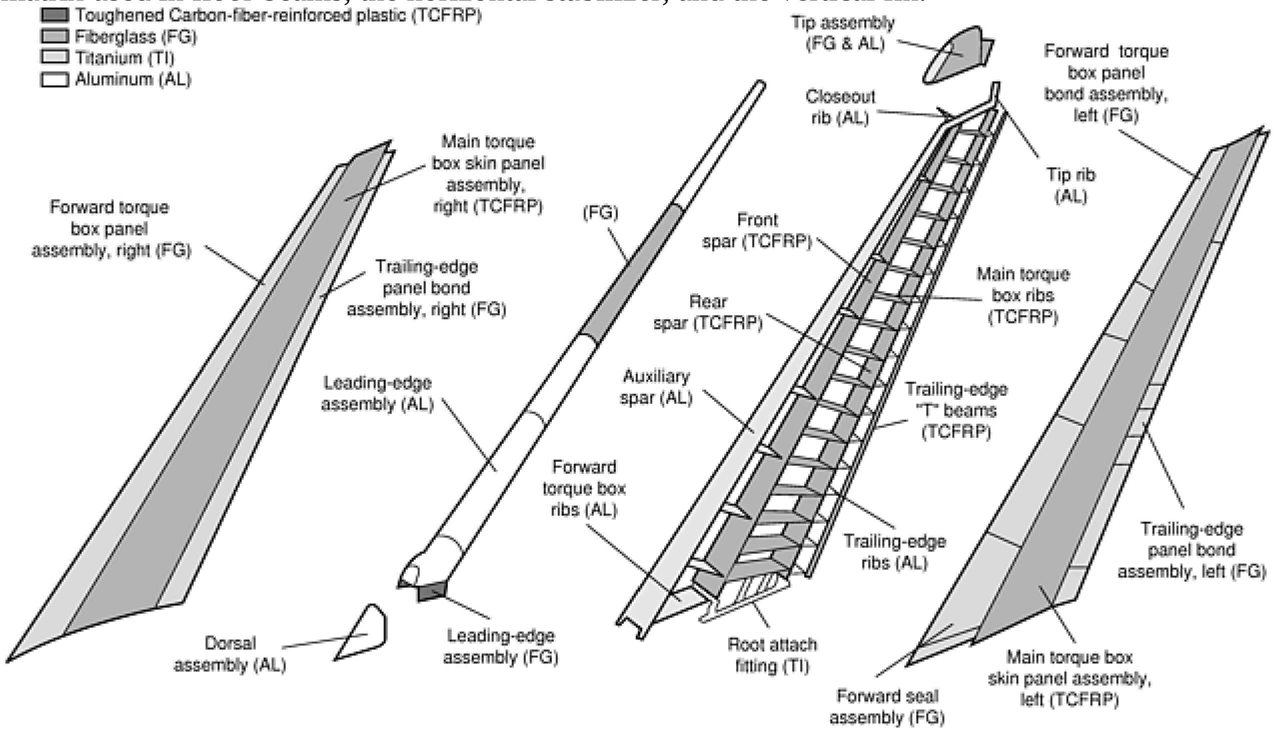

Fig. 6 Boeing 777 vertical fin

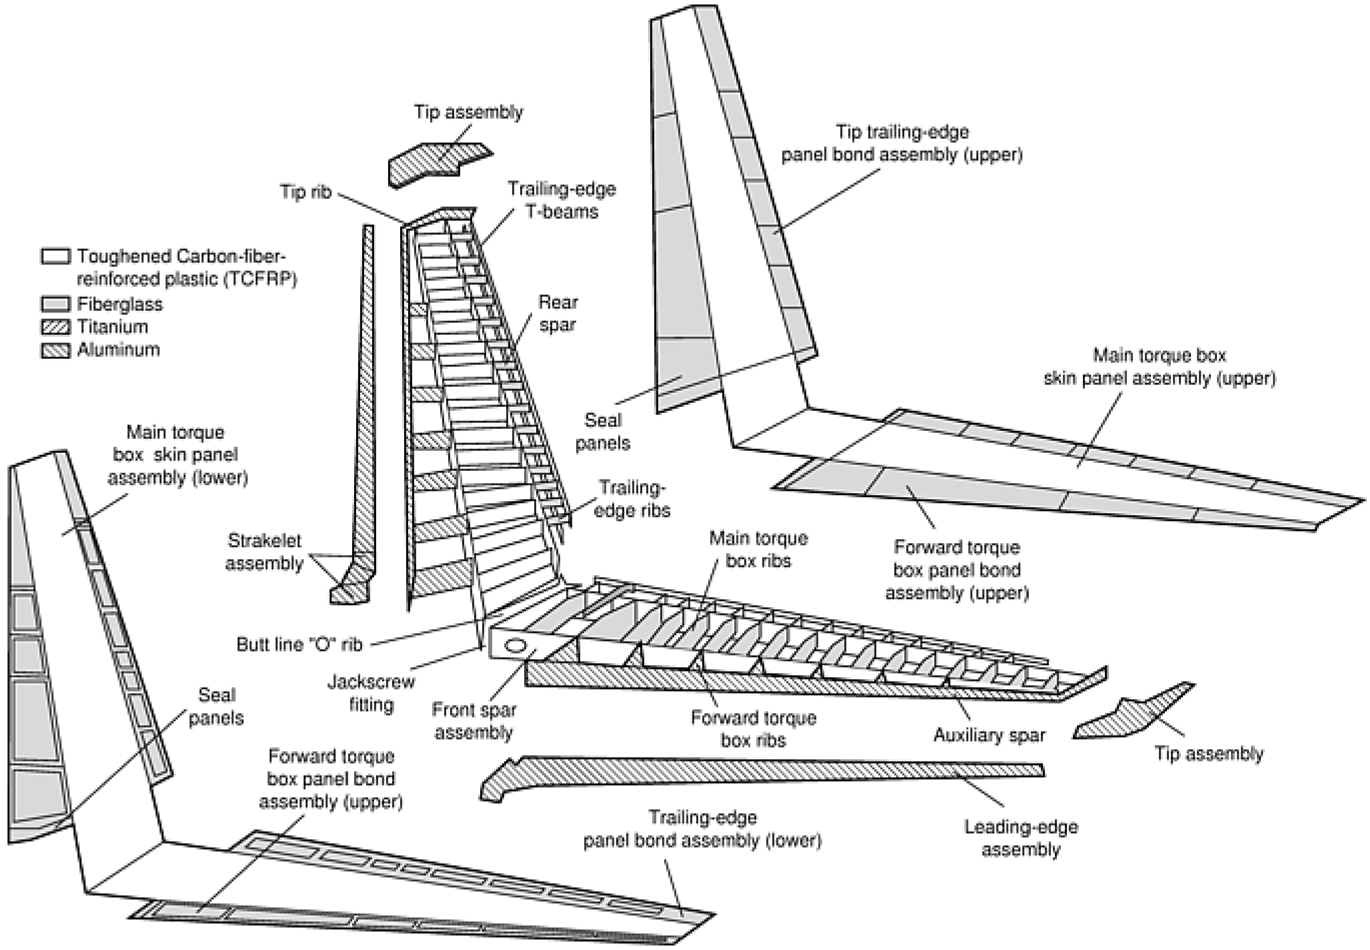

Fig. 7 Boeing 777 horizontal stabilizer

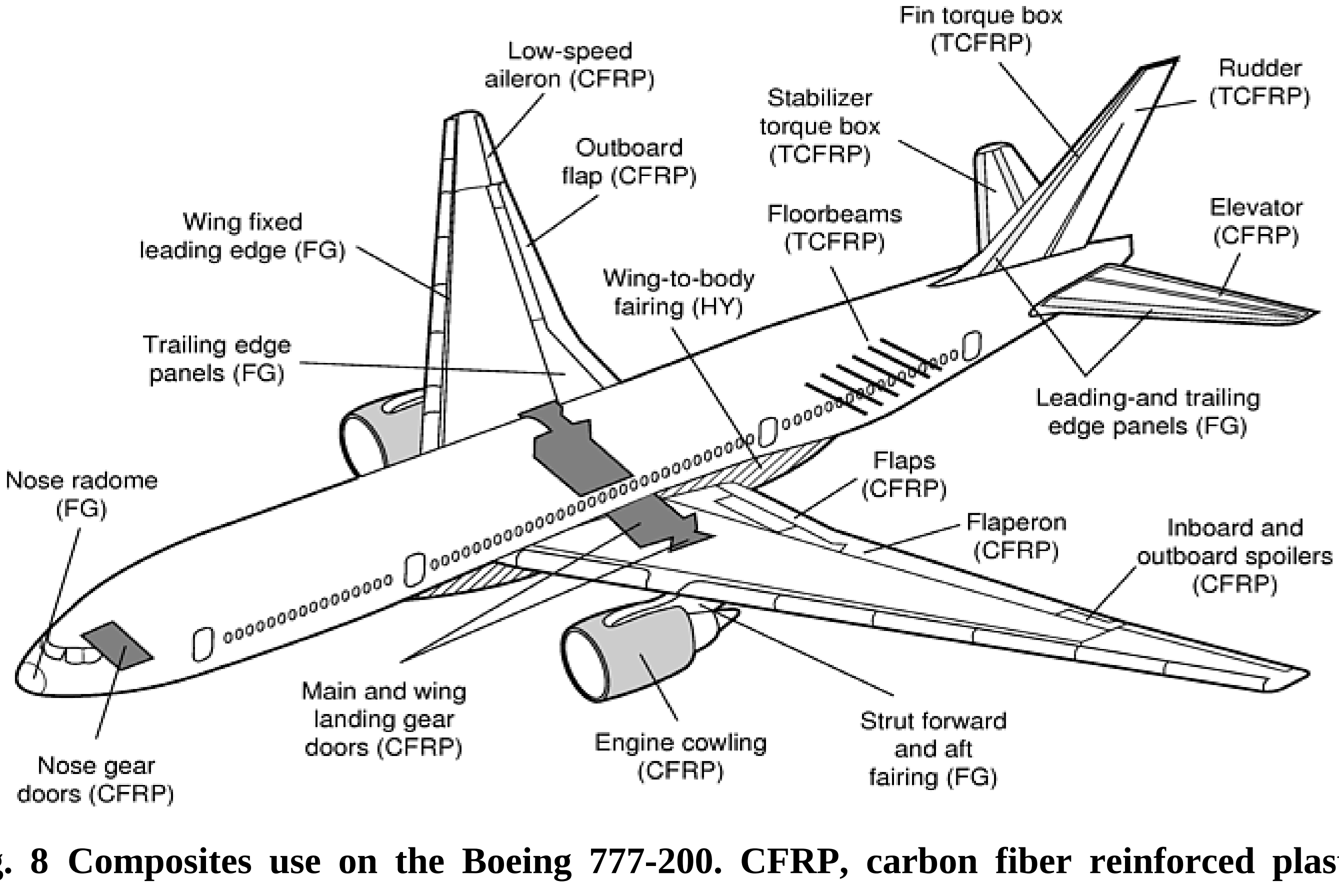

Fig. 8 Composites use on the Boeing 777-200. CFRP, carbon fiber reinforced plastic; TCFRP, toughened CFRP; FG, fiberglass; HY, hybrid

Table 2 Examples of advanced composites use and associated weight savings in commercial aircraft

Model	Total advanced composites		Weight savings	
	kg	**lb**	**kg**	**lb**
737-300	681	1500	272	600
757	1516	3340	676	1490
767	1535	3380	636	1400

On the 737, composites are used for control surfaces, fairings, and nacelle components for about 3% of the total structural weight of the aircraft. Individual composite parts are 20 to 30% lighter than their metallic counterparts.

Small, general aviation airplanes make extensive use of advanced composites. The Lear Fan 2100 uses carbon-, glass-, and aramid-fiber materials totaling approximately 820 kg (1800 lb) per aircraft. The Beech Starship I includes approximately 1360 kg (3000 lb) of composites.

With the exception of small detail parts, empennage primary structure spars, and skin panels, most composite components for commercial airplanes are of honeycomb sandwich construction. These may be either full-depth designs, such as the 767 outboard aileron shown in Fig. 9, or structures built of separate panels, such as the 767 rudder in Fig. 10. The 767 rudder is approximately 11 m (36 ft) long and 3 m (8 ft) in chord width at the root. Both examples use 177 °C (350 °F) curing materials. This elevated-temperature cure provides the most environmentally durable composite, particularly in its strength and modulus retention after moisture and thermal exposure.

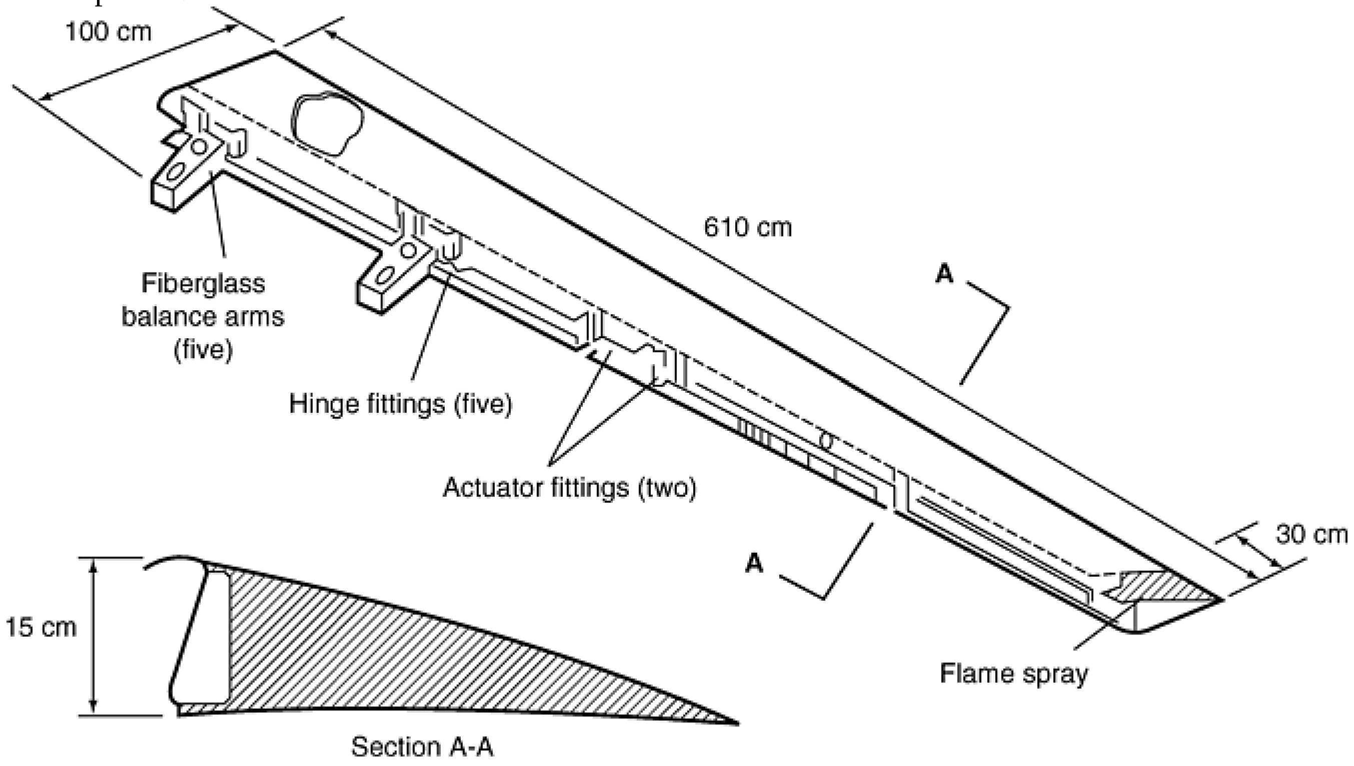

Fig. 9 Boeing 767 outboard aileron

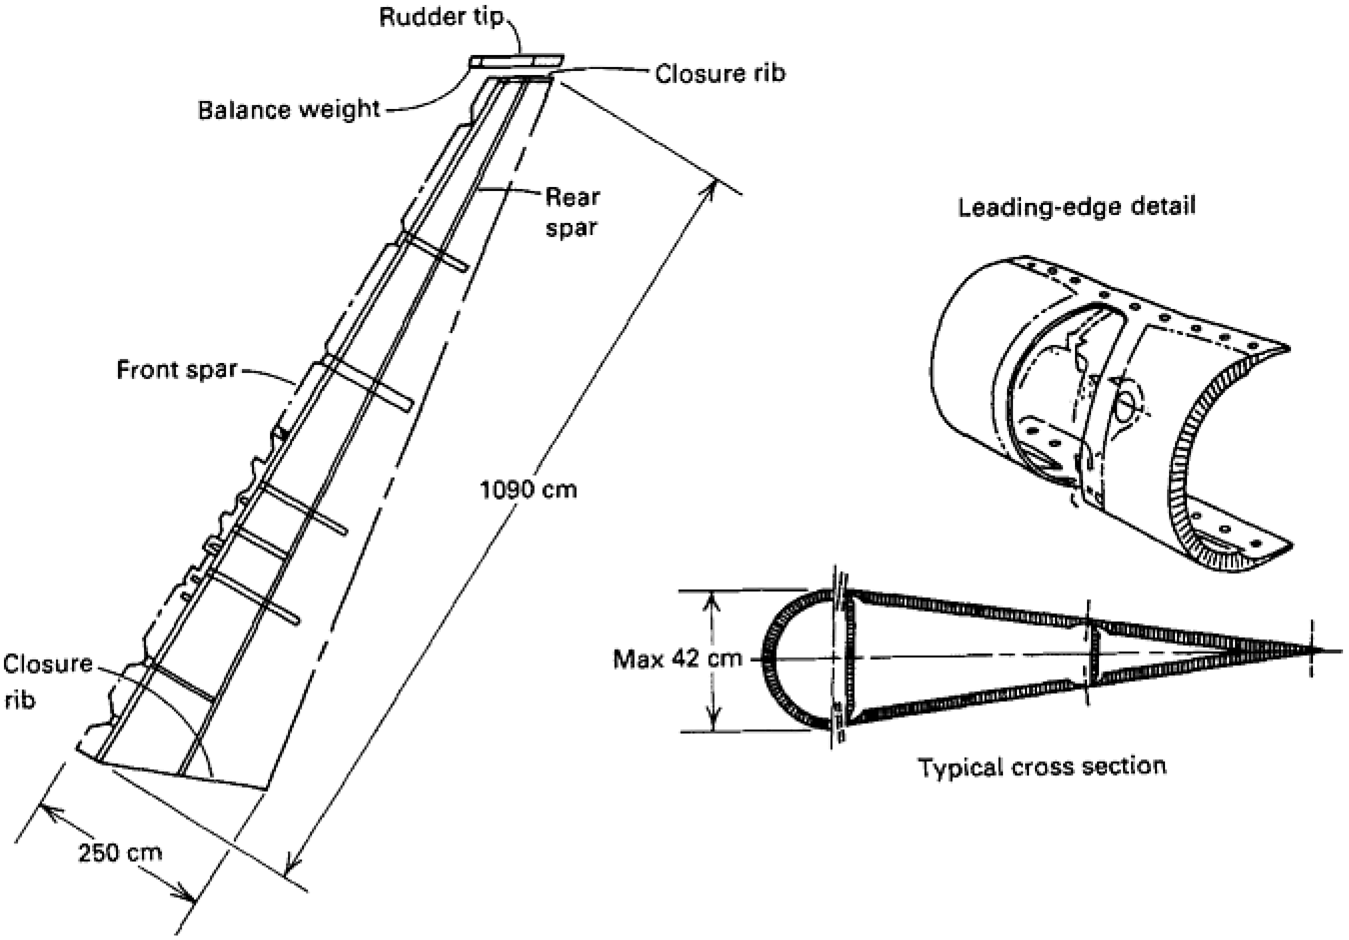

Fig. 10 767 carbon-fiber-reinforced epoxy rudder

Figure 11 shows a Boeing 757 as a typical example of composites used for an engine nacelle. Because the structure is in close proximity to the power plant, 177 °C (350 °F) curing materials are generally employed.

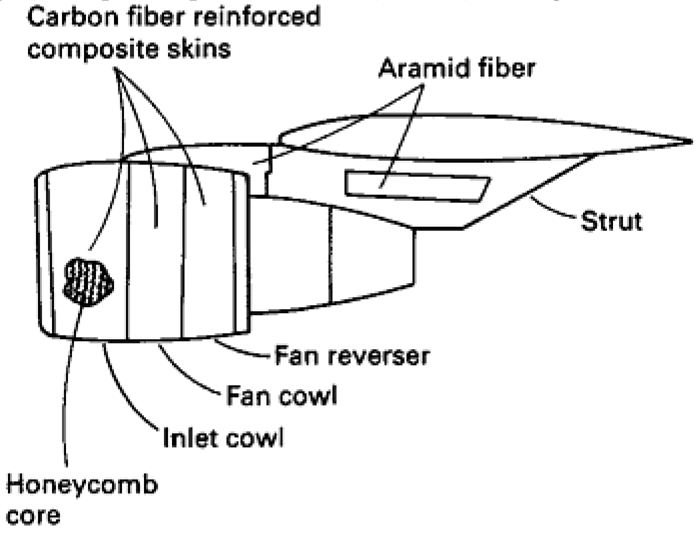

Fig. 11 757 engine strut applications

Structures such as fairings, fixed wing, and empennage trailing-edge panels are generally fabricated as a sandwich. Facesheets for these panels are made of carbon fiber or carbon fiber combined with aramid or fiberglass fabric. Such panels most often employ self-adhesive 120 °C (250 °F) curing systems. Phenolic-coated fiberglass or Nomex (DuPont) honeycomb core is used. The panels are fabricated in a single-stage curing process that provides significant cost advantages in addition to weight savings as a result of the use of self-adhesive prepregs.

Composites are also widely used in the interiors of commercial aircraft. In addition to meeting mechanical property and processibility requirements, all materials used within the pressurized portion of the aircraft must

meet both the flammability-resistance requirements defined by regulatory agencies and, if applicable, smoke and toxic-gas emission guidelines of the airframe manufacturers. Additionally, visible portions of interior components must meet stringent aesthetic requirements to satisfy the airlines and their customers.

Interior parts, such as overhead luggage compartments, sidewalls, ceilings, floors, galleys, lavatories, partitions, cargo liners, and bulkheads are routinely made of composite components. In general, these are fiber-reinforced epoxy or phenolic resin honeycomb sandwich constructions. The phenolic resin system is used because of its excellent fire-resistant properties, including low flammability and low smoke and toxic gas emissions. The predominant design considerations for interior components are impact resistance, stiffness, and surface smoothness.

The choice of fiber depends not only on structural requirements, but on part contour and fabrication method. For relatively flat parts, unidirectional or woven fabrics can be used. For compound contours, stretchable, knitted fabrics are often necessary. The predominant fiber used in interior composites is fiberglass; however, carbon fiber use is increasing as structural applications increase. For example, a filament-wound door spring is employed on the 767. Using unidirectional carbon fibers in an epoxy matrix, the springs are only one-third as heavy as comparable steel springs and only half the weight of state-of-the art titanium springs.

Aircraft Applications

Mark Wilhelm, Boeing Commercial Airplane Company

Military Applications

U.S. Military Applications. In the United States, the largest application by far of composite material is for military programs, which constitute more than 40% of the aerospace total. Most military aircraft applications use carbon-fiber-reinforced epoxy composites.

About 26% of the structural weight of the U.S. Navy's AV-8B is carbon-fiber-reinforced composites. Components include the wing box, forward fuselage, horizontal stabilizer, elevators, rudder and other control surfaces, and over-wing fairings. The wing skins are one piece tip-to-tip laminate, mechanically fastened to a multispar composite substructure; the design of the horizontal stabilizer is similar to that of the wing. Approximately 590 kg (1300 lb) of carbon-fiber epoxy is used on the AV-8B, providing a weight reduction of almost 225 kg (500 lb).

On the F-18 aircraft, carbon-fiber-reinforced composites make up approximately 10% of the structural weight and more than 50% of the surface area, as illustrated in Fig. 12. They are used in the wing skins, the horizontal and vertical tail boxes, the wing and tail control surfaces, the speed brake, the leading-edge extension, and various doors. The F-18 composite wing skins are solid laminate; their thickness varies from root to tip, with a minimum thickness of about 2 mm (0.08 in.). The tail primary structure is similar in construction.

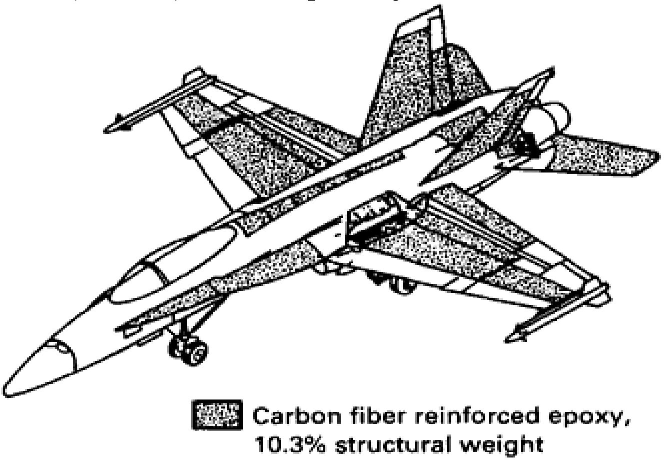

Fig. 12 F-18 composites applications

The B-1B bomber employs a number of composite structural components. Shown in Fig. 13, these include the dorsal longeron, weapons bay doors, aft equipment bay doors, and flaps. All of the materials, including adhesives, are 180 °C (350 °F) curing systems. The structures include laminate, full-depth honeycomb-reinforced panels, and composite facesheets bonded to aluminum core. The weapons bay doors shown in Fig. 14 employ carbon-fiber-reinforced tape facesheets, aluminum honeycomb core, and titanium fittings. Because the doors are in a position that is particularly vulnerable to foreign object damage, an aramid-fiber-reinforced phenolic outer layer provides penetration resistance. At a production rate of four aircraft per month, the B-1B uses 127,000 kg (280,000 lb) per year of composite structure—3040 kg (6700 lb) per aircraft—resulting in weight savings of approximately 1360 kg (3000 lb) on each bomber.

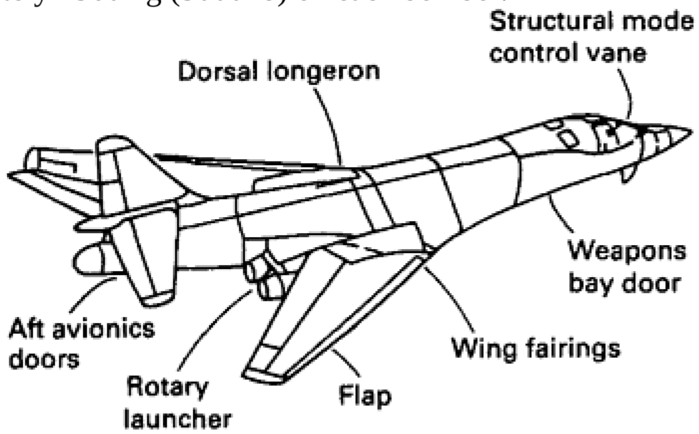

Fig. 13 B-1B composite applications

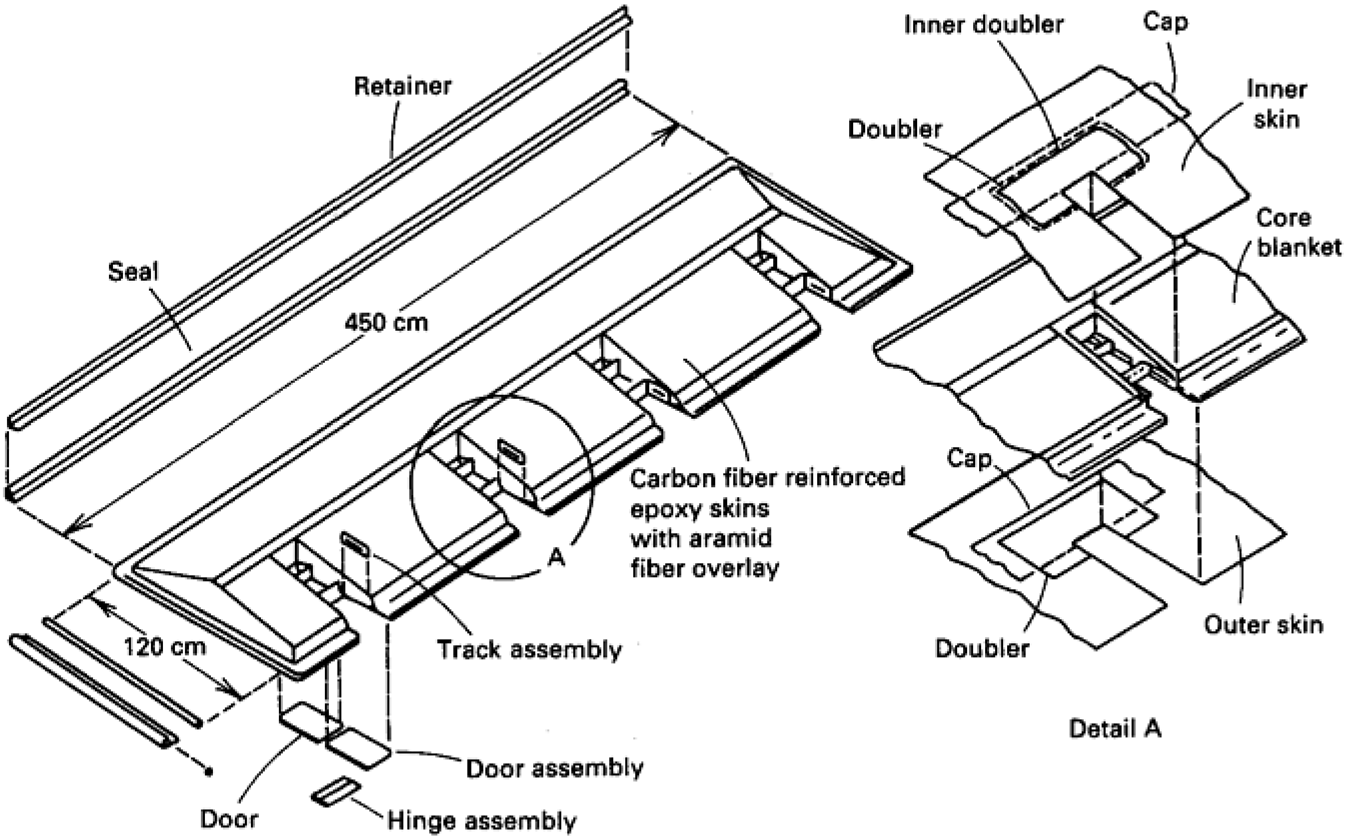

Fig. 14 B-1B weapons bay door

Grumman Aerospace Corporation fabricates F-14A horizontal stabilizers from a boron-fiber- reinforced composite material. The stabilizers are moving surfaces that pivot about shafts that protrude from the fuselage; each has an area of 6.5 m^2 (70 ft^2), with a thickness chord ratio of 5% at the root and 3% at the tip. The stabilizer consists of the main structural box, leading- and trailing-edge sections, and tip. The latter three components have conventional aluminum skins over a full-depth aluminum honeycomb core. The main box is a boron-fiber-reinforced composite structure consisting of the root rib, two intercostals, outer bearing, outboard

rib, front and rear beams, tip rib, honeycomb core, and two covers. Figure 15 shows the front and rear beams and the root tip, which are of fiberglass construction. The stabilizer was designed so that there are no mechanical fasteners through the boron. In regions of high shear transfer between the substructure and cover, titanium is carried over the areas to distribute load, and the stabilizer is mechanically fastened. In regions of reduced loads, bonded joints are employed. A unique feature of this structure is a bonded splice at the pivot region (Fig. 16). The total weight of the stabilizer is 350 kg (778 lb), a savings of approximately 20%.

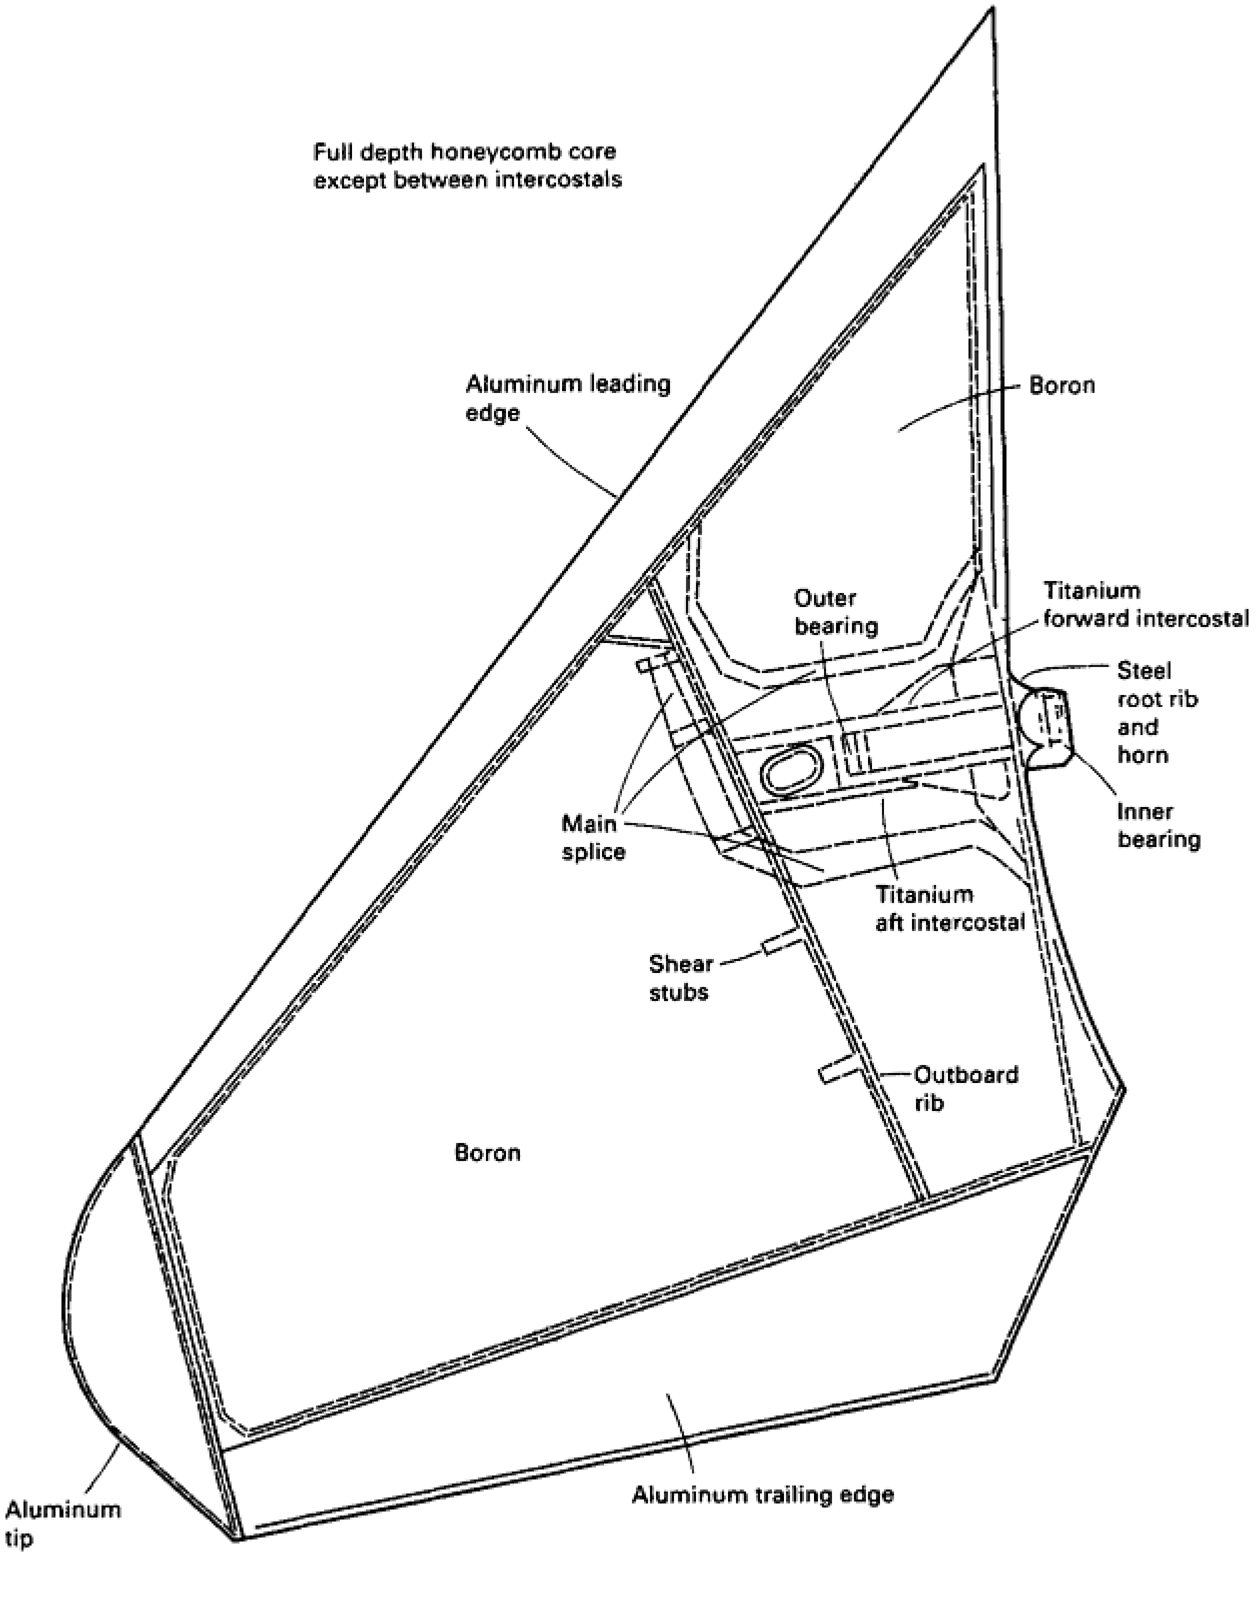

Fig. 15 F-14A boron-epoxy stabilizer, plan view

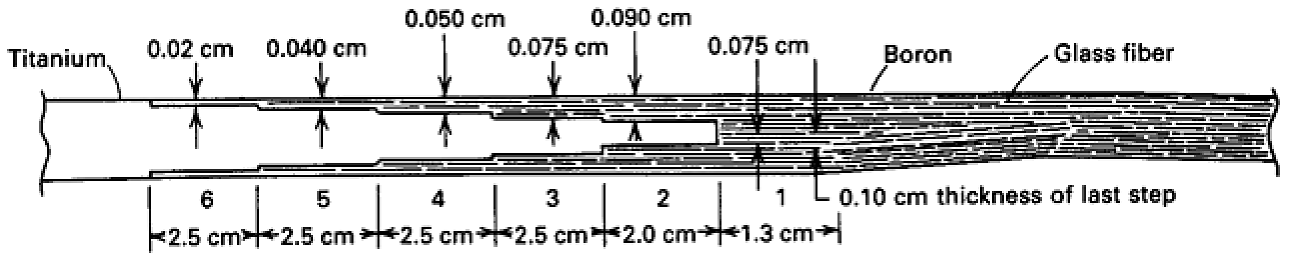

Fig. 16 Section through main splice of the F-14A stabilizer

The F-16 employs a carbon-fiber-reinforced epoxy horizontal stabilizer, vertical stabilizer, leading-edge, and rudder in the empennage of the fighter. The vertical stabilizer structural box is a multispar, multirib, laminate skin design. The horizontal stabilizer (Fig. 17) has composite skins with aluminum honeycomb core.

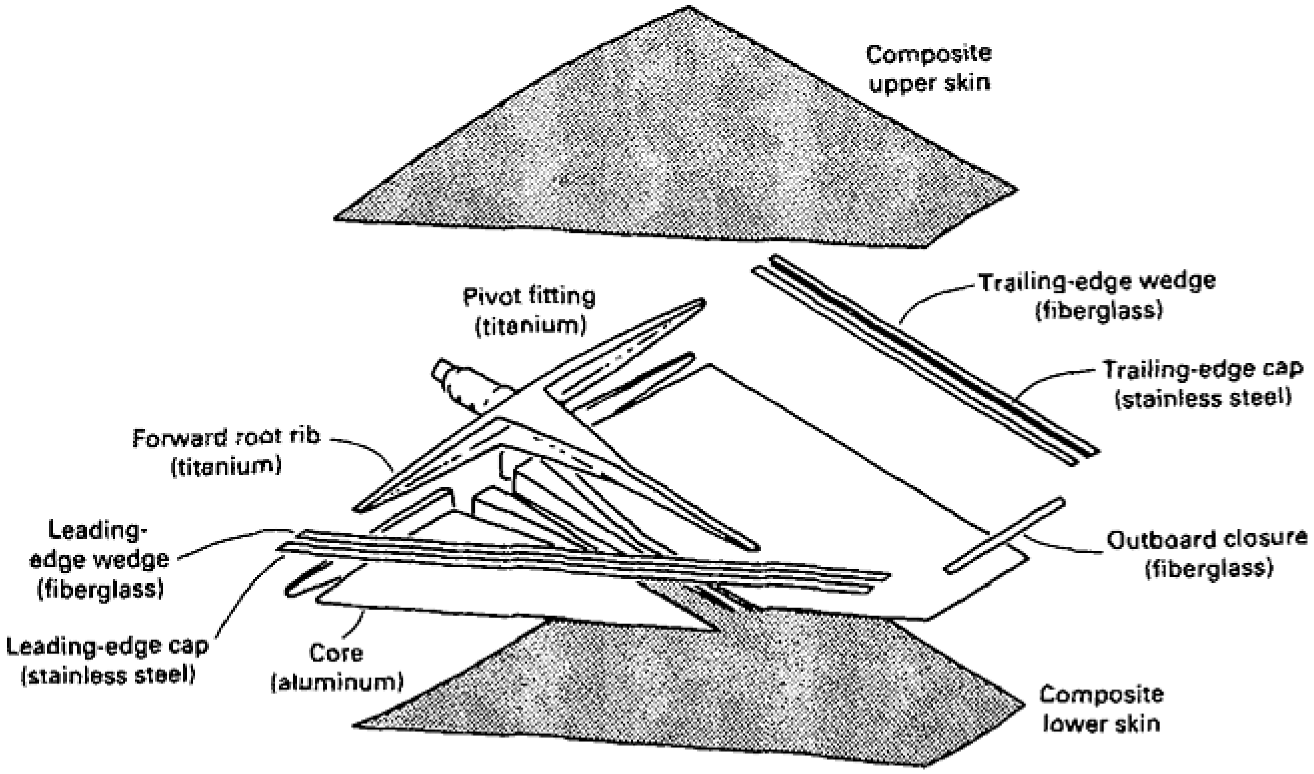

Fig. 17 F-16 composite horizontal stabilizer

Another program that employed a considerable amount of composite material is the A-6 wing replacement program. In the A-6 program, high-flight-time metal wings were being replaced by lighter composite wings with improved fatigue characteristics and much greater resistance to corrosion. The A-6 wing was being designed and built by Boeing Military Airplane Company. The A-6 replacement program requires a wing structural box made of carbon- fiber-reinforced epoxy. Figure 18 shows the design configuration of laminate skin fastened to composite intermediate ribs and spars, with titanium front and rear spars, and inboard and outboard lank end ribs. The skin panels were manufactured in a single piece using a 180 °C (350 °F) curing tape material.

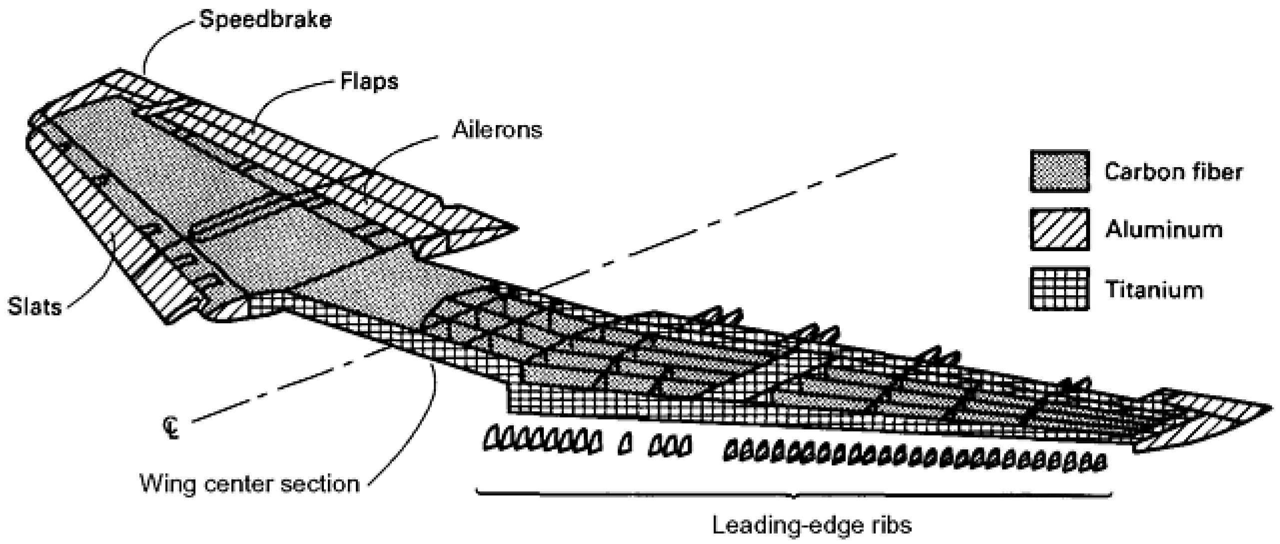

Fig. 18 A-6 composite wing

The V-22 Osprey aircraft is an innovative design that combines the advantages of the vertical takeoff and landing of a helicopter with the smooth, high-speed cruise and extended range of a fixed-wing airplane. The V-22 engines and propellers are vertically oriented for takeoff and landing, then pivot forward for cruise, with conventional wing surfaces providing aerodynamic lift. The V-22 wing panels have integrally stiffened laminate skins. The fuselage of the V-22 (Fig. 19) is also made of composite materials that make up 50% of its structural weight.

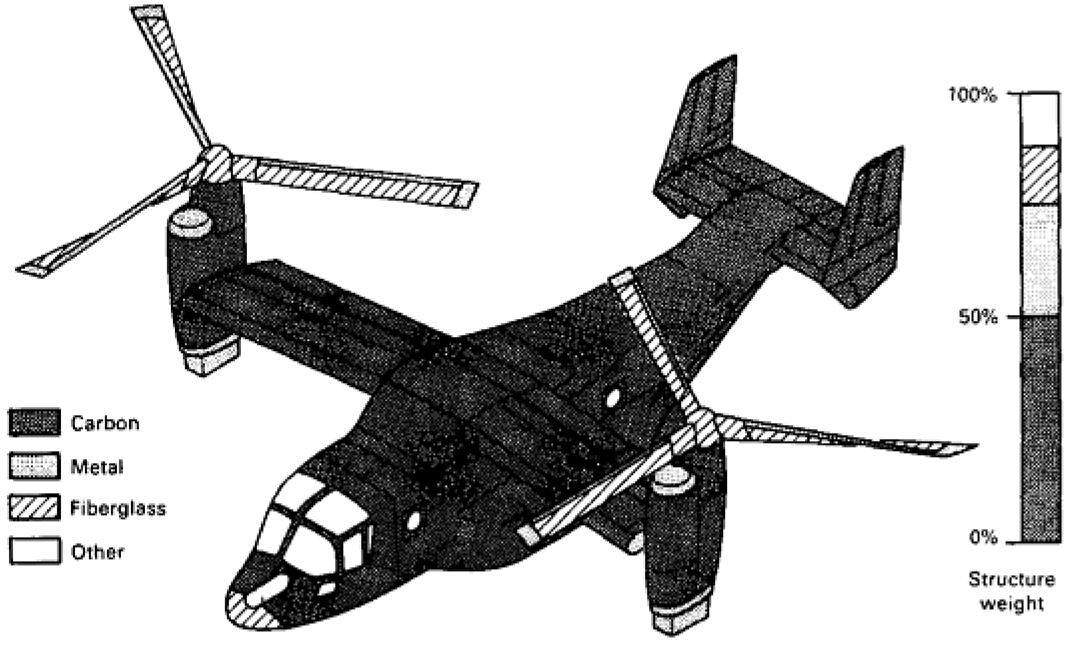

Fig. 19 V-22 material applications. Structure (wing, fuselage, empennage, nacelle, rotor): 6120 kg (13,496 lb). Carbon epoxy: 3100 kg (6856 lb)

European Military Application (the Eurofighter). On the Typhoon (Eurofighter) aircraft, carbon-fiber-reinforced composites make up approximately 30% of the structural weight and more than 70% of the surface area, as illustrated in Fig. 20. Almost all components are made of a 185 °C (365 °F) curing system (Hexcel 8552 toughened epoxy, Hexcel Corp.). Primary structures are made from unidirectional prepregs. Secondary structures may have portions of fabric prepregs.

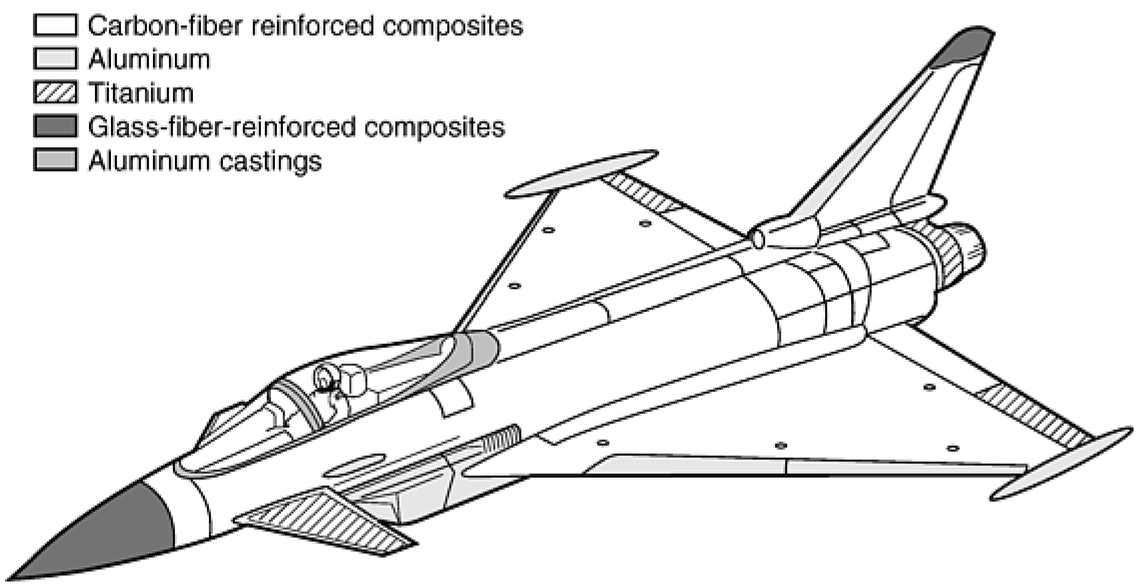

Fig. 20 Materials use in the Typhoon (Eurofighter) airplane

The skins of the wing (Fig. 21) are solid laminate, with thicknesses varying from root to tip between about 20 and 4 mm (0.8 and 0.16 in.). They are laminated by automated tape laying. During manufacturing, the wing skins are cured first. Afterwards, the solid laminate spars are cured and simultaneously bonded to the already cured lower skin in a second autoclave cycle (co-bonding process).

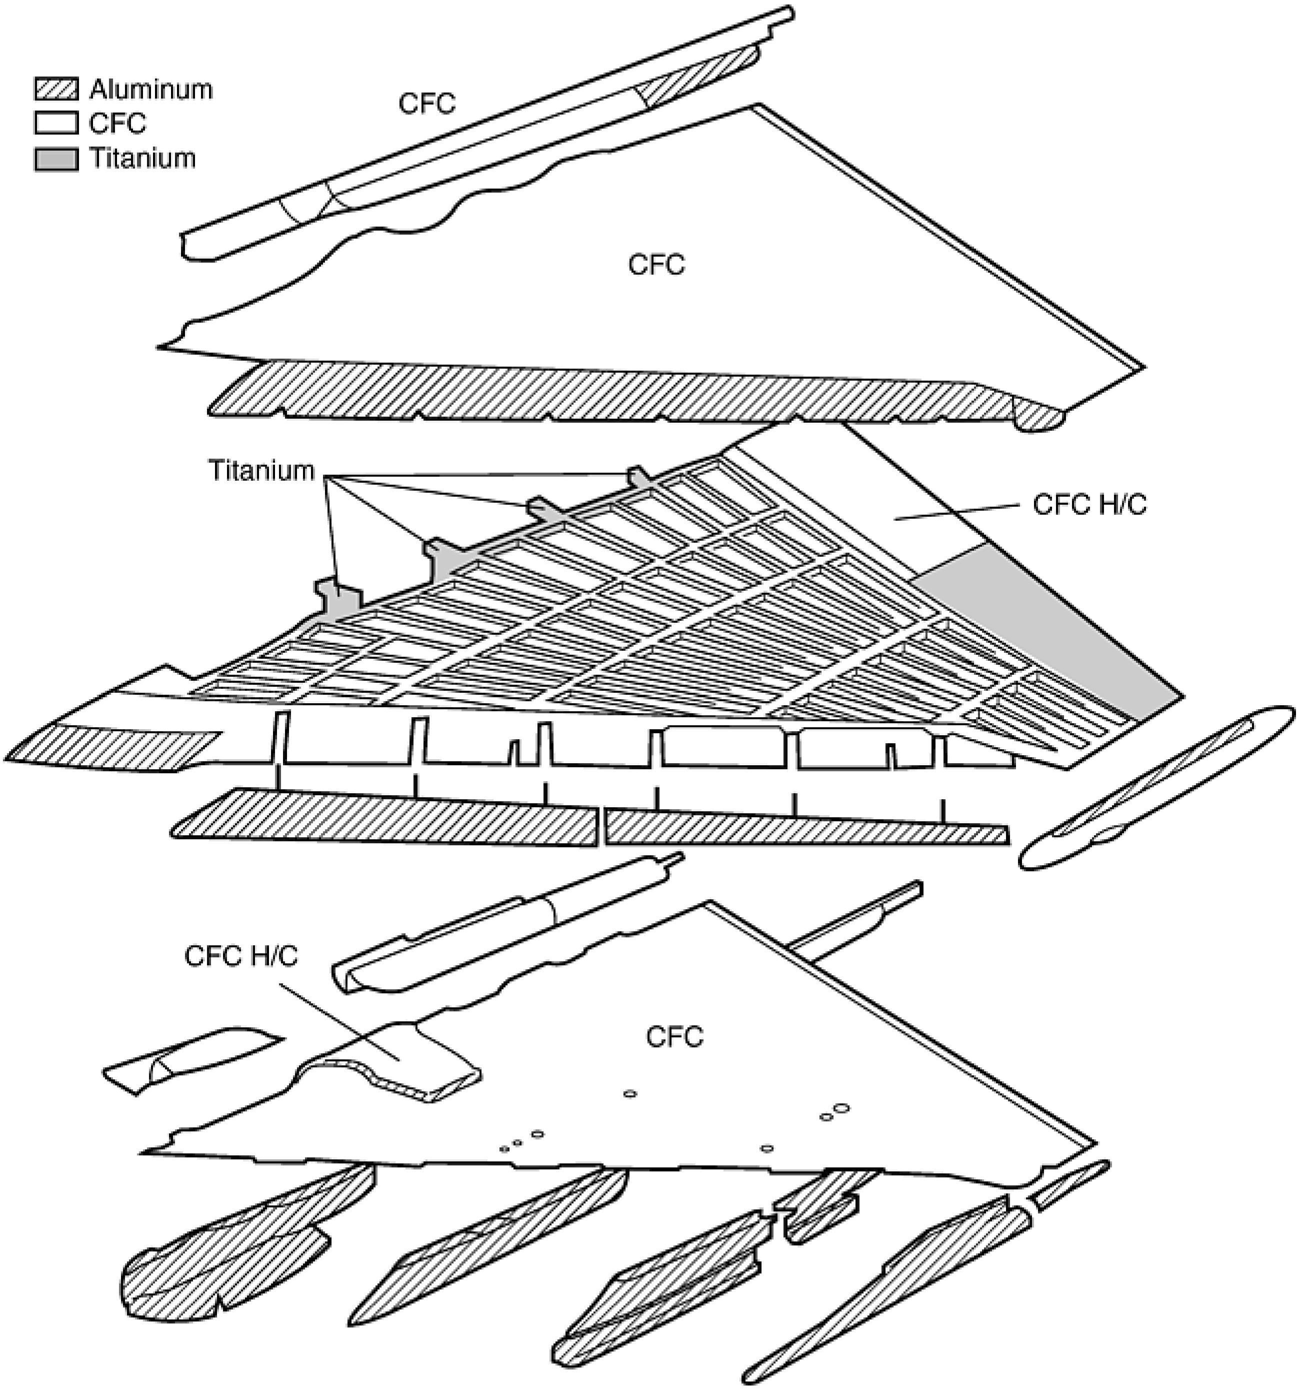

Fig. 21 Typhoon wing. CFC, carbon-fiber composite; H/C, honeycomb

The center fuselage skin (Fig. 22) is integrally J-stiffened solid laminate, with thicknesses varying between 11 and 3.5 mm (0.43 and 0.14 in.). During manufacturing, the skin and the stiffeners are jointly cured in one autoclave cycle (co-curing process).

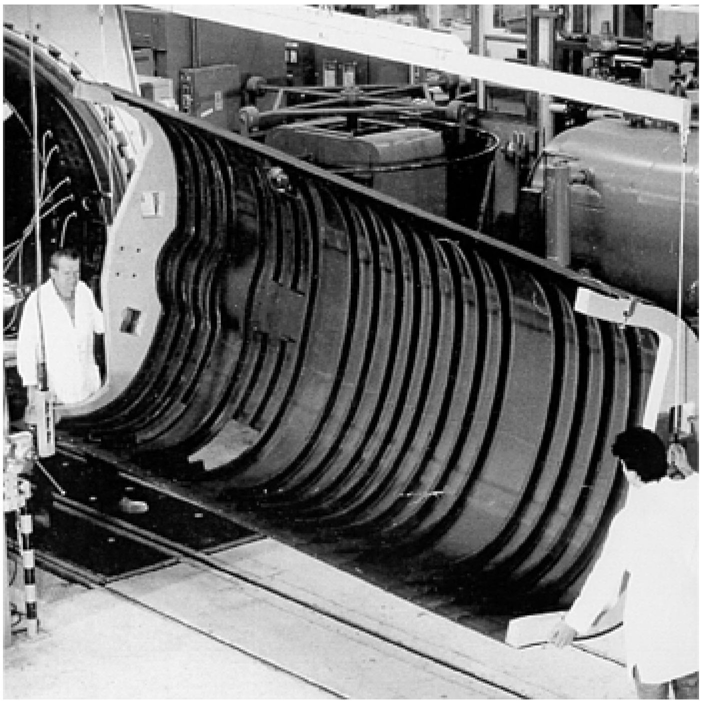

Fig. 22 Typhoon center fuselage skin with J-stiffeners

Fin, rudder, in-board aileron, and airbrake have skins of solid laminate. For rudder and in- board aileron, the substructure also is solid laminate. Sandwich panels are used for the side skins of the forward fuselage, the upper and side skins of the rear fuselage, the landing gear doors and for load-carrying covers of the center fuselage.

Aircraft Applications

Mark Wilhelm, Boeing Commercial Airplane Company

Outlook

Trends clearly indicate that the use of composite structures will continue to grow in both commercial and military aircraft. New materials, with both improved properties and increased suitability to new automated processes, will result in weight savings and cost competitiveness with traditional metal structures. Figure 23 depicts the rapid increase of composites in aircraft and an implied projection of increase in use.

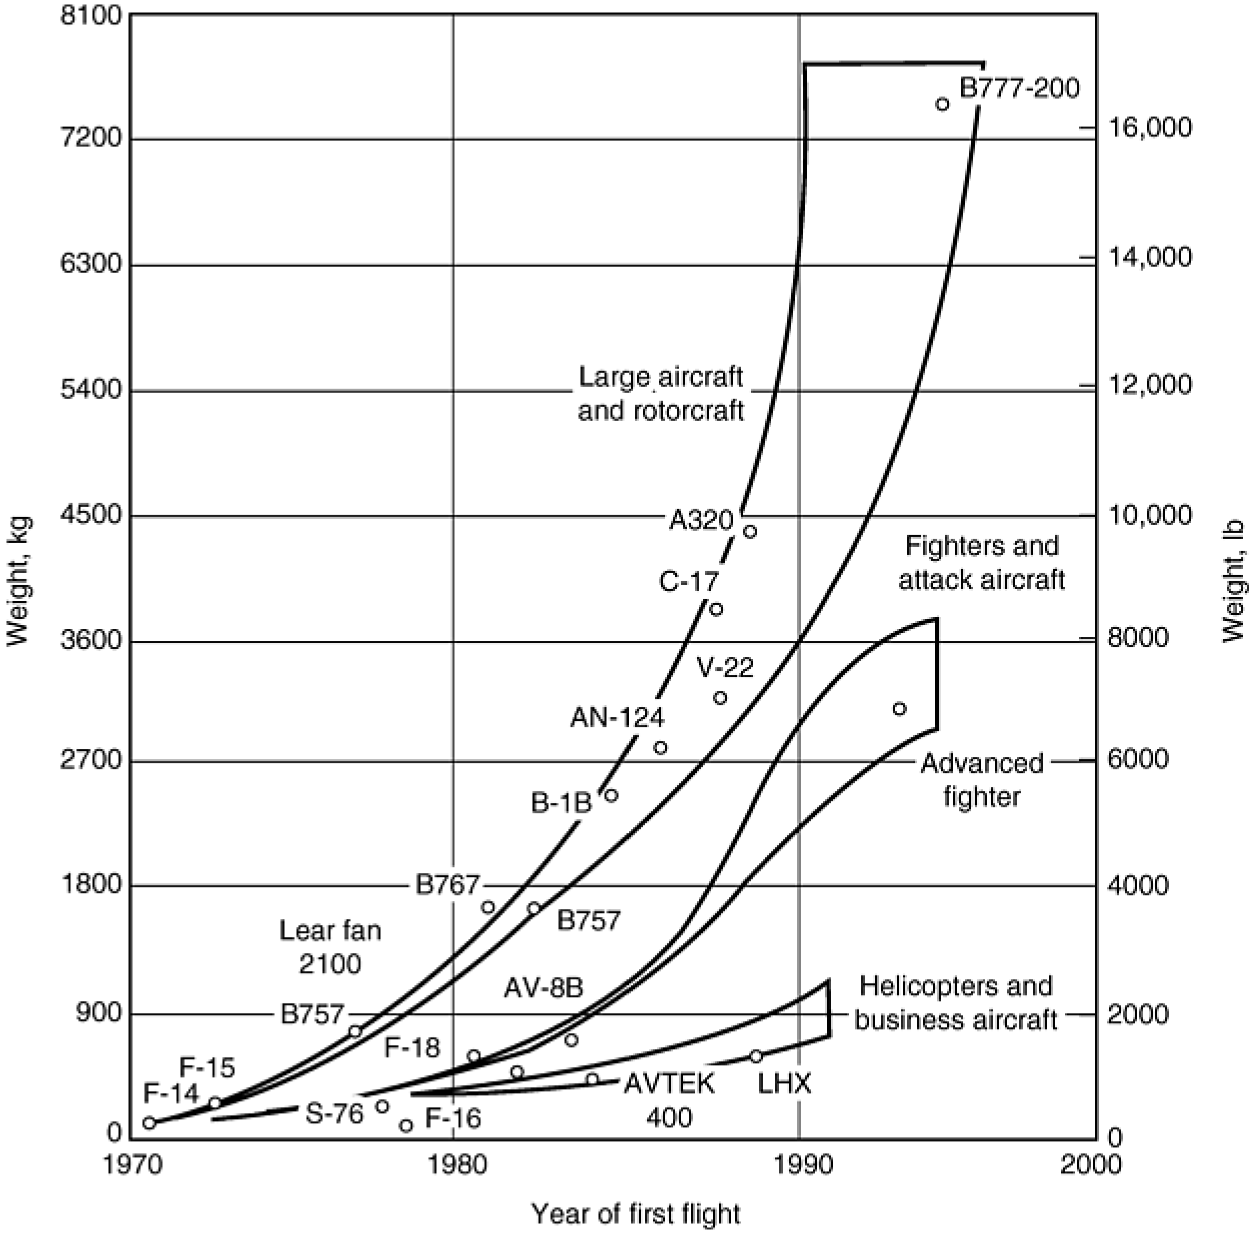

Fig. 23 Composite aircraft structure by weight

However, factors that may inhibit wider use of composites include cost, schedule, capital investment, and inspectability. Furthermore, unexpected variations in raw materials and poorly defined cost data, as well as a lack of uniform, industry-wide specifications, test techniques, environmental conditioning, standards, and design allowables all combine to create a degree of conservatism at this time. Because of these factors, a detailed business case must be prepared and analyzed in order to ensure selection of composites for applications for which they are technically and economically most appropriate.

From a commercial aircraft manufacturing perspective, the change in approach from the 1960s (technology rules) to the early 1970s (oil crisis) to the present (focus on shareholder and customer value) has been monumental. Technology for technology's sake and designs that consider only minimizing component weight are not relevant in the marketplace of 2001. The emergence of business-case analysis applied to potential projects has interjected needed discipline into the technology development process. Like- wise, knowledge of the composite value chain enables analysis of new technology and its potential to reduce cost and create value along the chain. Early involvement of existing and potential customers has been shown to be an effective tool to define composite utilization opportunities as well as to bring needed lessons learned from customer experiences.

The need to predict and understand design and fabrication costs continues to be important. It is apparent that currently employed cost collection systems do not adequately capture costs at a low enough level. As a result, this situation is responsible for data being suboptimal when used for value chain or business-cases development. Additionally, cost data is typically treated as proprietary information—not only outside, but also

often within organizations. Lack of detailed cost information complicates the analysis and identification of cost-reduction opportunities. It is imperative that these obstacles be eliminated in order to make meaningful inroads in the quest for cost reduction.

For commercial aircraft, a critical success factor is to ensure that certification via the appropriate regulatory agency is an integral part of any development program. The certification requirement forces the program structure to think of the big picture in terms of developing the necessary engineering and manufacturing data. An example of how this was successfully accomplished was demonstrated during the Boeing/NASA- ACEE program described in this article.

Applications of Carbon-Carbon Composites

Kristen M. Kearns, Materials and Manufacturing Directorate, Air Force Research Laboratory

Introduction

CARBON-CARBON COMPOSITES have historically been utilized for applications requiring ablation and high-temperature stability (i.e., rocket nozzles and exit cones) or wear resistance at moderate temperatures (i.e., aircraft brakes). These applications utilize thicker materials with moderate mechanical-performance requirements. The processes that have been developed for these thick material applications are tailored to produce a dense material with the required properties. The processes typically include fabricating some type of organic composite preform, heating that preform to high temperature to decompose the organic material to carbon (referred to as carbonization), and then infiltrating the composite to fill the gaps left after decomposition (referred to as densification). The carbonization and densification processes can be repeated as many times as needed until the materials reach the desired density.

Beginning in the mid-1980s, carbon-carbon was considered for applications requiring a stiff, structural material with very thin walls. This interest has led to the investigation into other properties of carbon that could be exploited in a carbon-carbon composite. One area that has been explored is carbon-carbon for thermal management. Many systems require heat control, either by rejecting or by absorbing "waste heat energy." This has led to much interest in carbon-carbon for such applications as electronic thermal planes; spacecraft thermal doublers, radiators, and thermal and shields; and aircraft heat exchangers.

Material Properties

Carbon has many characteristics that are appealing for many different thermal management applications. Carbon has a very low density, a tailorable thermal conductivity, and very low thermal expansion with acceptable mechanical properties. This means a carbon composite can be fabricated with high specific thermal conductivity and low thermal expansion. These properties are very desirable for many different thermal management applications.

Typical mechanical properties of carbon-carbon are shown in Fig. 1. These plots show the range of specific strength and modulus (actual modulus divided by the density) of a variety of carbon-carbon materials. Due to the fibers used in carbon-carbon composites used for thermal management applications, typical tensile strengths are approximately 70 to 280 MPa (10–40 ksi) and moduli are about 70 to 175 GPa (10 to 25 $\times 10^6$ psi) for two-dimensional isotropic (0/90/±45), woven composites.

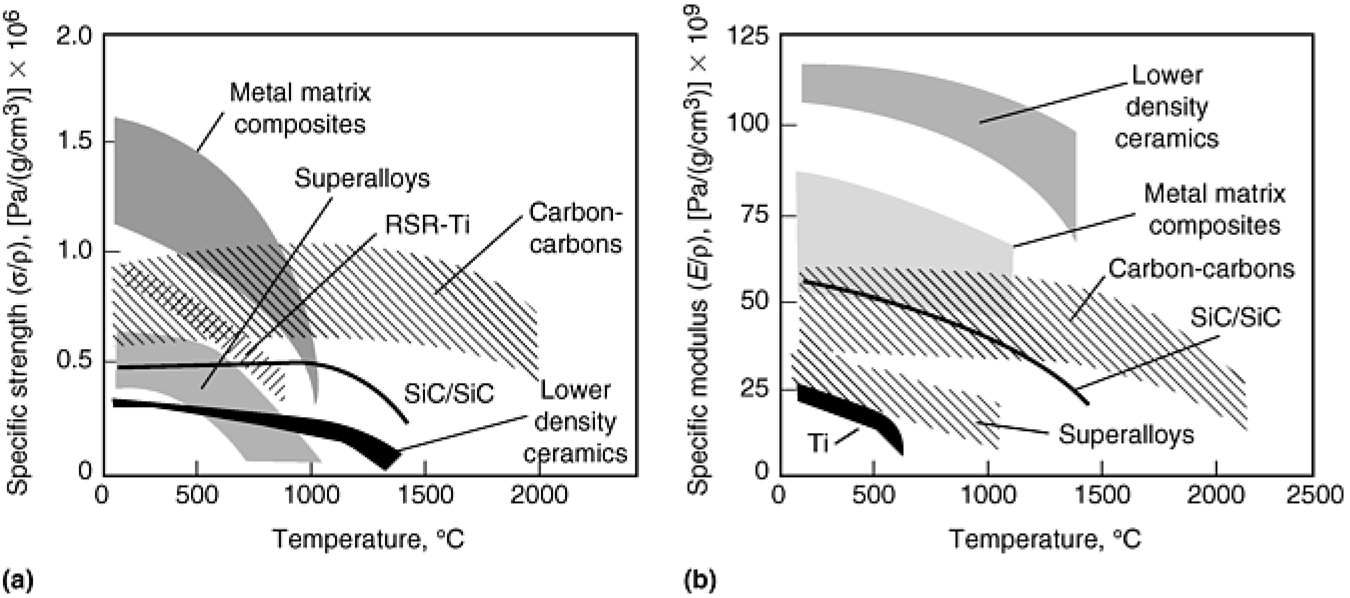

Fig. 1 Specific strength (a) and modulus (b) of carbon-carbon composites

For many thermal management applications it is desirable to have a material that has a very low thermal expansion or a thermal expansion close to the material to which it is bonding or attaching. Figure 2 shows how the thermal expansion of carbon compares to other metallic materials. Notice there is a range of values for carbon because it is not isotropic like the other materials.

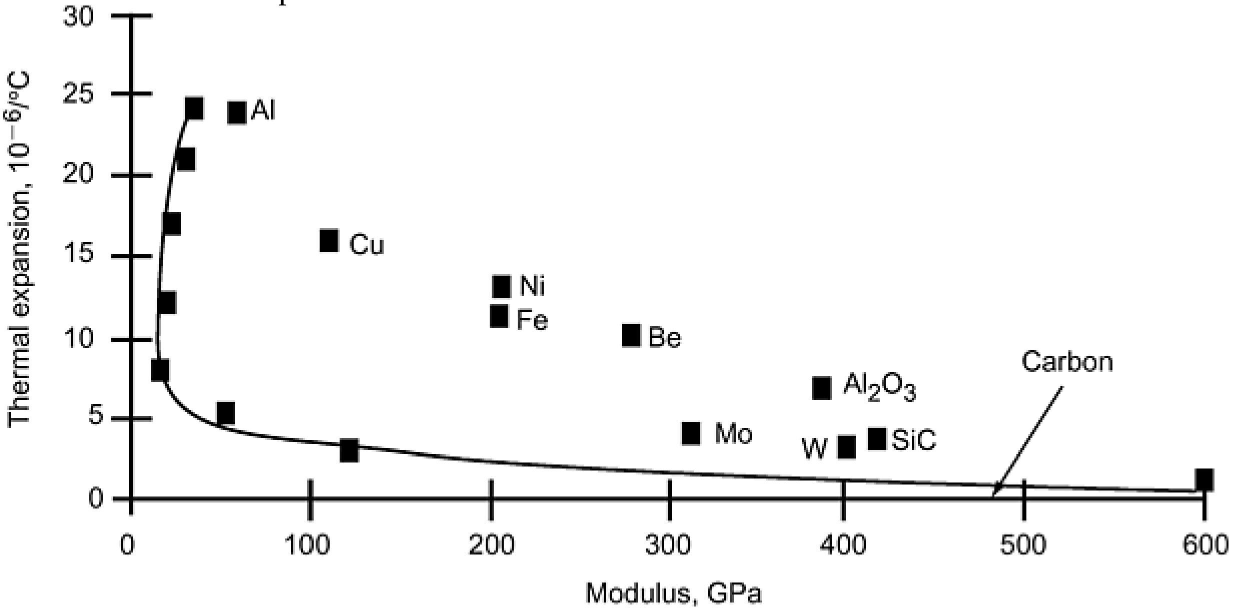

Fig. 2 Comparison of thermal expansion of various materials

Another important material property for thermal management is the thermal conductivity. Most applications need a material with good thermal conductivity and low mass; thus the specific thermal conductivity (conductivity/density) of various materials is shown in Fig. 3 below. It can be seen that metallic materials are isotropic, while the composite materials are directionally conductive. Composite thermal conductivity is achieved primarily from fiber contribution. An organic-matrix composite is essentially a thermal insulator through the thickness. The difference in the through-thickness and fiber direction (in-plane) conductivity of the carbon-carbon composite is due to the alignment of the carbon planes within the matrix versus the fiber. Typical pitch-derived fibers, such as P100 and K1100, possess well-aligned carbon/graphite planes within their microstructure (the greater the alignment the higher the thermal conductivity). Because the carbon/graphite planes are deposited semirandomly during processing, the matrix has no orderly alignment. This lack of alignment results in reduced thermal conductivity in the carbon matrix compared to the carbon fibers.

---

Applications

Electronic Thermal Planes. One of the first thermal management applications investigated for carbon-carbon was thermal planes for electronics. A thermal plane dissipates the heat from the electronic board to keep the chips at a temperature at which they can properly operate. The thermal plane also must not expand too much under heat loads so that it does not induce loads that wear the joints that attach the chips to the electronic board. Therefore, the thermal plane material must have high thermal conductivity as well as low thermal expansion. In addition, high stiffness material results in less vibration transmitted to the electronic board and thus a reduction in fatigue on the joints as well as reduced deflections. If the electronic boards do not deflect under loading, they can be packed together more closely without risk of impact. This allows a designer to get more electronic capability into a smaller volume.

From the application requirements it can be seen that carbon-carbon possesses many of the needed properties. Carbon-carbon has a low thermal expansion, thus reducing the thermal fatigue of the chip soldering. The high thermal conductivity allows the thermal plane to keep the electronics from overheating. Testing has shown that a carbon-carbon thermal plane reduces the electronic packaging temperature by 4 to 16 °C (7–29 °F), depending on the input power level, over the conventional aluminum thermal plane. This temperature reduction translates to increased reliability of the electronic package. Carbon-carbon also has a high stiffness that reduces deflections during vibrational loading. These properties combined with its low density make carbon-carbon composites an ideal material for electronic thermal planes. Figure 4 shows electronic modules utilizing carbon-carbon thermal planes.

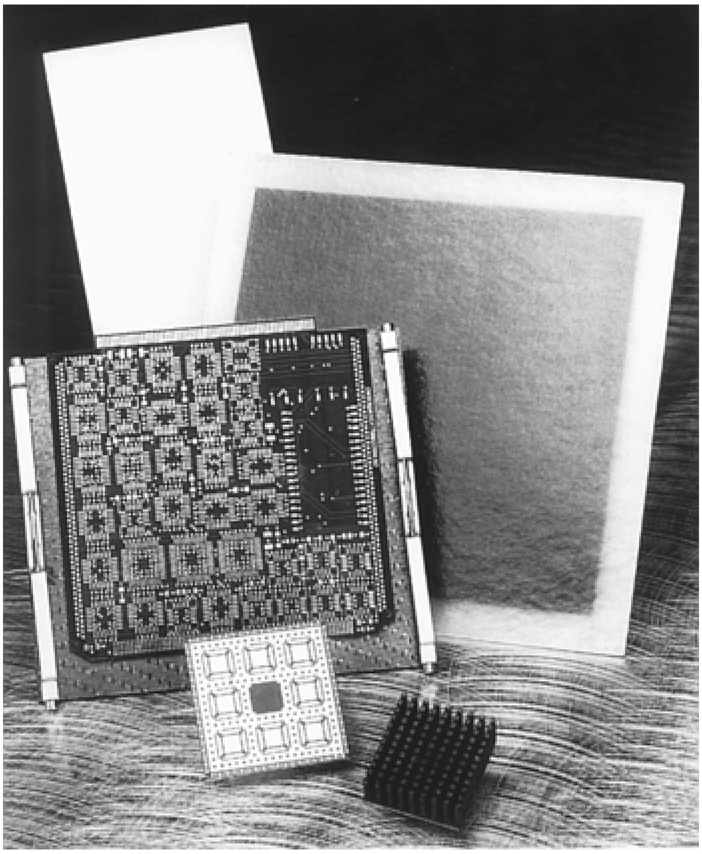

Fig. 4 Electronics with carbon-carbon thermal planes

Two major concerns, which have delayed the utilization of carbon-carbon, are electrical insulation from the electronics and cost of the composite. Carbon is a good thermal and electrical conductor and must be insulated from any electronics. This includes preventing any carbon on the surface from “dusting” and depositing carbon on the electronic modules or their solder joints. The coatings must be thin to minimize the effect on the thermal conductivity and must adhere well to the carbon surface. Efforts are underway to develop a coating and application technique. Current progress has shown various materials are capable of encapsulating carbon-carbon and allowing the composite properties to dominate performance. Cost of carbon-carbon must be reduced for it to be used in many systems. The costs associated with the long densification times and high costs prevent the composite from being regularly used.

Spacecraft thermal doublers perform a similar thermal function as thermal planes, but the mechanical requirements are different. The thermal doubler is typically used to remove heat from part of a spacecraft and then radiate that heat to space. Therefore, a high thermal conductivity material is needed. The components to which the thermal doubler attaches require the material to have a fairly low stiffness to reduce vibration (as opposed to the electronic thermal plane, which utilizes a high stiffness material). The final and very critical requirement for a thermal doubler material is it must be lightweight. The cost of launching a spacecraft is significant, and weight can considerably affect launch costs. Therefore, designers desire the lowest-density material that can meet the performance requirements.

Carbon-carbon can be fabricated for all of the required thermal doubler properties. It has a high thermal conductivity and a low density. By choosing a lower-modulus fiber with good conductivity and arranging it in the appropriate architecture, carbon-carbon can be made into a fairly low-modulus material. Carbon-carbon thermal doublers have been fabricated (Fig. 5) and used on some spacecraft.

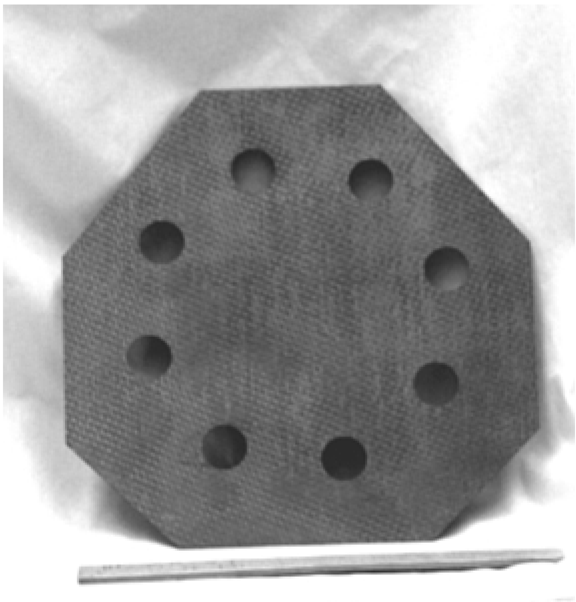

Fig. 5 Typical carbon-carbon space radiator. Courtesy of B.F. Goodrich

While procurement costs for space components are not the dominant issue, the fabrication time is significant. The average time to deliver a finished component from the time it is ordered is approximately three months due to the densification iteration. This required lead time is typically too long for users. Thus, producers have been working to significantly decrease the typical process time.

Spacecraft thermal shields represent a different type of thermal management application. The role of this component is to shield the remaining spacecraft system from the waste heat of the propulsion system. The material requirements include high-temperature stability and high stiffness at a low density. The high-temperature stability requirement is due to the amount of heat generated by the propulsion system. The material must be able to withstand this heat and still maintain mechanical integrity. The vibrational loading contributes the requirement for a material with high stiffness. The material must be able to survive under fairly high vibrational loading from the acoustics. A critical requirement for a thermal shield material is it must be lightweight, and therefore the most important advantage of a carbon-carbon thermal shield is the low density of the material. Carbon-carbon thermal shields have been shown to provide an approximately 50% weight reduction over metallic ones. The temperature stability and stiffness have been proven to be acceptable, as carbon-carbon thermal shields have performed successfully. Figure 6 shows a carbon-carbon thermal shield with Fig. 7 providing a concept of how it could be arranged in a spacecraft system.

Fig. 6 Uncoated, as-fabricated carbon-carbon thermal shield. Courtesy of Lockheed Martin Astronautics

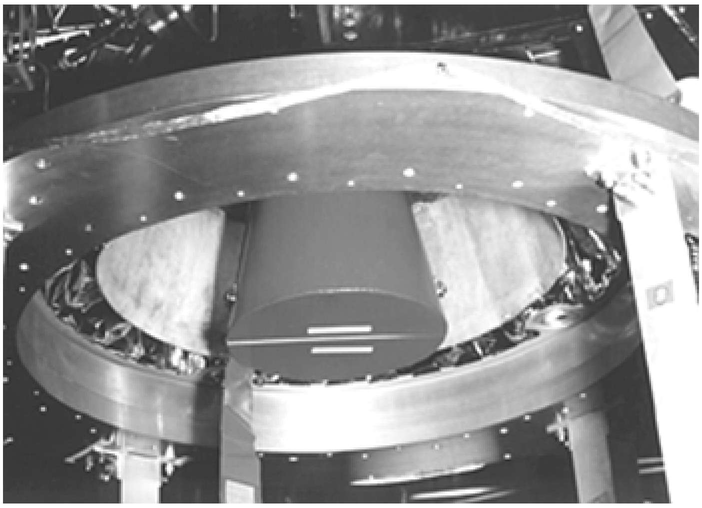

Fig. 7 Coated carbon-carbon thermal shield shown in spacecraft. Courtesy of Lockheed Martin Astronautics

Overall, the cost savings due to the weight savings overshadows any additional material costs. While procurement costs are not a significant issue, the time for composite fabrication is important, as it can be longer than desired by the customer.

Spacecraft radiators are another application in which the material must conduct “waste heat” from a source and radiate it to space. Its function is to keep whatever it attaches to cool enough to operate properly. Therefore, the material requirements include high thermal conductivity, reasonable strength and stiffness, and especially low density. A material with high thermal conductivity keeps the components from overheating. The material must have reasonable mechanical properties to support the components attached to it as well as survive any launch loads. Once again density is a critical material property.

From the application requirements it can be seen that carbon-carbon possesses many of the needed properties. The high thermal conductivity allows the radiator to provide the needed cooling capabilities. Carbon-carbon also has a high stiffness that reduces deflections during launch. These properties combined with its low density make carbon-carbon composites an ideal material for spacecraft radiators. Figure 8 shows an assembled carbon-carbon radiator with an aluminum honeycomb core and the attachments included.

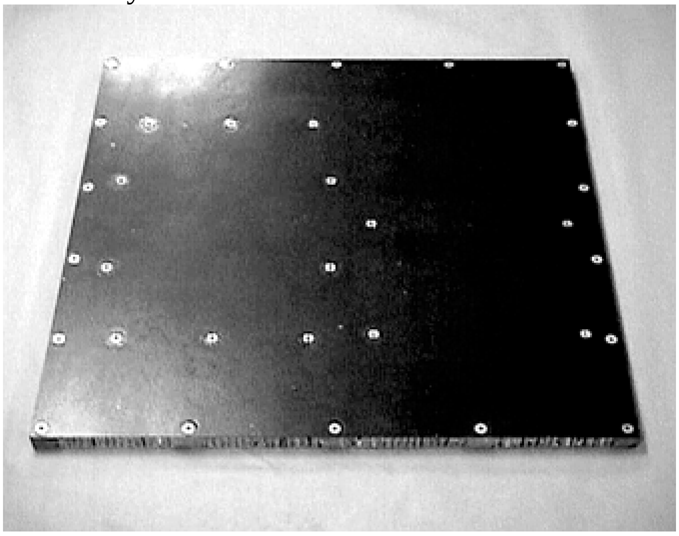

Fig. 8 Carbon-carbon space radiator with attachments. Courtesy of Lockheed Martin Astronautics

Attaching or bonding to a carbon-carbon radiator has not been an area of emphasis. Techniques have been tried, but have not been thoroughly tested. The radiator shown in Fig. 8 is based on the design required for an aluminum or polymeric-matrix composite radiator. There has not been enough work to determine the best design for carbon-carbon. Finally, the cost of carbon-carbon must be reduced for it to be used as a radiator material, and the fabrication time must be decreased. The current materials (aluminum or polymeric-matrix

composites) are providing adequate performance at lower acquisition cost and time. Without the demonstration of significantly improved performance, it will be hard to justify carbon-carbon radiators over current materials.

Aircraft Heat Exchangers. Many different heat exchangers are used on many different systems all over an aircraft. Figure 9 shows a metallic heat exchanger, housing, and core. The operating conditions can range from room temperature to as high as 650 °C (1200 °F) with low to fairly high fluid pressures. The specific conditions depend on where in the aircraft the heat-exchanger is located and its function. The role of the heat-exchanger material is basically to conduct heat from the hot fluid to the cold. The material requirements are high thermal conductivity, corrosion resistance, strength, stiffness, low permeability, and moderate temperature capability (depending on the specific heat exchanger). Corrosion resistance is required because of the composition of some of the fluids flowing through the heat-exchanger channels. For instance, an aircraft flying over the ocean will ingest salt spray as part of the cooling or heating fluid. So the heat-exchanger material must be resistant to saltwater corrosion or maintenance costs will be high.

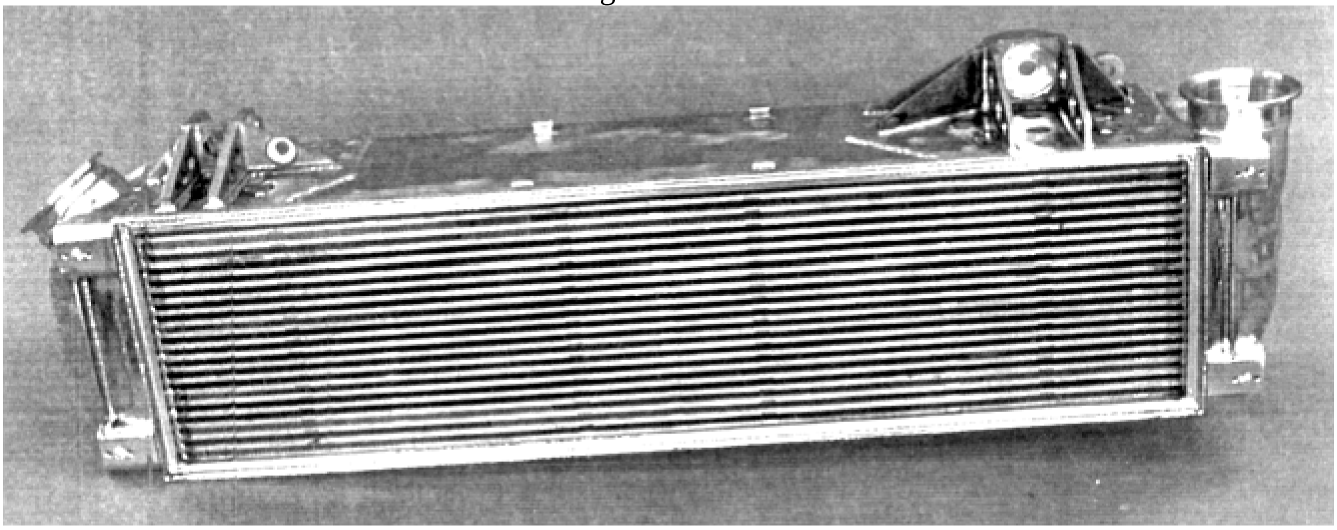

Fig. 9 Typical aircraft plate fin heat exchanger. Courtesy of SPARTA/Hamilton Standard

For the lower-temperature heat exchangers with air fluids, carbon-carbon may be the ideal material. It has a high thermal conductivity, reasonable strength and stiffness, and low density. Corrosion is not a concern at temperatures below 370 °C (700 °F). The higher-temperature heat exchangers are typically fabricated from very heavy metallic materials. The weight savings and high thermal conductivity of carbon-carbon offers the payoff of a higher-performance heat exchanger or a reduced-volume heat exchanger.

Many issues need to be resolved in fabricating a carbon-carbon heat exchanger. The structure of the core consists of parting plates and fins that are very delicate designs for any composite material. The core structure has been demonstrated with carbon-carbon, but must be more automated for better reproducibility and quality and lower costs. The higher-temperature heat exchangers require operating temperatures up to 650 °C (1200 °F). Above 370°C (700 °F), carbon begins to oxidize in the presence of oxygen (the higher the temperature the faster the oxidation rate). Oxidation protection schemes are being developed and tested to determine their capabilities.

Kristen M. Kearns, Materials and Manufacturing Directorate, Air Force Research Laboratory

Conclusions

The many properties of carbon have just begun to be exploited in carbon-carbon composites. Thermal management has become a logical application to explore with the composite material. Its tailorable thermal conductivity, stiffness, and strength in combination with its inherent low density make it an ideal replacement for some of the applications currently using a heavier metallic material. The applications discussed in this

article are being investigated with the potential payoff being more efficient heat dissipation and/or lighter-weight components. However, research and demonstration efforts are required before carbon-carbon can be considered the "baseline" material for any of the applications. The applications that are being investigated represent only a few of the many that could benefit from carbon-carbon.

Sports and Recreation Equipment Applications

Introduction

THE ADVANTAGES of composite construction have been applied to equipment for a wide range of sports and recreation activities. These advantages include strength, ductility, stiffness (modulus), and low density. This article opens with some historical background and then describes several examples of current composites applications for a variety of sports and recreation activities. A general overview of advanced materials for sports equipment is provided in Ref 1.

Reference cited in this section

1. K.E. Easterling, *Advanced Materials for Sports Equipment,* Chapman and Hall, 1993

Historical Background

Modern composite construction in recreational equipment and sporting goods has been used for over 100 years. The paper canoe manufactured in 1874 by E. Waters & Sons of Troy, New York, probably the first one ever built, was a very early example of modern composite structure in recreational equipment.

Construction proceeded over a wooden mold that was rabbeted to accept internal framing. Two kinds of paper were used: that made from Manila and that prepared from pure unbleached linen stock. Several sheets were laid on the mold, wetted, and then glued together. An analogy can be drawn directly to modern fiber-glass cloth-resin construction. After drying, the hull was removed from the mold, waterproofed, and the woodwork finished. The thickness of the paper layers was controlled to provide adequate strength at various positions on the hull; this was done to make the canoe as light and as strong as possible. This variable-strength feature of composite manufacture provides a unique design freedom that is still used in modern composites.

Unfortunately, Waters & Sons burned down for the last time in 1901. The first paper canoe, the *Maria Theresa*, perished in a 1920 fire at the New York Canoe Club. It had been made famous by Nathaniel Bishop, who paddled it from Troy, New York, to Cedar Keys, Florida. The entire matter is an amazing testimony to the soundness of composite construction in recreational equipment, even with materials that would now be considered inadequate.

Laminated wood construction, or plywood, was later used in various forms for sport and pleasure boating, as well as in such items as tennis rackets and the delicate, glued flyrods constructed of tapered bamboo sections. More recently, the term composite has been associated with such materials as fiberglass, carbon fibers, silicon carbide platelets and whiskers, and aramid fibers. These materials have greatly broadened composite use in sport and recreational equipment by introducing filamentary materials with tensile strength versus weight and stiffness versus weight properties that greatly exceed those of wood, steel, and other more common materials. All of these new materials are embedded in a resin matrix, such as an epoxy or polyester, for fiber alignment and stable form.

Composite construction permits a designer to vary the mechanical properties almost microscopically in any section of the composite. This is done by controlling the amount of fiber reinforcement inserted, as well as its direction, and by combining layers of different reinforcing fibers of varying elasticity and strength. The end result is a macroscopic body that can have nearly ideal stress-strain and strength properties for the application. This application-efficient construction, along with modern fiber reinforcements, markedly minimizes overall weight in recreational equipment.

The common component of these composites is the resin that binds the mass together. The early nonwaterproofed glues were a severe constraint on paper canoes. With the availability of waterproof adhesives, the use of plywood in recreational equipment increased greatly. However, the same development problems remain true today. One of the most recent discoveries is the long-term failure of certain polyester resins used in pleasure craft, which led to severe blistering of the hull surface due to water absorption. The story of composite development in recreational equipment could also be expressed in terms of resin and adhesive development. The combination of modern resins with advanced filaments of great strength and stiffness has created new opportunities for composites in recreational and sporting goods, as well as other applications.

Sports and Recreation Equipment Applications

Bats, Rackets, and Clubs

Baseball Bats. Many softball teams and college baseball teams are now using composite bats. The bats are made of a graphite-reinforced polycarbonate (PC) blend. The graphite-reinforced bat is light and durable like aluminum, with the sound of wood. The bat is highly resistant to impact. It is tested against an air cannon that rockets balls in at 290 km/h (180 mph), nearly twice as fast as a major league fastball.

Both baseball and softball bats are formed by molding the graphite-PC blend around a steel core pin. A hollow shell is produced, which can be selectively filled with cellular urethane foam. The foam provides a center of gravity for the “sweet spot” of the bat, the area from which the ball travels farthest.

The graphite-reinforced resin shell is lightweight, strong, and stiff, allowing minimum material to achieve high strength. The weight savings allows greater options in the placement of the urethane filler. The sweet spot can

be made larger. Graphite also reduces vibration and the sting of ball shock, the tingling feeling sent to the hands usually when a batter misses hitting the ball in the sweet spot of the bat.

The center of gravity of the bat also can be moved down the handle, permitting the hitter to generate more bat speed. With a larger sweet spot and greater bat speed, a batter can hit the ball farther.

Tennis Rackets. With many professional players smashing tennis balls at over 160 km/h (100 mph), tennis is a game of speed and control. Trying to hit the ball at high speeds and return it in-bounds requires concentration and a great degree of racket control. Rackets made from graphite-fiber composites give the player better ball control without increasing physical energy. The graphite rackets are stronger and stiffer than metal or wood and have a reduced head torque that provides a solid feel over a larger area of the racket head.

A graphite racket dissipates less energy, allowing the player to hit the ball with greater velocity. Manufacturers also can tailor the weight and balance the racket to a player's individual needs. The endurance life of a graphite racket is longer than that of conventional rackets.

Composite rackets are also being made with a combination of braided and unidirectional carbon fibers. Braided carbon fibers help prevent the racket from twisting. Rackets are made with 65% carbon, 30% glass, and 5% aramid. Graphite is stiffer, but more brittle; fiberglass is more flexible, but tougher.

Another racket is made with 84% carbon, 12% aramid, and 4% alumina fibers. The racket combines the performance of carbon with the comfort of a ceramic racket. Carbon adds stiffness and strength, resulting in controllable power. Aramid damps vibration, preventing “tennis elbow.” Alumina has a higher modulus and damps vibration better than silicon carbide, which is commonly used in ceramic rackets. The net result: the racket delivers power, stroking control, and a soft but solid feel that is easy on the arm.

Golf Clubs. One of the greatest professional golf players, Jack Nicklaus, once said, “To play strategic and tactical golf, you have to be able to hit the ball more or less in a predictable direction a good part of the time.” Thus, the key to better golf scores is not just strength but control. Composite golf shafts, reinforced with graphite fibers, give the golfer more control. They are 40% lighter than metal shafts, allowing weight to be added to the club head, while still reducing the overall club weight. With more weight in the head area, a golfer can drive the ball farther. The lighter club helps the golfer to improve the accuracy with his shots.

Composite golf shafts are usually made by either roll wrapping or filament winding. Filament winding, because it is an automated process, tends to maintain lower shaft frequency variations, often to ±1 cycle per minute (cpm) compared to ±4 cpm for roll-wrapped shafts (see the article “Filament Winding” in this Volume).

Golf club shafts are also being made of a combination of carbon- and boron-reinforcing fibers. Many Professional Golf Association (PGA) players prefer the carbon-boron club. Boron has much higher stiffness and fiber diameter than carbon, so it may serve better when used longitudinally. Compression-molded carbon cores serve to increase strength and power, while damping vibration.

To combat crushing loads, the manufacturing process begins with a close spiral wrap (to prevent the collapsing-straw effect), followed by a second spiral wrap that places the fibers at a lesser angle relative to the shaft axis. These layers form the effective core that handles torsional and radial impact loads. Here, the material of the wrap and the number of filaments in it control the off-center, springlike response of the golf club head to impact with the ball. The head should return to an appropriately neutral position when the ball leaves contact with the club in order to maintain optimal directional control. The inner windings, with resin applied, are enveloped by a layer of parallel fibers running along the axis of the shaft, which respond to flexural loads along the axis of the golf club. Using this method of construction, adjusting the thicknesses of the helical and parallel fibers, and using a predetermined inside and outside diameter for the shaft, the designer has enough variables under his control to construct the most efficient golf shaft available.

Even golf heads are being made of graphite- reinforced epoxy. The graphite heads are stronger, stiffer, and lighter, leading to more head speed and greater control. Golf club faces are being made by a combination of quartz yarn and carbon-fiber/epoxy composite, which compresses the ball more, leading to longer drives.

Bicycling

Bicycle races often end in sprints, with the cyclist achieving speeds of 80 km/h (50 mph). Cycling requires training, endurance, strategy, and equipment. Bike racing demands a high level of concentration. No energy is wasted in unnecessary movements. While pedaling, power should be applied all the way around, and the lighter the bike, the faster it can go.

Carbon-fiber-reinforced bicycle frames are stiffer than steel and lighter than aluminum. Hubs and wheels are being fabricated with glass- fiber-reinforced nylon. Drive plates are being made of polyethylene terephthalate reinforced with glass fibers. Even the drive chains are being replaced with polymer composites.

Bicycle Frames. Graphite/epoxy composite frames allow more flexibility in design, permitting designs that reduce drag. They also provide vibration damping. The Softride suspension system from Allsop, Inc. employs a graphite and glass, cantilevered seat beam to reduce shock.

Bicycle frames are being braided with graphite prepreg. Braiding provides high strength and resistance to torsion, or twisting.

In a Kestrel design, the carbon/epoxy frame has no seat tube (Fig. 1). The one-piece frame has integrally molded tubes and junctures and eliminates the seat tube by using a passive suspension system for a smoother, more aerodynamic ride.

Fig. 1 One-piece carbon/epoxy bicycle frame. Courtesy of Kestrel

In another one-piece design, the frame is molded with true airfoils to reduce drag. It is reinforced with a hybrid of carbon and polyethylene (PE) fibers. Carbon fibers supply stiffness, while PE fibers provide lightweight strength. Polyethylene fibers also damp shock and resist fatigue. The frame has no bonded joints, which are regions of stress concentration. The frame is very stiff in-plane, so energy goes to driving the bike forward. Unlike metal, the composite frame is more flexible out-of-plane, so it is easier on bumps, especially important in long races. Further, the composite frame can withstand fatigue and crushing three to four times better than steel.

Air resistance accounts for up to 90% of the total force slowing a cyclist down. The U.S. Olympic team used carbon composite tubes in the bicycle frame. Each tube is shaped like an airfoil to reduce drag, yet it is stiffer and lighter than steel. Olympic cyclists also used an aerodynamic bicycle frame that is laid up with carbon-fiber/epoxy prepreg and glass-fiber prepreg sandwiched around a closed-cell foam core. Spoke and disc wheels are also composite.

Bicycle frames are being fabricated with boron-reinforced aluminum. Boron-reinforced aluminum is lighter, stronger, and stiffer than pure aluminum, yet it retains much of the toughness of aluminum. Hybrid frames, such as carbon- fiber-reinforced polymer composites combined with titanium, have been provided.

Bicycle Wheels. The SPIN bicycle wheel from Innovations in Composites is made with a long carbon-fiber-reinforced nylon blend. The long fiber compounds are prepared in a pultrusion process that permits a high level of fiber impregnation. The three-spoke 1 kg (2.2 lb) SPIN wheel is a one-piece hollow construction made by a lost-core injection molded process. An aluminum rim is bonded to the wheel. The result is a strong and lightweight composite wheel at half the cost of a traditional carbon/ epoxy hand-laid-up wheel.

Aramid-fiber composites are being made into disc wheels. The aramid wheels cut the wind resistance of a normal bicycle wheel in half. The spokeless wheels knife through the air, eliminating the drag of numerous spokes. Aramid-reinforced tires weigh less than 0.1 kg (¼ lb) each. The feather-light wheels and tires reduce rolling friction.

A one-piece bicycle wheel rim is being formed with braided carbon-fiber/epoxy prepreg. The braided prepreg permits closer tolerances— down to 0.05 mm (0.002 in.)—so less energy is lost to sideways motion.

Winter Sports

Hockey sticks must be light and stiff like golf clubs. However, hockey sticks take a beating from slapping against the ice, crashing into the boards, and swinging at other players. The average hockey stick lasts only 5 to 15 games.

Hockey stick handles from Sherwood Products are made with a core of aspen wood surrounded by layers of fiberglass. Fiberglass lowers the weight while adding stiffness and durability. The critical region of the blade consists of 80% fiberglass and 20% graphite fibers for increased stiffness. Aramid is sometimes added to the heel of the blade for impact.

Hockey sticks are also being fabricated by Easton Aluminum Inc. with an aluminum tube overwrapped by layers of bonded high-modulus carbon-fiber/epoxy. The hockey stick is said to be the lightest and stiffest made.

Sleds. Olympic bobsleds race at speeds up to 90 mph, rounding a turn at five times the force of gravity. A composite monocoque replaces previous steel sleds. The composite sled is four times stronger than steel. It is also safer; the driver's body is protected during a crash by the composite monocoque. In a steel sled, the driver bangs into the steel rods; in the composite sled, there are no protrusions to bang into.

The composite sled is comprised of Nomex (DuPont) honeycomb, sandwiched between layers of aramid and graphite-fiber-reinforced epoxy. The epoxy withstands subzero temperatures without losing its adhesive properties. The composite sled allows greater freedom in aerodynamic design, reducing drag by 40%. The sled weighs only 45 kg (100 lb), a fifth as much as a metal sled. The result: greater speed and greater control.

Luge sleds are also made of composites. They are composed of a carbon-fiber/vinyl ester resin that withstands the subzero temperatures without a loss in properties. The sled is highly resistant to impact, which is important in a sled that can tip over at speeds up to 130 km/h (80 mph).

Snowboards. A composite snowboard is constructed by Hexcel Corporation. The board consists of a thermoplastic cap or top layer, a layer of glass, carbon, or hybrid prepreg, a polyurethane honeycomb core, another layer of glass, carbon or hybrid prepreg, and a PE running surface. Prepregs are used, because they provide easier handling and a better working environment than wet lay-up. They also are lighter than wet lay-up, because they have a lower resin content. Further, they are easier to mass produce to an exact specification (thickness and weight).

The composite board has a polyurethane (PUR) honeycomb core, because it provides significant weight savings over a wood core, with no loss of stiffness. Polyurethane reduces production times (less than 10 min from mold preparation to demolding) and reduces the number of components. Polyurethane provides excellent adhesive properties and an ideal balance of flexibility and stiffness when combined with laminates. The use of PUR reaction injection molding material makes production extremely quick and provides excellent adhesive properties. Honeycombs combine very low weight with excellent stiffness.

A snowboard from Morrow Snowboards has a Baydur polyurethane foam core from Bayer Corporation (Fig. 2). Polyurethane is poured into a clamshell mold to form the composite core. The mold is heated to 55 to 60 °C (130 to 140 °F), with pressure reaching 240 kPa (35 psi). After 10 to 12 min, the foam core is demolded. Thicknesses range from 9 mm (0.35 in.) in the center, tapering down to 2 mm (0.08 in.) at the front and back. The foam core is covered with fiberglass that has been impregnated with epoxy resin. A decorated top layer is applied last.

Fig. 2 Fiberglass/epoxy snowboard with a polyurethane foam core. Courtesy of Bayer Corp.

Snow Skis. The world's record for downhill racing is nearly 210 km/h (130 mph). To reach these speeds, high-strength, lightweight materials are essential. Snow skis are made out of graphite-reinforced epoxy. The high stiffness and reduced damping of graphite permit sharper, faster turns.

Some skis are made with glass-fiber-reinforced epoxy. The fiberglass/epoxy skis do not break as easily as wood. Aramid fibers are also reinforcing skis. The aramid fibers dampen vibration for smoother, more comfortable skiing. The fibers resist abrasion and lessen fatigue, so skiers can ski faster and longer, while retaining control.

Snow skis have been made with braided composites. Braiding is an automated process that ensures uniformity, while it eliminates seams and overlaps. Braided skis resist torsion better and weigh 0.45 kg (1 lb) less than hand lay-up skis—due to closer tolerances and less excess resin.

Hexcel Corporation is manufacturing Alpine and cross-country skis using honeycomb cores. The skis have a layered structure, consisting of an aluminum/epoxy/fiberglass top layer, a rigid foam/wood/honeycomb core, a reformed thermoplastic cap, a layer of epoxy/fiberglass prepreg, a polyurethane rigid foam core, another epoxy/fiberglass bottom laminate, and a PE running surface. The multilayered skis have the toughness and durability to resist the stresses and strains of Alpine and cross-country skiing, yet the skis are ultralight and comfortable to use.

Ski poles are manufactured by pultruding glass fibers. Ski poles are also made out of graphite-reinforced epoxy. Both woven and unidirectional graphite fibers are used. In a ski pole, swing weight is critical. Composites allow the center of gravity to be moved closer to the handle, reducing the swing weight. In a 15 km (9 mile) cross-country ski race, the poles swing 5,000 times, so carbon-fiber shafts, which weigh only 100 g (3.4 oz), can save 3400 J (2,500 ft · lbf) of energy during a race. Ski poles also need compressive strength, with the carbon/epoxy pole at 860 MPa (125 ksi) compared to 550 MPa (80 ksi) for aluminum.

Ice skates and boots, from K2 Exotech have long fiber-glass-reinforced nylon with chopped carbon fibers injection molded into the ice skate frames, boot base, and heel counters. K2 also produces 4-wheel and 5-wheel cross-training skates, made from fiberglass/epoxy prepreg and graphite/epoxy prepreg continuous woven fabric. Merlin Technologies developed a low-cost/ high-production system for hybrid glass-carbon composite structures used in lightweight skating boots. The composite components replace 90% of the structural leather in traditional boots, reducing the overall weight while improving control response for ice, roller, and blade skaters. In figure skating, the reduced weight means higher leaps and a greater chance of completing multiple-spin movements, while increased stiffness allows better blade control at landing impact. Reebok makes a fiberglass/carbon-fiber hybrid arch support in their athletic footwear.

Aquatic Sports

Water Skis. Like snow skiing, water skiing is a sport that relies heavily upon balance and coordination. Skiing slalom, on just one ski, requires an even greater degree of control. Composite slalom skis are reinforced with PE fibers. The PE fibers are 10 times stronger than steel for the same weight. The stronger, lighter PE-fiber-reinforced skis help the skier to regain speed after turns and jumps and to accelerate faster. The ski is more stable in rough water and provides the skier with greater control. The impact resistance and toughness are improved, giving the skier a competitive edge.

Slalom water skis are also being made of a hybrid of glass and carbon fibers to achieve the desired combination of flex and performance. The skis are constructed by wrapping fiberglass and carbon-fiber-reinforced epoxy prepreg around a high-density PUR foam core that has been premolded, sanded, and cured so that shrinkage takes place before the ski is fabricated. Skis are typically cured by compression molding at around 95 °C (200 °F). Trick skis and jump skis are constructed from carbon-fiber prepreg with aluminum honeycomb cores.

Another water ski from Connelly Skis, Inc. has Baydur PUR foam core surrounded by a graphite-fiberglass composite, with an acrylic top shell and acrylam (acrylic) base. The PUR foam core gives the basic shape to the ski, has a high strength-to-weight ratio and provides structural stability and torsional control. It helps skiers maintain control—providing the right amount of acceleration and deceleration and enabling them to carve smooth turns without losing edge.

A hybrid composite containing aramid and boron fibers is being fabricated into water skis. Aramid provides lightweight tensile strength and toughness. Boron offers stiffness and strength in both compression and bending.

A wake board, or surfboard, from Connelly Skis, Inc. (Fig. 3) is compression molded with a core of Baydur PUR. The core is then wrapped with a graphite-fiberglass composite. This in turn is sandwiched between the top and bottom layers of the board. The top layer is an acrylic material. The bottom of the board is made with acrylam (acrylic). The wake board is stiff, light, and strong.

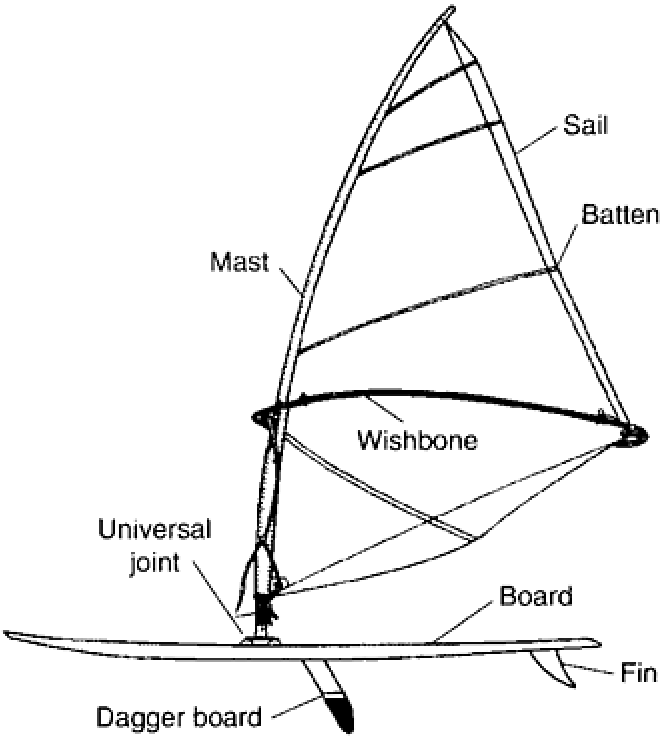
Fig. 3 Composite wake board. Courtesy of Connelly Skis Inc.

Windsurfers. Windsurfing boards are constructed of high-density 6 mm (0.25 in.) polyvinyl chloride foam sandwiched between layers of high-strength, epoxy-impregnated fiberglass. This sandwich construction is then wrapped around an expanded polystyrene foam core. The board lay-up is placed in die molds and cured under heat and pressure. The resulting board is light and very strong. Carbon strips are used for strategic placement, such as in the area under the feet of the sailor, which can see high stress from landing jumps from up to 6 m (20 ft) high, typical when sailing in ocean waves.

Another design of windsurfing board is started from the inside out. The dry laminate (roving, mat, and carbon) is stapled with plastic stitches to the foam blank, coated with acrylonitrile-butadiene-styrene (25 to 50 μm, or 1 to 2 mil, thick), and thermoformed in an injection press.

Windsurfer masts (Fig. 4) are braided with carbon and glass fibers by Fiberspar. The masts are 5 m (16 ft) long with a base diameter of 48 cm (19 in.) and a tip diameter of 25 cm (10 in.). The masts weigh only 2.3 kg (4.7 lb) and must endure considerable torsional forces, because bend in the mast is critical for speed. Braiding the masts helps control the torsion within the design limits. The lighter masts are easier to hang on to, manipulate, and lift out of the water.

(a)



(b)

Fig. 4 Windsurfers. (a) Windsurfer with a braided composite mast. Courtesy of Fiberspan. (b) General design of a windsurfer. The flexure of the mast controls the shape of the sail; its pivoting about the universal joint controls the response of the craft.

A case history in materials selection for a windsurfer mast is provided in the article "Performance Indices" in *Materials Selection and Design,* Volume 20 of *ASM Handbook*.

Canoes, kayaks, and racing hulls are being made with carbon-fiber/epoxy as well as aramid and glass fibers. The lighter-weight boats travel faster in competition. Canoes are being built with carbon fibers, aramid fibers, and a core material called Spheretex (Spheretex GmbH), a woven fabric with high silica glass. These boats provide greater tensile strength and abrasion resistance.

Composite canoes from We-No-Nah Canoe, Inc. are manufactured using Tuf-Weave fiberglass-orthopolyester 0.3 kg (10 oz) fabric blend, with a small amount of aramid for stiffening in the bow and stern. They also make vinyl ester/ aramid canoes. Both are thin-skin laminates formulated with a high fiber-resin ratio and cured under vacuum bag pressure to provide good flexibility and resilience.

Personal watercraft, such as the JetSki from Kawasaki Motors Corporation, are being manufactured with sheet molding compound, which uses half-inch chopped glass and precision- matched steel dies. Personal watercraft are also being made by hand lay-up fiberglass and resin transfer molding with glass reinforcement for structural parts, such as hulls and decks.

A composite kayak is reinforced with PE fibers. The high strength-weight ratio of the PE fibers causes the ends of the boat to be lighter, allowing it to go over waves more easily. The composite kayak sustains travel over rocks without damage. The kayak is 4 kg (9 lb) lighter than comparable carbon or aramid kayaks, leading to faster acceleration.

Canoe paddles are made out of a hybrid composite. The paddle has a rigid polyimide foam core covered with a layer of unidirectional graphite/epoxy tape. On top of that is a hybrid braid of aramid, fiberglass, and selectively placed graphite wraps, with twice the amount of graphite on the compression side as the tension side. The compression side of the paddle blade is comprised of unidirectional graphite/woven fiberglass hybrid cloth. The tension side of the paddle blade is comprised of unidirectional aramid/woven fiberglass hybrid cloth.

The overall result of this bent-shape canoe paddle is high strength and ultralightweight. The paddle is tough, yet provides smooth and efficient propulsion.

A Big Blade oar from Concept II is combining graphite/epoxy with glass fibers for durability and light weight. The short, fat, meat-cleaver- shaped oar has 15% more surface area on the blade, leading to more force on the water per stroke with less effort than longer conventional- shaped oars.

Use of composites in larger watercraft is addressed in the article "Marine Applications" in this Volume.

Fishing Gear. To catch a large number of fish, a fisherman needs a lightweight rod that requires minimum casting energy. Fishing rods, with glass-fiber-reinforced epoxy wound around a mandrel, are lightweight and flexible. The rods are made by a combination of pultrusion and modified filament winding.

Graphite-reinforced rods are even lighter, typically weighing 38 g (1.3 oz). Lighter weight rods increase the response and "handfeel." When casting, vibrations in a graphite rod dampen more rapidly than other rods, minimizing the line drag. The reduced drag helps the fisherman to cast a greater distance and more accurately. Graphite rods vibrate less than bamboo, wasting less energy and allowing 20% greater casting distance.

A hybrid graphite/glass/epoxy fishing pole made by Shakespeare Products is ultralight, allowing a fisherman to cast farther and make more casts without tiring out his arm, yet the rod is strong enough to pull in a large bass. The rod can actually be bent 360° without breaking. These rods use a hollow tubular structure to minimize weight and to optimize the strength and sensitivity of the rod in sport fishing. All such tubular fishing rods are created around a removable metal mandrel, which forms the tapered inner diameter of the finished product. The taper and diameter of this cylindrical cone constitute the starting point of the design. On this inner mandrel are placed the various fibers that provide the strength of the fishing rod and the resin that bonds the fibrous structure together.

One particular construction (Fig. 5) begins with an inner layer of carbon fiber, wound spirally around the mandrel from the butt end to the tip of the rod. This continuous spiral of fibers dramatically improves the radial integrity, or hoop strength, of the rod blank by distributing pressure over a larger area. It virtually eliminates the collapsing-straw effect that can plague hollow rods constructed with a fiber direction (for example, rolled woven fibers) that does not take into account the actual stress distribution in a bending tube. A second layer of fiberglass fibers is then placed over the initial graphite layer and oriented longitudinally along the axis of the rod, which increases the sensitivity of the rod, because the vibrations of the fish are readily transmitted in the direction of the fiber. The final function of these fibers is to increase the overall bending strength of the fishing rod. In a premium rod, a third layer of longitudinal carbon fiber is added to the blank for further strength and

controlled stiffness. The small, solid tip on such a rod becomes a light, very strong section of 100% carbon fiber embedded in resin.

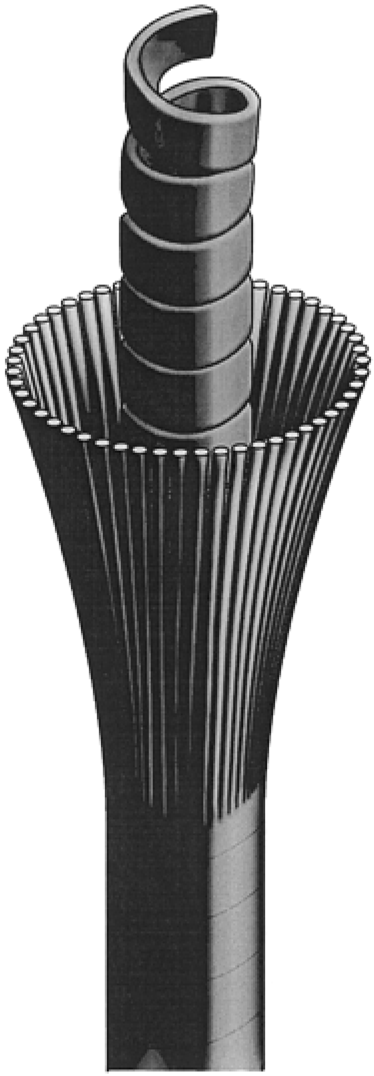


Fig. 5 Composite fishing rod construction. Courtesy of Shakespeare Products

The end result is a piece of recreational equipment in which material choice, material configuration, and overall shape maximize the strength and sensitivity of the rod at minimum weight, illustrating how modern composite materials and design permit optimization to suit the final purpose of the application. Such design freedom is simply not available with metal or wood.

Figure 6 shows the equipment used to produce high-quality composite rods. The machine starts at the butt of a rod mandrel and uses the maximum number of fiberglass or graphite rovings required by the design. These are then cut out or reduced in number in a preset manner as the rod blank is formed from butt to tip. Consequently, some of the fiber filaments run the full length of the mandrel, and others run only a partial length. Impregnation with resin, usually an epoxy, is carried out simultaneously. By altering the mandrel and changing the amount and locations of the fibers used in construction, fishing rods of different characteristics can be made for all segments of the market on a few basic pieces of manufacturing equipment.

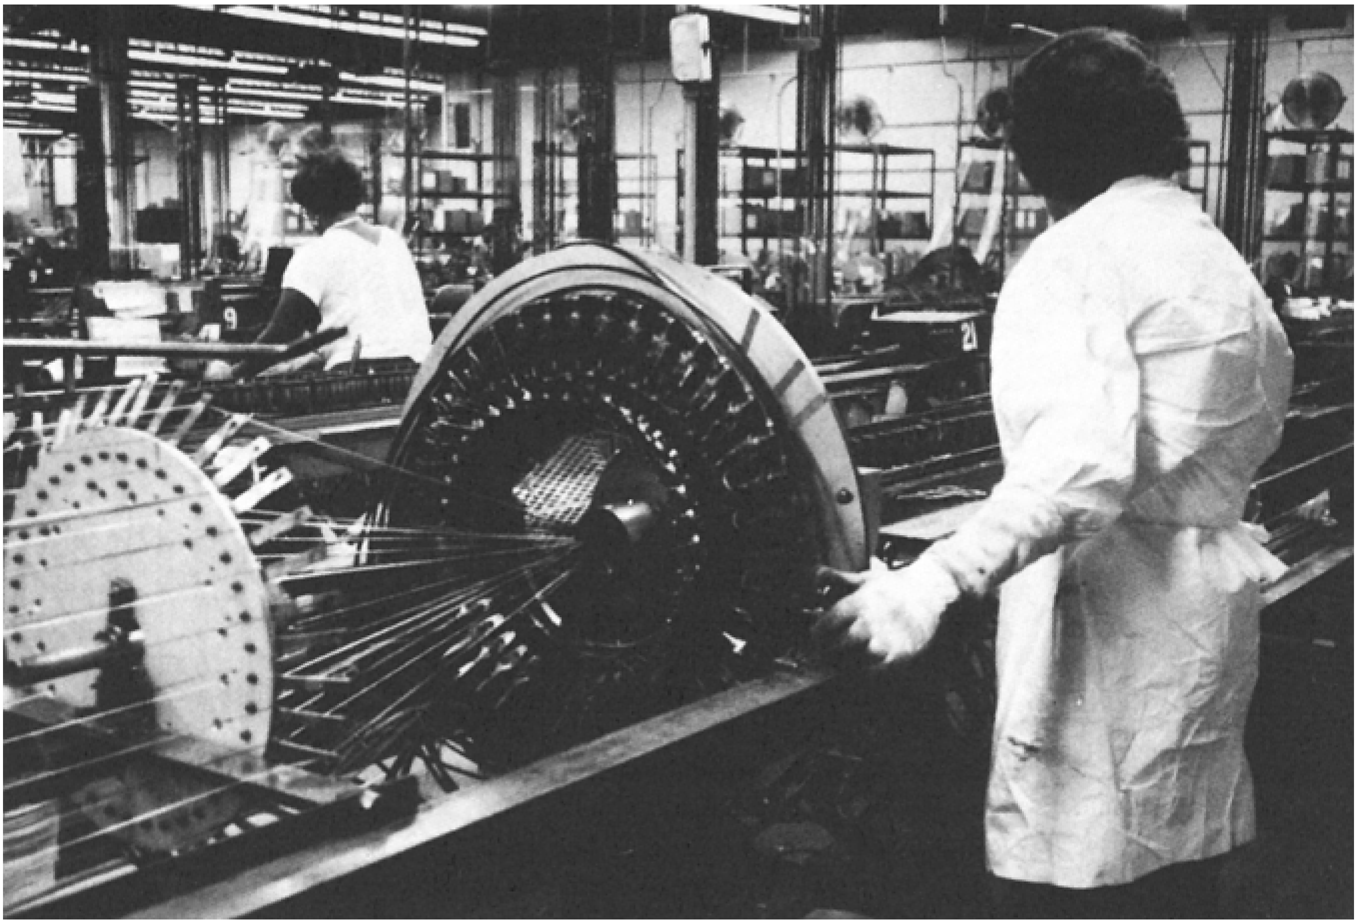

Fig. 6 An inner layer of spiral wrapping of carbon filaments being applied to a carbon-fiberglass fishing rod. Courtesy of Shakespeare Products

The spool of a bait-casting fishing reel should be light to start rotating quickly and stop quickly with a minimum inertia. A heavy spool is hard to start or stop. A glass-fiber-reinforced polybutylene terephthalate (PBT) reel is significantly lighter than its metal counterparts.

The PBT reel costs less to manufacture than a metal reel. By means of part consolidation, the PBT reel has only 47 parts compared to 58 parts for metal reels, while eliminating many assembly and finishing steps. It also resists corrosion better.

A trolling motor shaft from Strongwell Company is being manufactured from a 29 mm (1.125 in.) diam by 760 mm (30 in.) long pultruded tube, threaded to fit into a steel housing and given a black satin finish. The fiberglass- polyester shaft does not transmit motor sound waves, a big advantage to a fisherman. For fishing underwater, Bedford Reinforced Plastics Inc. pultrudes fiberglass-isopolyester rods and tubes that are used for diving spears, diver's flag floats, and tickle sticks for poking lobster out of holes.

Track and Field Equipment

Pole-Vaulting Poles. Pole vaulting as a sport has never imposed any particular constraints on the construction or design of the pole. However, there was little change in the design or materials of construction until the advent of fiberglass composites. The poles had been made of bamboo, steel, or wood, but in the 1950s, fiberglass- resin poles were successfully introduced. These poles copied the earlier wood or metal poles without any pronounced use of empty cores or changing of diameters or fiber concentrations to improve the pole in a way comparable to that described for fishing rods or golf clubs.

The engineering problem involves the design of a very light, highly efficient tubular spring that is loaded by impact when the running vaulter places one end of the pole in the planting box beneath the vertical bars of the vault. The kinetic energy of running must be converted into a rotational energy that is sufficient to carry the vaulter to a vertical position and over the measuring rod. The basic vibrational period required for the pole to straighten from its initial loading must equal the time it takes for this quarter revolution of the vaulter to occur. The spring constant must therefore be designed to take the weight of the vaulter into account. Because the vaulter tries to maximize the kinetic energy by sprinting toward the vault, the pole needs to be as light as possible. Above all, it should not break.

This is the type of problem that, once thoroughly understood in engineering terms, makes it impossible to become a successful vaulter. This point may seem facetious, but the customer for recreational equipment must be approached with this matter in mind. The acceptance of an innovative piece of sports equipment is often achieved through performance factors recognizable by the athlete in a framework entirely different from that used by the engineer.

The strength of the composite fiberglass poles per unit weight was greater than earlier materials. Therefore, the poles were made lighter and were more flexible. This required vaulters to develop new techniques for their successful use. The early fiberglass poles were not yet designed for all the desirable requirements from the viewpoint of the vaulter, and this probably slowed their initial acceptance.

The requirements of the vaulting pole have led to a specialized form of fishing rod, rather than a pole that bends uniformly from end to end. The major manufacturers have recently redesigned the poles to be nonlinear springs, which are stiffer at the butt end than at the other. Carbon fiber has also been introduced in an attempt to reduce weight while improving stiffness. Fiberglass, with about five times the strength-to- weight ratio of steel, is roughly equal to steel in specific stiffness. Carbon fibers have about five times the specific strength and about five times the specific stiffness of steel. The resultant optimal pole is therefore likely to be a combination of these two fibrous materials in a suitable resin matrix.

The pole design consists of two layers of fiberglass tape spiral wrapped to the outside of a hollow aluminum mandrel. Next, unidirectional fiberglass/epoxy prepreg is ironed to the spiral wrap. Carbon fiber is added in the inner wrap. A “sail piece” of the same prepreg material is cut to a taper and wrapped around the pole. The pole is put into a silicone bag, air pressure is applied to the outside of the bag, and steam heat is directed into the aluminum mandrel, curing the part from the inside.

Sports wheelchairs used for racing and sports such as basketball, use graphite/epoxy frames, weighing only 1 kg (2.3), integrally laid- up lugs, and elliptically shaped tubes that are 29% stronger than round tubing across major load planes. Composites allow varied wall thickness to build in stress reinforcement. They also dampen shock. The Power Bar, a T-shaped graphite/epoxy wheelchair frame, has a wall thickness of 2.54 mm (0.10 in.). The Power Bar also has a braided prepreg sock. Composites in the frame have four times the longitudinal stiffness as aluminum.

Sprinters' Prostheses. Springlite manufactures a one-piece graphite-fiber/epoxy sprinter foot prosthesis that features a radial shape and high strength and stiffness, allowing sprinters to run on their toes without fear of the prosthesis breaking. The Flex Sprint from Flex Foot has graphite-fiber/epoxy pylons that allow length variation and a balance of strength and flexural properties that vary with a runner's weight and speed (Fig. 7). Composite plantar flexes are designed to angle forward and down, striking first in the toe, thus storing and returning more energy to the runner.

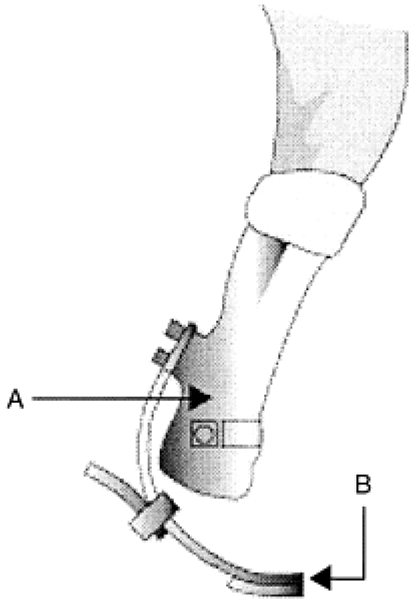

Fig. 7 Schematic of a sprinter's prosthesis, used by Tony Volpentest at the 1992 Barcelona Paralympics. Born without feet, Volpentest won gold metals in Barcelona in the 100 meter (11.63 s) and 200 meter (23.07 s). The socket of the prosthesis (A) is flexible, allowing for various muscles, tendons, and bones to function inside. It also features a flexed toe (B) that ensures landing on the forward 5 cm (2 in.) of the toe—the normal gait for sprinting. Source: Ref 2

For above-knee runners' prosthetics, the Endolite Sports Limb (Chas. A. Blatchford & Sons Ltd) contains a graphite/epoxy knee. The Sports Limb features a lightweight composite cradle able to withstand loads generated during running, which can be four times the athlete's body weight.

Archery Equipment

In competition, an arrow must be shot usually 55 m (180 ft), but it must be shot right on target. Both distance and precision depend upon arrow speed. Compounded bows formed of pultruded fiberglass produce greater arrow velocity than bows of laminated wood.

Fiberglass archery limbs have a higher strength than wood and superior resistance to fatigue. They can endure higher stresses when flexed and still return to their original shape. Labor costs are up to 50% less in production. Laminated wood limbs are produced by hand, requiring time-consuming spraying, finishing, and sanding operations.

Graphite fibers also are reinforcing bows. The high strength of graphite fibers helps to shoot the arrow farther and faster. The high modulus of graphite helps give the archer bull's-eye accuracy. Another bow has a syntactic foam core sandwiched between unidirectional glass and graphite fibers. The design is strong, light, and stable, allowing the archer to shoot an arrow at high speed. The bow accelerates the arrow to a velocity of over 67 m/s (220 ft/s), with forces that cause the arrow to buckle and vibrate all the way to the target.

Arrows are also being made of composites. One arrow shaft is made from a carbon composite. Through a special wrapping process, the several layers of carbon are combined as one super- strong and extremely smooth arrow. The arrow resists bending and shattering better than aluminum arrows.

Composites are being pultruded into arrow shafts. Each Carbon Tech arrow shaft starts as 348,000 separate carbon fibers. Through a pultrusion process, they are bonded together with a matrix resin, producing a seamless shaft with an extremely smooth surface. The lighter, smoother arrows travel swiftly and accurately to their target.

In Olympic competition, a hybrid composite arrow has won gold and bronze medals. The arrow, manufactured by Easton Aluminum Inc., is fabricated with an aluminum tube overwrapped by layers of bonded, high-modulus carbon-fiber/ epoxy. The arrow shaft is said to be the lightest and stiffest made. Because the arrow is stiffer, it oscillates at higher frequencies. The higher-frequency oscillation increases velocity. The shafts travel at up to 8 m/s (25 ft/s) faster than pure aluminum arrows. Because the flight time is shortened, it lessens the effect of wind and weather on the arrow, thereby increasing accuracy.

Conclusions

Modern composite construction has been applied in some degree to almost every modern sport. The design flexibility and, in some cases, lower production costs are used to build equipment that provides superior performance. For example, few people who have used a light, well- designed carbon-fiberglass fishing rod would return to an older steel or bamboo version. The penetration has been so complete that the revolution is almost over in the sport and recreational markets. What remains, however, is continuous improvement within the general fiber-resin composite concept as designers learn how to optimize the use of these materials to fit the distinct mechanical loads applied to various parts of sporting equipment.

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Introduction

A VARIETY of new advanced composite materials that provide great advantages over conventional materials for thermal management and electronic (also called microelectronic) packaging are available now. Their advantages include:

- Extremely high thermal conductivities (over twice that of copper)
- Low, tailorable coefficients of thermal expansion (CTE)
- Weight savings up to 80%
- Size reductions up to 65%
- Extremely high strength and stiffness
- Reduced thermal stresses
- Increased reliability
- Simplified thermal design
- Potential elimination of heat pipes
- Low cost, net-shape fabrication processes
- Potential cost reductions

Composites are in a state of continual development that undoubtedly will result in improved and new materials providing even greater benefits. The number of production applications is increasing rapidly, and composites are well on their way to becoming the twenty-first century materials of choice for thermal management and electronic packaging. This article provides an overview of advanced composites used in thermal management and electronic packaging, including properties, applications, and future trends. The focus is on materials having thermal conductivities at least as high as those of aluminum alloys. Future trends in thermal management materials and the potential for composites in other aspects of the electronics industry, such as high-speed assembly machine materials of construction, are also examined.

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Application Requirements and Candidate Materials

In the *Electronic Materials Handbook,* Volume 1 (Ref 1), published in 1989, an overview of composites developed for use in electronic packaging and thermal management was presented. This article presents an update on that work, expanding the topic to include other types of composites and advanced materials. Electronics packaging is an important industry with worldwide sales of $100 billion; sales are expected to double by 2005 or 2010.

Although this article deals with composites developed for thermal management aspects of electronic packaging, the use of and potential for composites in packaging is much broader. Combining two or more constituents makes possible the creation of materials with unique combinations of properties that cannot be achieved any

other way. Perhaps the best example is printed circuit boards (PCBs) for which dielectric properties are critical. The most common PCB material, E-glass fiber-reinforced epoxy, was first developed over a half century ago.

In addition to microelectronic packaging, composites are well suited for other packaging applications, such as optoelectronic components and microelectromechanical systems (MEMS). Both are important growth areas.

Application Requirements. Electronic packaging provides a number of primary functions: it provides power, transfers signals in and out, provides mechanical support and protection to the components it houses, and dissipates heat generated in the package. In addition, electronic packaging may have to be hermetic and provide electromagnetic interference (EMI) shielding.

The continuing increase in packaging density has resulted in a need for materials with high thermal conductivities. In addition, to minimize thermal stresses that can cause component or solder-joint failure, packaging materials must have CTEs matching those of the materials to which they are attached, especially ceramic substrates and semiconductors, which are weak, brittle materials. Further, low density is desirable in many applications, including portable systems such as laptops, handheld telephones, and avionics. Reducing weight also minimizes potentially damaging stresses resulting from shock loads that can occur during shipping and other activities. Of course, low cost is also a key consideration. Traditional materials used in electronic packaging do not meet all of these requirements. In response to this need, new composite materials have been and continue to be developed.

Improved materials are also needed in other thermal management applications. One of the best examples is spacecraft, for which mass and thermal management are critical issues.

Candidate Composite Materials. A composite material can be defined as two or more materials bonded together (Ref 2). Composites are nothing new in electronic packaging. For example, polymer-matrix composites (PMCs) in the form of E-glass fiber-reinforced polymer (GFRP) PCBs are well-established packaging materials. Similarly, a variety of particles are added to polymers to reduce CTE and increase thermal conductivity, electrical conductivity, or both. These materials are particle-reinforced PMCs. New composites have been developed in recent years that provide unique combinations of properties that make them outstanding candidates for packaging applications.

The four key classes of composite materials are PMCs, metal-matrix composites (MMCs), ceramic-matrix composites (CMCs), and carbon-matrix composites, which encompasses carbon-carbon composites (CCCs). At this time, PMCs, MMCs, and CCCs are the key composites of interest for thermal management, the focus of this article.

Figure 1, which plots thermal conductivity as a function of CTE for a variety of materials used in electronics, illustrates the limitations of traditional packaging materials. In order to minimize thermal stresses in many packaging designs, it is necessary to match the CTEs of semiconductors like silicon and gallium arsenide and ceramics used for substrates, such as alumina, beryllia, and aluminum nitride. These materials have CTEs in the range of about 4 to 7 ppm/K (shaded area). As the figure shows, aluminum and copper have good thermal conductivities but CTEs that are much higher than desired.

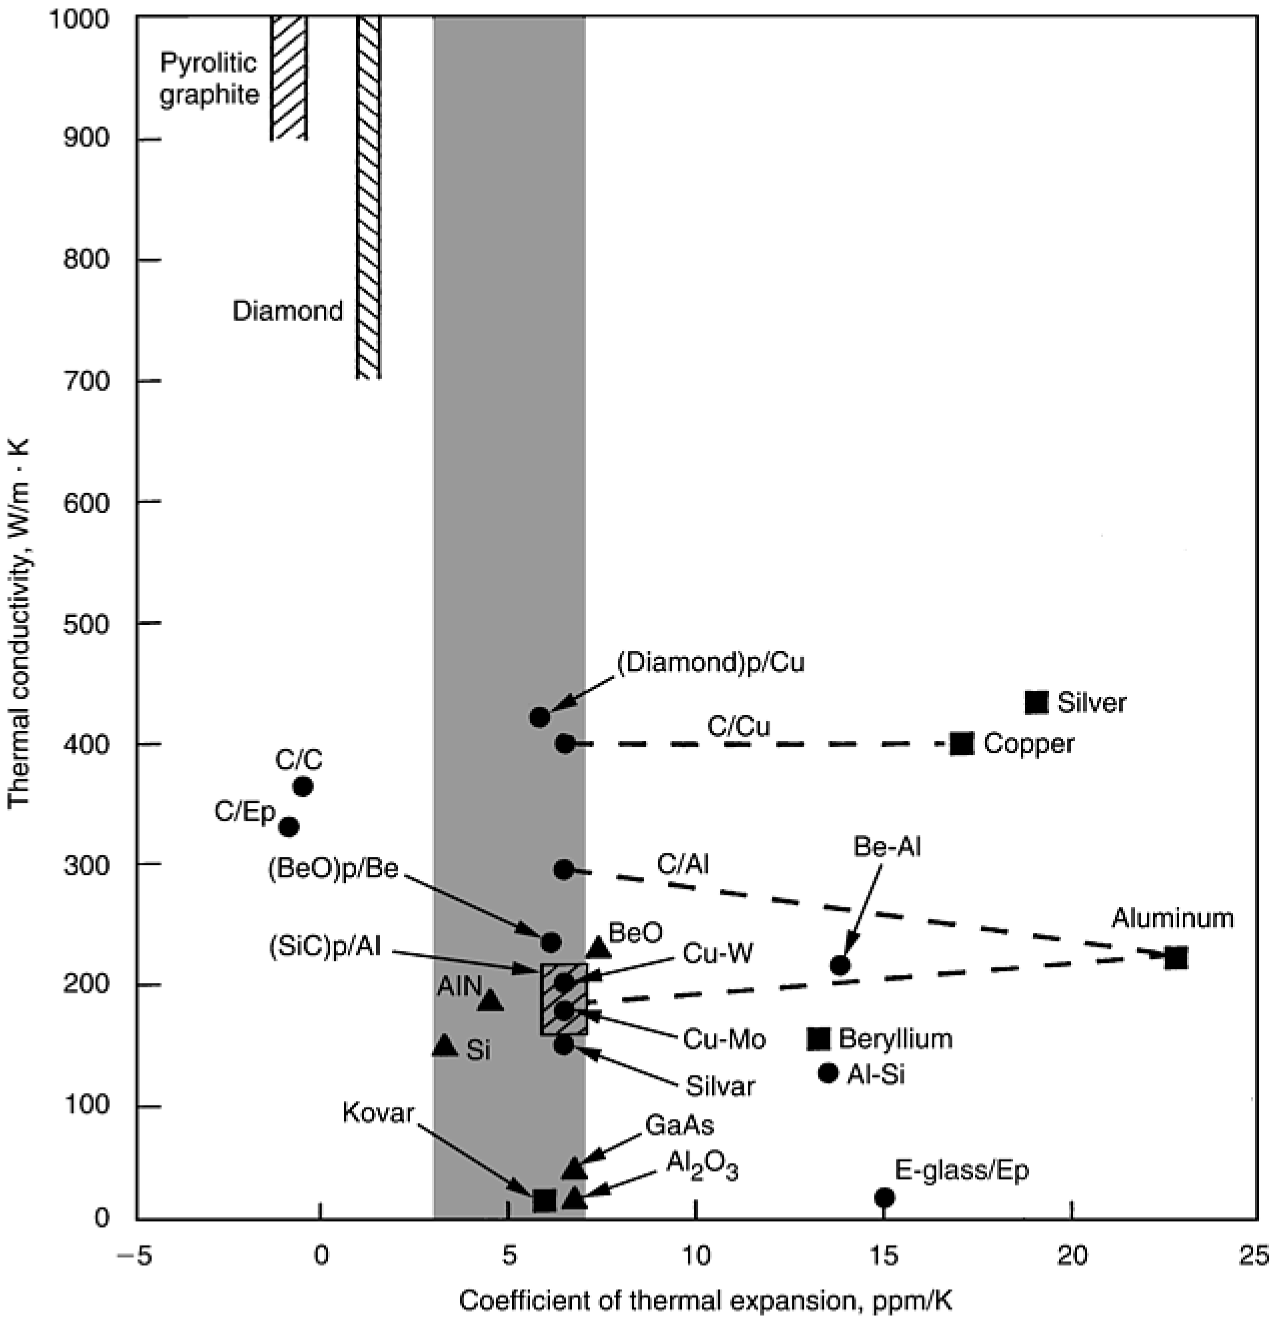

Fig. 1 Thermal conductivity as a function of coefficient of thermal expansion for materials used in electronic packaging

Traditional microelectronic packaging materials used to achieve low CTEs include Kovar, a nickel-iron alloy, and blends of copper and tungsten (Cu-W) or copper and molybdenum (Cu- Mo). Kovar has a low thermal conductivity and a density much higher than that of aluminum. Low-CTE materials with higher thermal conductivities than Kovar are obtained by blending copper with tungsten or molybdenum. As the two constituents are not alloyed, these materials can be considered composites; that is, they satisfy our definition of a composite material as two or more materials bonded together. For clarity in this article, materials consisting of two distinct metals bonded together are referred to as metal- metal composites. The term metal-matrix composite is reserved for metals reinforced with fibers or particles. Table 1 presents more detail about the properties of many of the materials in Fig. 1.

Table 1 Properties of selected electronic packaging materials

Reinforcement	Matrix	Thermal conductivity, W/m · K	Coefficient of thermal expansion, ppm/K	Modulus of elasticity		Specific gravity
				GPa	10^6 psi	
Unreinforced	Silicon	150	4.1	…	…	2.3
	Alumina	20	6.7	380	55	3.9
	Aluminum	120	23	69	10	2.7
	Copper	400	17	117	17	8.9
	Epoxy	1.7	54	3	0	1.2
	Kovar	17	5.9	131	19	8.3
	Pyrolitic graphite	1600–1700	–1.0	…	…	2.3
Copper	Tungsten	167	6.5	248	36	16.6
	Molybdenum	184	7.0	282	41	10.0
Beryllium	Aluminum	210	13.9	179	26	2.1
E-glass fibers	Epoxy	0.16–0.26	11–16	16–19	2–3	2.1
Invar	Silver	153	6.5	110	16	8.8
Continuous carbon fibers	Epoxy	300	-1.1	186	27	1.8
	Copper	400	6.5	158	23	7.2
	Aluminum	290	6.5	131	19	2.5
Discontinuous carbon fibers	Aluminum	185	6.0	14	2	2.5
	Polymer	20	4–7	30–50	4–7	1.6
	Carbon	400	-1.0	255	37	1.9
Silicon	Aluminum	126–160	6.5–13.5	100–130	15–19	2.5–2.6
SiC particles	Aluminum	170–220	6.2–7.3	225–265	33–38	3.0
Discontinuous carbon-graphite	Aluminum	400–600	4.5–5.0	90–100	13–15	2.3
Diamond particles	Aluminum	550–600	7.0–7.5	…	…	3.1
Beryllia particles	Beryllium	240	6.1	330	48	2.6

Coefficients of thermal expansion, thermal conductivities, and elastic moduli for composites reinforced with continuous fibers are in-plane isotropic values. Fiber volume fractions for metal-matrix composites reinforced with continuous fibers are selected to achieve an in-plane coefficient of thermal expansion of 6.5 ppm/K.

Although the thermal conductivities of Cu-W and Cu-Mo are much greater than that of Kovar, they are in the range of aluminum alloys. Higher values, along with low CTE and density, are desired.

There are several composite materials in Fig. 1 that have CTEs in the desired range and significantly higher thermal conductivities than traditional materials. These materials include silicon carbide particle-reinforced aluminum ($[SiC]_p$/Al), carbon fiber-reinforced copper (C/ Cu), carbon fiber-reinforced aluminum (C/Al), diamond particle-reinforced copper ($[\text{diamond}]_p$/ Cu), and beryllia particle-reinforced beryllium ($[BeO]_p$/Be). A number of other materials are seen to have high thermal conductivities, but these materials lie outside the shaded area. In addition to silver, aluminum, and copper, such materials include pyrolitic graphite, CCCs, carbon fiber-reinforced epoxy (C/Ep) and, of course, diamond.

The CTE of E-glass fiber-reinforced epoxy (E- glass/Ep), the most widely used PCB material, is much higher than that of silicon. Coefficients of thermal expansion range between 12 and 18 ppm/K. This can give rise to warpage and high thermal stresses in solder joints when integrated circuits (ICs, or chips) made from silicon and other semiconductors are directly attached to PCBs. To reduce stresses in the solder joints and ICs, which can cause premature failure, adhesive called an underfill is commonly introduced between the chip and PCB. However, this is a relatively slow, costly step, which does not necessarily eliminate undesirable warpage.

In some designs, lids used to remove heat from chips are bonded to the PCB, and a compliant thermal grease, gel, or other interface material is used between the chip and lid. In this case, it is desirable to have the CTE of the lid match that of the PCB. One of the big advantages of composites is that it is possible to tailor properties like CTE over a wide range. For example, we find commercial metal-metal and metal-matrix composite formulations with CTEs similar to those of both silicon and E-glass/Ep.

To compare packaging materials in applications for which both thermal conductivity and density are important, a useful figure of merit is specific thermal conductivity, defined as thermal conductivity divided by density (for simplicity, specific gravity, which is dimensionless, is used). Materials with high specific thermal conductivities are desirable in weight critical applications. Figure 2 presents specific thermal conductivity as a function of CTE for packaging materials. The specific thermal conductivities of traditional low-CTE packaging materials like Kovar, Cu-W, and Cu-Mo are very low. However, the low density of many composites combined with their high thermal conductivities enhances their relative position. In fact, the specific thermal conductivities of some composites are more than an order of magnitude greater than those of traditional materials like Kovar, Cu-W, and Cu-Mo.

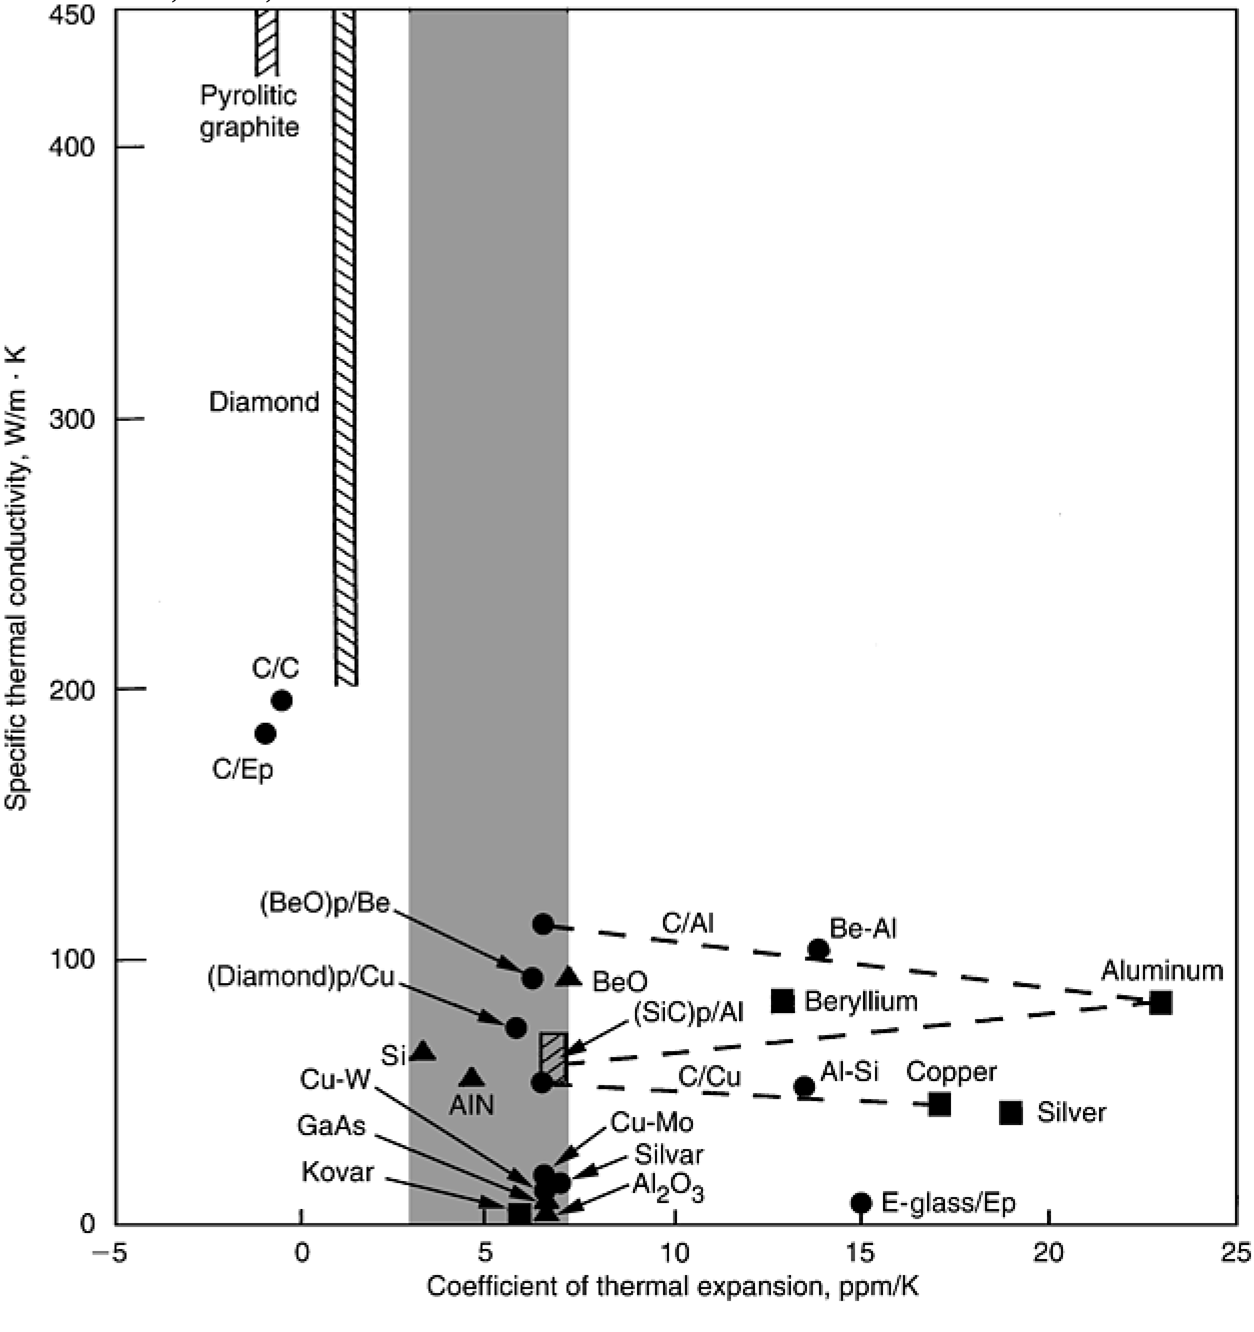

Fig. 2 Specific thermal conductivity (thermal conductivity divided by specific gravity) as a function of thermal expansion for materials used in electronic packaging

A rule of thumb states that improving a critical property by an order of magnitude produces revolutionary change in a technology. It is not surprising, therefore, that composites are making significant inroads in thermal management and electronic packaging.

A key advantage of some of composites is that they can be used with processes that produce parts having the final desired shape (net-shape processes) or that require only a small amount of machining (near-net shape processes). Minimizing machining enhances the cost effectiveness of these materials. This is particularly true for silicon carbide particle-reinforced aluminum (often called Al/SiC in the electronic packaging industry and discontinuously reinforced aluminum, or DRA, in the aerospace industry), which is one of the most important of the new composite packaging materials.

In the following sections, the key types of reinforcements and composites used for microelectronic packaging and thermal management, significant applications, and future directions are considered.

Important issues must be taken into account when considering properties of composites and ceramics. First, there are a large and increasing number of materials in these categories, all of which are proprietary. In addition, there are a variety of test methods used to measure properties. As a consequence, reported properties may vary significantly. For example, reported properties of aluminum oxide from one manufacturer may differ significantly from a nominally identical material made by another manufacturer. This is particularly true for composites, for which reinforcements, reinforcement volume fractions, reinforcement geometry, matrix materials, and processes may differ significantly. The properties of composites are very process sensitive. Another consideration is that many properties, including CTE and thermal conductivity, are often strongly temperature dependent. Room temperature values are presented in this article. A fundamental issue is that, especially in the early stages of development, the only source of material properties may be the manufacturer rather than an independent source.

For the reasons cited, properties presented in this article should be considered representative values. They are intended to be used for comparative purposes, not design allowables. It is always good practice to verify material properties used for design.

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Reinforcements

Several types of reinforcements are used in composite materials: continuous fibers, discontinuous fibers, whiskers (elongated single crystals), and particles. Flakes are included in the last category. At this time, the most important reinforcements for obtaining high thermal conductivity are pitch-based carbon (also called graphite) fibers, which are used in continuous and discontinuous forms, and two types of ceramic particles, silicon carbide (SiC) and beryllia (beryllium oxide, BeO). As a rule, continuous fibers are much more efficient than discontinuous fibers and particles for achieving high thermal conductivity, stiffness, and strength. An increasing number of reinforcements are of interest.

Composites reinforced with discontinuous fibers or particles may have processing advantages in some instances. A key characteristic of materials reinforced with equiaxed (roughly spherical, sandlike) particles is that they tend to be isotropic. That is, their properties are similar in all directions. This is not true of materials

reinforced with continuous fibers or platelike flake particles, which are almost always anisotropic, which means that their properties vary with direction.
If a composite is reinforced with discontinuous fibers that are truly randomly oriented, its properties are statistically isotropic. However, virtually all processes produce some degree of preferred fiber orientation, and there are no strictly isotropic random-fiber composites. It is possible and quite common to make fiber reinforced materials with properties that are approximately isotropic in a plane. These materials are called quasi-isotropic or pseudoisotropic materials.
A major advantage of using continuous fibers is that it is possible to vary directional properties significantly. For example, it is possible to produce composites with very high thermal conductivities, stiffnesses, and strengths in particular directions by orienting a high percentage of fibers along these axes. In some instances, this can make fiberreinforced composites more efficient than heat pipes in transporting heat over relatively short distances. An additional benefit is that solid-state methods of heat transfer are more reliable.
Carbon Fibers. The most important types of commercial carbon fibers at this time are made from polyacrylonitrile (PAN) and pitches derived from petroleum and coal. Figure 3, which is adapted from one developed by Amoco Performance Products (now BP-Amoco), shows how thermal conductivity varies with electrical resistivity for selected metals and carbon fibers. There are commercial pitch-based carbon fibers with thermal conductivities almost three times that of copper. At the upper end of the spectrum are experimental fibers made by chemical vapor deposition (CVD) that have thermal conductivities in the range of 2000 W/m · K, five times that of copper. These reinforcements are also called vapor-grown carbon fibers.

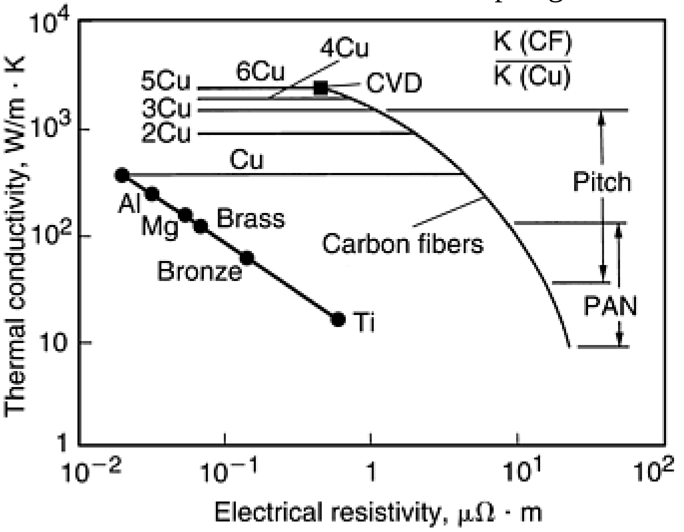

Fig. 3 Thermal conductivity as a function of electrical resistivity for metals and carbon fibers

At the time of publication, the commercial fiber with the highest thermal conductivity was K1100, manufactured by BP-Amoco (Chicago, IL), which has a nominal axial thermal conductivity of 1100 W/m · K. Other companies also produce pitch-based carbon fibers with high thermal conductivities.
Note that carbon fibers are generally strongly anisotropic. For example, the radial thermal conductivity of K1100 carbon fibers is at least an order of magnitude lower than the axial value.
In addition to their high thermal conductivities, pitch-based carbon fibers have other attractive attributes for packaging and structural applications: elastic moduli as high as 965 GPa (140×10^6 psi), more than an order of magnitude greater than that of aluminum, and very low densities. These reinforcements are being used with polymer, metal, and carbon matrices to create light, stiff composites with extremely high thermal conductivities and low, tailorable CTEs.
Additional information is available in the article “Carbon Fibers” in this Volume.
Ceramic Particles. As previously noted, ceramic particles have been used to increase the thermal conductivity and reduce the CTE of polymers for some time. Although these particulate PMCs are significantly more thermally conductive than monolithic (unreinforced) resins, their thermal conductivities are still an order of magnitude lower than that of aluminum. Since the 1980s, however, ceramic particles have been added to metals to achieve the same objectives as for polymers, high thermal conductivity and low CTE, creating MMCs that are now used in significant production applications. These composites also have much lower densities than traditional low-CTE metallic materials used in packaging.

As mentioned earlier, the two key materials currently used as particulate reinforcements are silicon carbide and beryllia. Diamond particles also have been used to reinforce metals on an experimental basis. Because of the difficulty of measuring the thermal conductivity of particles, it is common to assume that they have values similar to those of bulk materials. However, there are considerable differences in published thermal conductivities for ceramics. In general, transport properties like thermal conductivity are more difficult to measure than bulk properties such as modulus.
Additional information is available in the article "Ceramic Fibers" in this Volume.

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Thermal Management Composites and Other Advanced Materials

In this section, the three key classes of composite materials used in thermal management and electronic packaging at this time, PMCs, MMCs, and CCCs, are considered. Pyrolitic graphite, a monolithic material, some forms of which have very high in-plane thermal conductivity, is also discussed.
Polymer-Matrix Composites. Polymers reinforced with continuous K1100 carbon fiber offer the highest thermal conductivity of all commercial PMCs. Table 1 shows the in-plane properties of quasi-isotropic epoxy-matrix composites reinforced with continuous K1100 fibers. Composite properties depend strongly on reinforcement content; the fiber volume fraction of the composites listed in Table 1 is 0.60. The in- plane thermal conductivity and elastic modulus of this composite are much higher than the corresponding properties of aluminum, and its density is much lower. The specific thermal conductivities of these composites are greater than that of copper. Note that the in-plane CTE is negative. This is not an error; carbon fibers generally have negative CTEs. Although the CTE of this composite does not fall in the desired range of 4 to 7 ppm/K, it is much closer to it than those of aluminum and copper.
Note that a K1100 carbon-fiber-reinforced PMC with a fiber volume fraction of 0.60 having all fibers oriented in the same direction, which is called a unidirectional composite, would have a nominal axial thermal conductivity of 660 W/ m · K, over 150% greater than that of copper (approximately 400 W/m · K).
Although continuous fibers offer the best properties, PMCs reinforced with discontinuous fibers can be used with relatively inexpensive net-shape processes such as injection molding. Table 1 shows representative properties of a composite with discontinuous K1100 fibers. Note that both thermal conductivity and elastic modulus are much lower than those for composites reinforced with continuous fibers. Despite these limitations, the manufacturing advantages of discontinuous fiber PMCs have led to some very high production volumes.
Metal-Matrix Composites. At this time, the key electronic-packaging MMCs are:

- Silicon carbide particle-reinforced aluminum (Al/SiC, also known as discontinuously reinforced aluminum, or DRA)
- Beryllia particle-reinforced beryllium
- Carbon fiber-reinforced aluminum
- Aluminum-silicon, a metal-metal composite

Table 1 presents properties of these materials.
In recent years, a number of new metal-metal composites also have been developed, including beryllium-aluminum, Invar-silver (Silvar) and Invar-copper (Cuvar). An Al-Si composite consisting of 60% aluminum and 40% silicon that has been commercially available for many years also has been used for packaging. It is interesting that one manufacturer of this material, who for many years called it an aluminum-silicon alloy, now refers to it as a metal-metal composite. Because the solubility of aluminum and silicon at room temperature is relatively low, the material consists of an interpenetrating network of aluminum and silicon. Recently, a new family of Al-Si materials with higher levels of silicon has been made by a powder spray process. One formulation has a CTE in the range of ceramic substrates and semiconductors and another a CTE similar to that

of E-glass/epoxy (Ref 3). A key advantage of Al-Si is that it is much easier to machine than Al/SiC. Table 1 presents properties of these materials.

The most successful of the newer MMCs presently is silicon-carbide particle-reinforced aluminum (Al/SiC), which was first discussed as a packaging material in Ref 4, 5, 6, 7, 8, 9, and 10. Figure 4 shows how the CTE of Al/SiC varies with particle content. For particle volume fractions in the range of 0.7, it is possible to match the CTE of silicon. That, and its low density and net-shape- fabrication capability, have led to rapidly increasing use of this material. As discussed earlier, Al/SiC formulations with CTEs matching that of E-glass/epoxy PCBs are being used in IC lids. The particle volume fraction of these MMCs is in the range of 20%. They are relatively ductile and can be formed by stamping, a low-cost process. Lids made of this material are cost competitive with the machined-copper parts they are replacing.

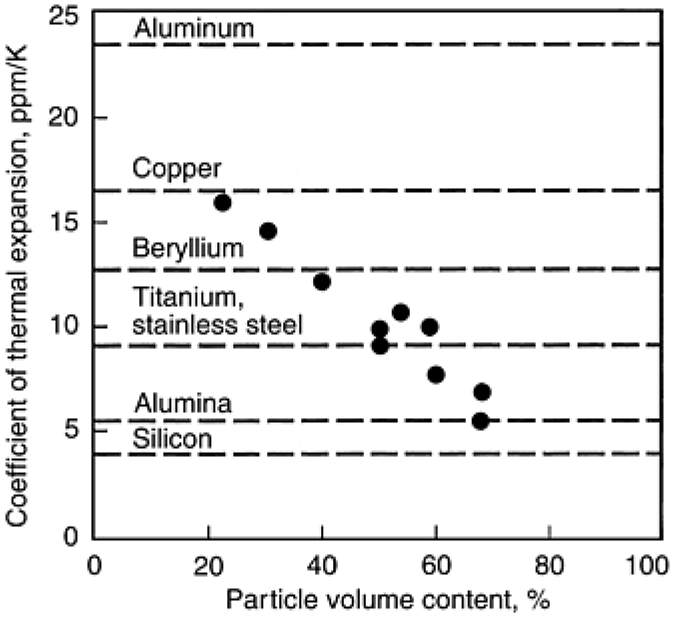

Fig. 4 Coefficient of thermal expansion as a function of particle content for silicon carbide particle-reinforced aluminum

Beryllia-particle-reinforced beryllium also has been used in production applications, although not as widely as Al/SiC because of higher cost.

Metal-matrix composites consisting of continuous and discontinuous thermally conductive carbon fibers are also being employed in packaging and thermal management applications. Materials made with continuous fibers are relatively expensive, and there have been relatively few applications to date. However, recent developments have resulted in significant cost reductions for discontinuous-fiber MMCs, and these materials are now entering production systems. It should be noted that, like common laminated metals used in electronic packaging such as copper-Invar-Copper and copper-molybdenum-copper, MMCs reinforced with continuous fibers may display significant hysteresis when subjected to large thermal excursions or mechanical stresses (Ref 1).

Other MMCs with high thermal conductivities are made by infiltrating porous carbon/carbon composites and fibrous carbon-fiber preforms or felts with aluminum or copper. For materials with highly oriented fibers such as ThermalGraph, axial thermal conductivities as high as 890 W/m · K have been reported (Ref 11). Another MMC infiltrated with copper has reported in-plane and through-thickness thermal conductivities of 700 W/m · K and 250 W/m · K, respectively.

A recently developed MMC consists of aluminum reinforced with nonfibrous discontinuous carbon graphite. The reported in-plane and through-thickness thermal conductivities are 420 to 600 W/m · K and 100 to 150 W/m · K, respectively.

The thermal conductivity of particle-reinforced MMCs depends greatly on the thermal properties of the interface. Early experimental diamond-particle-reinforced aluminum composites had thermal conductivities in the range of aluminum alloys, perhaps because of nonoptimum heat transfer across particle-matrix interfaces. Recent improvements have resulted in materials with a reported isotropic thermal conductivity in the range of 550 to 600 W/m · K and a CTE of 7 to 7.5 ppm/K.

Carbon-Carbon Composites and Pyrolitic Graphite. There are a large number of materials that fall in the category of CCCs, including ThermalGraph, which was discussed in the previous section. Carbon-carbon composites made from P120 carbon fibers, which have a nominal axial thermal conductivity of about 600 W/m · K, are reported to have an in-plane isotropic thermal conductivity of 250 W/m · K (Ref 11). This attribute, combined with a specific gravity of only 1.85, makes CCCs very attractive thermal-control materials for weight-sensitive applications (Ref 12). These materials are highly anisotropic, and through-thickness thermal conductivities are much lower.

CCCs with in-plane thermal conductivities as high as 400 to 450 W/m · K have been reported. Through-thickness values are in the range of 40 to 50 W/m · K.

There are other characteristics of CCCs worth noting. For one, they have relatively low strengths perpendicular to fiber directions. In addition, as discussed earlier, their in-plane CTEs are usually small, negative values. This is a characteristic they share with many PMCs reinforced with continuous fibers.

As shown in Fig. 1 and 2, pyrolitic graphite, a monolithic material, has very high in-plane thermal conductivity combined with a relatively low specific gravity of 2.5 (Ref 13). In-plane thermal conductivities as high as 1600 to 1700 W/m · K are reported. This material is highly anisotropic, and the through-thickness conductivity is only 25 W/m · K. One of the deficiencies of pyrolitic graphite is that, like other forms of monolithic graphite, it is relatively weak and brittle. To overcome this problem, pyrolitic graphite is being used as a laminate in which it is encapsulated with structural materials such as aluminum, copper, beryllium, Kovar, and two composites, Al/SiC and carbon/epoxy.

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Applications

Composites are now being used in important commercial and aerospace thermal management and microelectronic packaging applications. Annual production for some packaging parts is in the hundreds of thousands. At this time, the most widely used composites are Cu-Mo, Cu-W, Al/SiC, and discontinuous thermally conductive carbon-fiber-reinforced polymers.

Microelectronic packaging components include carriers, complex hermetic microwave packages (modules), power semiconductor packages, solid and flow-through liquid-cooled PCB cold plates (thermal planes), heat sinks for integrated circuit packages, including pin-fin heat sinks, thermal straps, enclosures, and support structures (Ref 3, 4, 5, 6, 7, 8, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23 and 24).

Spacecraft applications, in addition to electronic packaging, include radiators, radiator panel thermal doublers, and battery sleeves (Ref 25, 26, 28, 29, and 30). Additional information is provided in the article "Space Applications" in this Volume.

The composite electronic packaging components cited in the previous paragraph are being used in numerous commercial and aerospace products, including electric vehicles, motor controllers, cellular telephone ground stations, laptop computers, and aircraft and spacecraft microwave and power supply subsystems. In addition, composites are key materials in developmental integrated multifunctional structural/ electronic systems (Ref 30).

Thermal Management and Electronic Packaging Applications

Carl Zweben, Composites Consultant

Future Trends

Virtually all of the experts predict that packaging density will continue to increase, and, with it, the need for continuing improvements in thermal management. This will require a variety of new solutions including use of heat pipes and active fluid cooling. However, it is unlikely that the latter two approaches will solve all thermal management problems. Further, a passive solution, such as use of materials with improved thermal conductivities, simplifies thermal management and improves reliability. In addition, use of active cooling and heat pipes does not eliminate the issue of thermal stresses resulting from thermal-expansion mismatch.

Another important trend is the continuing competition to reduce the weight of portable systems, such as laptop computers and handheld cellular telephones. In addition to these commercial products, the drive to reduce weight in electronics and thermal management systems used in aircraft, spacecraft, and even shipboard applications will continue.

Based on these facts, it is concluded that there will continue to be a need for improved materials that have high thermal conductivities and low, tailorable CTEs. In addition, there is a need for low-density materials in many applications. Cost will continue to be a critical issue in both the aerospace and commercial industries.

It is clear that the early stages of an important new materials technology are underway. The future will undoubtedly see development of improved and new reinforcements, matrix materials, material systems, and manufacturing processes. Increasing material production volumes and improved processes will reduce costs, making composites even more competitive.

As a historical point of reference, carbon fibers sold for \$500/kg (\$225/lb) when they were first introduced commercially in the early 1970s. It is now possible to buy commercial structural grade fibers for as little as \$4/kg (\$2/lb). Further price reductions appear likely as volume builds. In particular, the following trends in reinforcements appear likely:

- Silicon carbide particles with much higher thermal conductivities (over 400 W/m · K has been measured for high-purity single crystals)

- Use of diamond, aluminum nitride, and cubic boron nitride particles
- Commercial pitch-based and vapor-grown carbon fibers with higher thermal conductivities, perhaps approaching 2000 W/m · K
- Commercial diamond and diamond-coated carbon fibers with thermal conductivities also approaching 2000 W/m · K
- Reinforcement coatings to promote adhesion, reduce reinforcement-matrix reactions, and improve thermal conductivity
- Use of carbon nanotubes, which have very high thermal conductivities

Based on experience in the field of structural composites, expecting the development of polymer, metal, and carbon-matrix material systems, which are tailored for use in thermal management and packaging applications with the reinforcements listed previously, is also reasonable. In addition, use of inherently electronically conductive polymers could be advantageous in providing EMI shielding.

The field of nanocomposites, which includes the carbon nanotubes cited previously, is likely to contribute some interesting new materials. For example, incorporation of ceramic nanoparticles could be useful in tailoring CTE and increasing thermal conductivity.

Current development efforts are likely to result in improved processes for production of net- shape components. This will eliminate machining costs and make composites more competitive with traditional materials.

In summary, the need for improved thermal management and microelectronic packaging materials will continue for the foreseeable future. The present infancy of an important materials technology will continue to produce new and improved composite materials and manufacturing processes. Advances will make composites more technically attractive and also reduce costs. The result will be increasing use of composites in many thermal-control and electronic-packaging applications.

Beyond the thermal management materials discussed in this article, major opportunities for composites in other areas of electronic packaging exist. For example, there are great needs for new materials with improved dielectric properties and high thermal conductivities for use in PCBs and electrically insulating substrates. Materials of interest here include ceramic fibers and particles in ceramic and polymeric matrices. Because the requirements of packaging materials for optoelectronics and MEMS are similar to those of microelectronics, composites also have great potential in these important and rapidly growing applications.

Extending to other aspects of the electronics industry, great potential also exists for composites in high-speed, precise manufacturing and assembly machinery, such as pick-and-place machines. Lasky dramatically points out the inefficiency inherent in current equipment (Ref 31). He observes that gantries used to place a 1 mg component may weigh 100 kg, or 100,000,000 times as much.

When components of current electronic- industry assembly machines are examined, the materials of construction, that is, steel, cast iron, aluminum, and granite, are found to have been developed in previous centuries. There is little doubt that in the twenty-first century, composites will be the materials of choice in high-performance machinery because of their unmatched properties. Benefits of composites in machinery include:

- Order of magnitude improvements in specific stiffness (stiffness divided by density)
- Outstanding fatigue resistance
- Excellent corrosion resistance
- Low CTEs (some nearly zero)

Other applications of composites in the electronics industry include photolithography equipment and wafer-handling devices.

As a result of their unique attributes, all four classes of composites, PMCs, MMCs, CMCs and CCCs, are now being used in countless commercial-production applications including automobile engine blocks, automobile and truck diesel engine pistons, automobile and pickup truck-brake rotors and drive shafts, rollers used in printing presses, audio- and videotape production machines, coordinate-measuring machines, automated ultrasonic inspection equipment, cutting tools, and equipment used in the manufacture of optical fibers and glass products (Ref 19, 20). In short, the limitless potential for composites has barely been explored, not only in electronics packaging, but also throughout the electronics industry.

Marine Applications

A.P. Mouritz, RMIT University, Australia; C.P. Gardiner, Defence Science & Technology Organisation, Australia

Introduction

THE FIRST MARINE APPLICATION of fiber-reinforced polymer (FRP) composite materials was in the construction of boats shortly after World War II. This was about the time that composites were first used for other applications, such as in aircraft, electrical devices, and building materials. Boat builders began to use FRP composites instead of timber, which was traditionally used in small maritime craft, because wood was

becoming increasingly scarce and expensive. Timber was also losing favor with many boat builders and owners, because wooden boat hulls are degraded by seawater and marine organisms and therefore require ongoing maintenance and repairs that can be expensive. The earliest attempt to fabricate boat hulls with FRP composites was in 1947 when twelve small surfboats were made for the United States Navy. At the time, little was known about the design and construction of composite boats, the fabrication technologies were underdeveloped, and the materials had low strength and poor durability in seawater. This combination of factors led to the construction of composite boats that were not seaworthy, and many had to be scrapped. The early history of the development and application of composites to marine craft has been reported (Ref 1, 2, and 3).

The design techniques, processing technology, fiber reinforcements, and resins improved rapidly after the early problems, and composites were used successfully during the 1950s in small leisure craft, yachts, and naval boats as well as in ship and submarine structures, such as radomes, sonar domes, and casings. Knowledge and confidence in composites grew with these applications, and this further expanded the number and types of maritime craft made of composites. For example, by the mid-1960s, over 3000 boats had been built of composite materials for the United States Navy, including over 800 motor whaleboats, 330 utility boats, 250 landing craft, 220 personnel boats, and 120 patrol boats. Since the 1970s, composites have also been used in niche applications on offshore oil drilling platforms and, as with maritime craft, the use of FRP materials is expanding into new platform applications.

Most maritime craft are built using glass-reinforced polyester (GRP) composites, although sandwich composites and advanced FRP materials containing carbon or aramid fibers with vinyl ester or epoxy-resin matrices are commonly used for high-performance structural applications. Composites are now used in a wide variety of craft, ranging in size from canoes, dinghies, and yachts to racing maxis, hovercraft, patrol boats, naval minehunting ships, and corvettes. Composites are also used in lightweight structures on warships, such as advanced mast systems and superstructure sections. The application of composites to leisure craft, yachts, boats, ships, submarines, and offshore structures has been extensively reviewed (e.g., Ref 4, 5, 6, 7, 8, 9, and 10). The purpose of this article is to briefly outline current and potential applications of composites for maritime craft and offshore drilling platforms. The key benefits gained from using FRP materials together with an examination of the drawbacks and major issues impeding the more widespread use of composites in marine structures are given.

Marine Applications

A.P. Mouritz, RMIT University, Australia; C.P. Gardiner, Defence Science & Technology Organisation, Australia

Naval Applications of FRP Composites

The application of FRP composites to maritime craft was initially driven by a need for lightweight, strong, corrosion resistant, and durable naval boats (Ref 1, 2, and 3). The United States Navy sponsored most of the early design, research, and development work that led to the production of composite boats. Initially, the navy funded the production of small personnel boats, although this was followed in the 1950s by support for a variety of other craft, including patrol boats, landing craft, and minesweeping boats. The United States Navy was also the first to use composites on large ships for deckhouses, pipes, and fuel and water tanks, as well as on submarines for fairwaters and mast shrouds (Ref 1, 2 , and 3). From the 1950s, other navies, most notably the British, French, and Swedish Navies, began to use composites on their vessels, which further expanded the marine applications of FRP materials (Ref 11, 12). The expansion in the use of composites on naval ships and submarines during the 1950s and 1960s was dramatic, and by the mid-1960s the number of applications was extremely diverse, as shown in Table 1. Most of these early applications were driven by the need to overcome corrosion problems experienced with steel or aluminum alloys or environmental degradation suffered by wood. Another reason for using composites was to reduce weight, particularly the topside weight of ships. The high acoustic transparency of composites also resulted in their use in radomes on ships and sonar domes on submarines.

Table 1 Early naval applications of FRP composites (1945–1965)

Minesweeper (15.5 m, or 51 ft, long)
Landing craft (15.2 m, or 50 ft)
Personnel boat (7.9 m, or 26 ft)
Sheathing of wood hulls
Submarine sonar dome
Submarine fins
Masts and mast shrouds
Rudders
Tanks (fuel, lube oil, water)
Torpedo tubes
Hatch covers
Landing craft reconnaissance (15.8 m, or 52 ft)
River patrol boat (9.5m, or 31 ft)
Pilot boat
Submarine fairwater
Submarine nonpressure hull casing
Deckhouses for small ships

Radomes
Antenna trunks
Piping
Crew shelters
Rope guards

Up to the 1960s, however, the only naval boats built entirely of composites were under 20 m (66 ft) in length. It was not safe to build larger warships with composites, because they would not have adequate hull girder stiffness due to the low Young's modulus of FRP materials. Low hull girder stiffness would cause excessive hogging and sagging of a composite ship in heavy seas. Such large hull deflections cause fatigue- induced failures of the hull, bulkheads, and joints and also cause serviceability problems, such as shaft misalignment and loss of sealing to watertight hatches. The problem of low hull girder stiffness for small warships (less than ~50 m, or 165 ft, long) was overcome in the early 1970s with the construction of the Royal Navy minesweeper HMS *Wilton* (Ref 13, 14). This ship was 46.6 m (153 ft) long with a full-load displacement of 450 tons, making it the largest all-composite ship at the time. High hull girder stiffness was achieved by building the ship with an innovative composite hull known as the framed single-skin design. The hull basically consisted of a thin FRP laminate shell stiffened with longitudinal and transverse frames, mostly of “top hat” cross-section sandwich composite construction. Not only did the hull have adequate stiffness, but it also had excellent impact and underwater blast damage resistance that is essential for naval ships.

Since the mid-1970s, hundreds of patrol boats and minehunter ships in the 50 to 60 m (165 to 200 ft) length range have been built using composites (Ref 8). While the framed single-skin hull remains popular, two other hull forms have been developed for composite ships up to about 70 m (230 ft). These forms are monocoque construction, which basically consists of the thick laminate hull, and sandwich construction, which consists of thin FRP face skins over a thick core of medium-density polyvinyl chloride foam or polyurethane foam or end-grain balsa (Ref 5). Figure 1 shows examples of naval ships with the framed single-skin, monocoque, and sandwich hull types.

Fig. 1 Composite naval ships. (a) Sandown class minehunter ship with a framed single-skin hull form. (b) Huon class minehunter ship with a monocoque hull form. (c) Bay class minehunter ship with a sandwich composite hull form

Increasingly, naval patrol boats are being built with an all-composite design or a composite hull fitted with an aluminum superstructure (Ref 8). The growing popularity of FRP patrol boats is due mainly to their excellent corrosion resistance, which reduces maintenance costs, and light weight, which can result in higher speeds and better fuel economy. It is estimated that composite patrol boats are usually approximately 10% lighter than an aluminum boat and over 35% lighter than a steel boat of the same size (Ref 15). However, the fabrication cost of a composite patrol boat is estimated to be about 30% higher than for a steel boat, which is a major impediment to their construction. An example of a modern composite patrol boat is the Skjøld class operated by the Royal Norwegian Navy, as shown in Fig. 2. The Skjøld is 46.8 m (154 ft) long with a full-load displacement of 270 tons and is made of a sandwich composite material (Ref 16). The core of the sandwich composite is polyvinyl chloride foam, and the face skins consist of glass- and carbon-fiber polymer laminates. Carbon-fiber composites are rarely used on naval vessels because of their high cost, however it is used in the Skjøld for structures requiring high stiffness, such as the mast, beam frames, and the support base to the gun.

Fig. 2 The Skjøld class patrol boat

The other type of naval vessel that is commonly built of composites is minehunting ships. Nearly 250 minehunter ships have been built since the mid-1970s using composite materials. A wide variety of minehunter ships made of single-skin or sandwich composites are in service, and three types are shown in Fig. 1. The main reasons for building minehunting ships with composite are they are nonmagnetic and corrosion resistant (Ref 5, 8, and 17).

As a general design rule, the structural performance of ships less than approximately 50 to 60 m (165 to 200 ft) long, such as patrol boats and minehunters, is determined by the response of local structures, such as bulkheads and decks. On the other hand, the performance of ships longer than about 60 m (200 ft) is dominated by the hull girder stiffness. Because of the relatively low stiffness of most glass-reinforced polymer materials, almost all composite ships are under 60 m (200 ft) long. The only composite naval vessel built to date above this size is the 72 m (236 ft) long Visby class corvette for the Royal Swedish Navy (Ref 18), which is shown in Fig. 3. The Visby uses a sandwich composite incorporating a polyvinyl chloride foam core and carbon-fiber/vinyl ester laminate skins manufactured using a resin-infusion laminating method. The use of carbon-fiber composite reflects the increased demand on hull girder stiffness from a vessel of this length. The composite design also affords a high level of strength and durability, good shock resistance, a low magnetic signature, and a lightweight structure, as necessary for a ship designed for a multimission capability. The ship is undergoing sea trials and evaluation, and five more corvettes will be built.

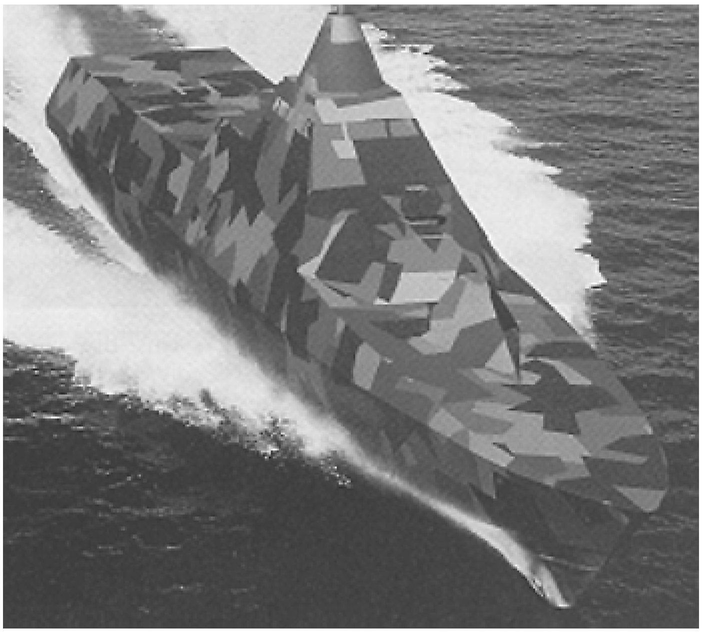

Fig. 3 Artist drawing of the all-composite Visby class corvette

An all-composite patrol boat/corvette, known as the NGPV class, is being designed for the Royal Singapore Navy and is expected to be 80 m (260 ft) long with a full-load displacement of 1016 tons. The United States Navy is also considering building their next-generation corvettes with composite materials (Ref 19). Navy ships longer than about 100 m (330 ft), such as frigates, destroyers, and aircraft carriers, are not likely to be constructed entirely with composites because it is much cheaper to build large ships with welded steel construction. At this stage in the development of large composite ships, it is glass-fiber-reinforced structures that have the longest service history. However, as carbon-reinforced ships, such as the Visby corvette, enter

service and as the price of carbon-fiber material continues to drop, larger carbon-reinforced ship structures may become practical.

While it is not feasible to build large naval ships using composites, these materials are now used in a wide variety of topside structures and internal equipment on frigates, destroyers, and aircraft carriers. Composites are used in the superstructures on some naval ships to eliminate corrosion and fatigue cracking, lower topside weight, and reduce the radar cross section (Ref 20, 21 and 22). The first large naval ship built with a composite superstructure was the La Fayette class frigate (Ref 23), which is shown in Fig. 4. Sandwich composite is used in the aft section of the superstructure, which includes a helicopter hangar and funnels. The aft section is 38 m (125 ft) long, 15 m (50 ft) wide, 6.5 to 8.5 m (21 to 28 ft) high from the main deck, and weighs 85 tons, which makes it the largest and heaviest composite superstructure on a naval ship. The forward section of the superstructure, which includes the bridge and combat and telecommunications centers, is built of steel because it was considered that a composite structure would not provide adequate protection against a high-pressure air blast. It is estimated that composite superstructures are 30 to 40% lighter than a steel structure, which results in better ship stability and fuel savings (Ref 21, 22, 24, and 25). Composite superstructures are also more resistant to corrosion and fatigue, and therefore require less maintenance and fewer repairs. However, composite superstructures are estimated to be 35 to 50% more expensive to build (Ref 24, 25), and for this reason, most naval ships will continue to be built with steel or aluminum superstructures for at least the next ten years. However, the United States, British, and Norwegian Navies are considering fitting composite superstructure sections and helicopter hangars to some of their next-generation warships (Ref 24, 25).

Fig. 4 La Fayatte frigate with the composite superstructure section shown within the circled region

Another major composite topside structure being developed for future use on large naval ships is masts. The feasibility of fabricating advanced communication and surveillance masts using composites is being explored because of numerous problems with conventional steel truss masts. The major problems with steel masts are that they corrode, increase the radar signature of the ship, and interfere with the ships own radar and communications systems because of their open structure. In 1997, the advanced enclosed mast/sensor (AEM/S) system was installed on the Spruance class destroyer USS *Arthur W. Radford* as a technology demonstrator (Ref 26). The entire mast is made of sandwich composite material and is 28 m (92 ft) tall and up to 10.7 m (35 ft) wide, as shown in Fig. 5. A major reason for building the AEM/S system with composites is that these materials enable the passage of radar and communications signals with very little interference or attenuation, unlike metals. This, then, allows all the antennas, sensors, and other sensitive electronic equipment to be enclosed within the mast structure and thereby protected from the weather. Other benefits of the AEM/S system are that it is lighter and more corrosion resistant than steel truss masts; however, composite masts are much more expensive to build. The AEM/S system has performed beyond the expectations of the United States Navy, and consideration is currently being given to installing advanced composite masts on future amphibious ships, destroyers, and sea-lift vessels (Ref 26). A composite mast structure similar to the AEM/S system is also being

developed in the United Kingdom for next-generation warships (Ref 27). Smaller composite masts have been fitted to some naval submarines to lower weight, reduce corrosion, and dampen vibrations (Ref 28).

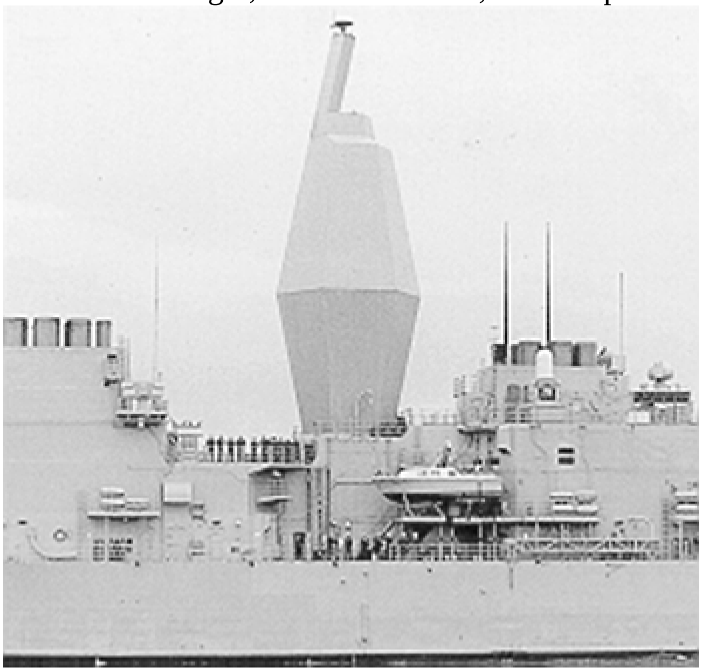

Fig. 5 Advanced enclosed mast/sensor (AEM/S) composite mast on the USS *Arthur W. Radford*

The feasibility of using composites in a wide variety of secondary structures and equipment on warships and submarines is under investigation. For example, a major effort is being given to the development of composite propellers, propulsors, and propulsion shafts (Ref 29, 30, 31, 32, 33, 34, 35, and 36). Composites are expected to offer a number of important benefits over metals when used in propulsion systems, including lower costs, reduced weight, lower magnetic signature, better noise- damping properties, and superior corrosion resistance (Ref 29, 30, 31, 32, 33, 34, 35, and 36). It is anticipated that propulsion shafts made of composites will be 25 to 80% lighter than a steel shaft of the same size and will reduce life-cycle costs by at least 25% because of fewer problems associated with corrosion and fatigue (Ref 33, 35, and 36). Despite the projected benefits, the use of composites in propulsion systems has been limited. Composite propellers have only been used on torpedoes and one minehunter ship (Ref 33), composite propeller shafts have only been installed on a small number of patrol boats, including the Skjøld (Ref 16), whereas composite propulsors have not yet been used. However, within the next ten years the use of composites in these applications is expected to increase, albeit at a slow rate.

Composites are also being evaluated for use in rudders for ships and control surfaces for submarines (Ref 22, 37, and 38). Other potential applications include funnels, bulkheads, decks, watertight doors, machinery foundations, pipes, ventilation ducts, and components for diesel engines, pumps, and heat exchangers on large warships (Ref 8, 22, 36, 39, 40, and 41).

Leisure, Sporting, and Commercial FRP Composite Craft

The diverse application of composite materials to naval vessels is matched by their wide- ranging use in leisure, sporting, and commercial vessels and small submersibles. Composites were first used in leisure craft and yachts in the 1950s and in commercial craft, such as fishing trawlers and pilot boats as well as submersibles, in the late 1960s (Ref 4, 5, and 42). The use of composites in these vessels was due to the successful application of FRP materials to naval boats during the 1950s and 1960s. It is interesting to note, however, that the experience and knowledge gained from using composites in leisure and commercial craft later facilitated the wider use of these materials in naval ships.

Since the 1970s, the use of composites in the hulls of marine craft has increased dramatically, and currently most vessels under a length of 15 to 20 m (50 to 65 ft) are built with FRP materials. The types of craft in this size range that are made of composites include kayaks, canoes, dinghies, jet skis, lifeboats, yachts, and powerboats (Ref 4, 5). Vessels longer than approximately 20 m (50 ft) are usually made of steel or aluminum alloy, although the use of composites is increasing as their fabrication cost continues to fall and as boat operators become aware of the reduced through-life costs. Among the largest commercial vessels that are built using composites are luxury cruisers, passenger ferries, hovercraft, and fishing trawlers. Several years ago, between 50 and 60% of all fishing boats under 60 m (200 ft) were made of GRP, and the proportion of trawlers built of composites is expected to continue to rise (Ref 5). Composites are often used because the lightweight construction allows a heavier fishing haul to be carried, the fish holds are easier to clean than wooden holds, and the hulls are easier to maintain and repair. Composites have also been used in propellers of fishing trawlers as well as powerboats to overcome corrosion and noise problems that can be experienced with metal propellers (Ref 35, 43). Composites are also being used increasingly in high-speed ferries capable of carrying 350 to 400 passengers. The ferries are usually built with a composite hull and an aluminum superstructure. Ferries are rarely built with a composite superstructure because of the poor fire resistance. The hoisting decks and bow gates on car ferries have also been made of sandwich composite material.

As with naval ships, the composite material most commonly used in leisure and commercial craft is GRP in the form of a thick laminate or a sandwich composite. Over 95% of all composite marine craft are built with GRP because of its low cost, which is similar to the cost of steel and aluminum alloy. There are, however, a number of other reasons for the popularity of GRP composites in marine craft, and these include:

- Ability to easily and inexpensively mold GRP to the near-net shape, even for marine structures with a complex shape, such as boat hulls, thus making it suitable for mass production
- Excellent corrosion resistance
- Light weight, resulting in reduced fuel consumption
- Simple to repair
- Good ability to absorb noise and dampen vibrations, which makes for a more comfortable ride on motor-powered boats

High-performance yachts competing in the world's most prestigious races, such as the America's Cup and Admiral's Cup, are built with aerospace-quality composite materials rather than GRP (Ref 44, 45, 46, and 47). Advanced composites are also used in the construction of racing powerboats and skiff sailing hulls (Ref 44, 45). A state-of-the-art International America's Cup Class (IACC) yacht and a racing powerboat that have been built using advanced composites are shown in Fig. 6. Racing yachts and boats such as these are built using ultralight sandwich composite materials that have thin laminate skins containing carbon, glass and/or aramid (Kevlar, DuPont) fibers and a core of polyvinyl chloride foam or Kevlar honeycomb. Advanced fabrication processes, such as resin transfer molding, resin film infusion, or autoclaving, are used in the construction of the hull and decks to produce composites that are defect-free, excellent dimensional tolerance, and a high fiber content for maximum stiffness, strength, and fatigue resistance (Ref 48).

(a)

(b)

Fig. 6 Boats built almost entirely from aerospace-grade composite materials. (a) 2000 Team New Zealand IACC yacht. (b) F-2 series race boat

The main advantages of using advanced composites are optimal weight distribution, good fatigue resistance, vibration damping, and most importantly, high stiffness-to-weight and strength-to-weight ratios. The use of advanced composites with high stiffness- and strength-to- weight ratios allows lighter hull structures to be built with stiffness and strength equivalent to much thicker GRP hulls. This is desirable for planing craft, such as powerboats and sailing hulls, for reducing hydrodynamic resistance. Similarly, for displacement craft such as yachts, a reduction in hull structure weight allows increased ballast to be used for a given displacement. Appendages such as centreboards and rudders on high-performance sailing hulls, trim tabs on powerboats, and rudders on high-performance yachts are also commonly constructed using advanced sandwich materials. This is beneficial for hydrodynamic performance because the overall weight is minimized, higher appendage stiffness is obtained, and a reduction in the weight of the rudder contributes to lower hull- pitching moments.

Composites are also commonly used for spars (mast, boom, and spinnaker poles), fittings, and fitting reinforcements on sailing boats and yachts (Ref 49). Mast tips, which are about the top one- third of the mast, on sailing boats are made of glass- or carbon-reinforced composite to obtain desired flexibility for optimal gust response (Ref 50). Carbon-fiber composite is also used in masts for IACC and other high-performance-class yachts. Composite masts are 40 to 50% lighter than similar masts made of aluminum alloy, which results in a reduced heeling moment and therefore, improved performance. The high stiffness obtained with carbon-fiber composite spars is also beneficial for maintaining sail shape under high rig loads. Similarly, the use of high-performance composites in hull structures is beneficial for maintaining high rig loads with minimal hull distortion and added hydrodynamic resistance.

Offshore Applications of FRP Composites

FRP composites have been used in offshore drilling platforms for many years, although the oil industry has only used these materials in niche applications and not in major structural elements. Steel is the primary

structural material used in drilling platforms and is expected to remain so for the foreseeable future, because it has many benefits that other materials, including composites, cannot match. The benefits include low materials cost, the ability to fabricate large structures at low cost, good flame resistance, well-established design rules, and a long service history for using steel in offshore platforms. However, steel has a number of drawbacks that have allowed composites to be used to a limited extent.

The greatest problem with using steel in an offshore structure is the poor corrosion resistance against seawater and other highly corrosive agents, such as hydrogen sulfide and hydrogen chloride, that occur during drilling. It is estimated that the oil industry spends several billion dollars each year in maintaining, repairing, and replacing corroded steel structures (Ref 51). Composites offer the potential to reduce these costs because of their outstanding corrosion resistance against most types of chemicals.

Composites also offer the possibility of reducing the topside weight of offshore platforms when used in such applications as accommodation modules, helicopter landing pads, and decks. It is estimated that composites provide a weight saving of 30 to 50% compared to steel for many non-structural components (Ref 52). The increased use of composites in topside structures is expected to make the transportation and installation of platforms easier, reduce the weight of tethers, foundations, and piles needed to anchor platforms, and allow drilling in deeper waters than is currently possible with heavier steel platforms.

Composites are used in a variety of structures and components on offshore platforms because of their better corrosion resistance and lighter weight compared with steel. The most common types of composites used are GRP and phenolic composites, with the latter being used because of good fire resistance. Advanced composites containing carbon fibers, Kevlar fibers, or epoxy resins are used sparingly because of their high cost. Some of the current applications of FRP materials are (Ref 7, 10, 51, 52, 53, 54, 55, and 56):

- Low pressure pipes
- Diesel storage tanks, lube tanks, and utility tanks
- Walkway gratings, stair steps, and handrails
- Cable ladders and trays
- Fire protection panels and sections of accommodation modules
- Buoys and floats
- Strengthening of primary steel structures
- Helicopter landing decks

It is worth noting that not all offshore platforms use composites, and in most applications, composite components have been used to replace corroded steel sections. New platforms are rarely built with significant amounts of composite, although this may change as the oil industry assesses the feasibility of using FRP materials for new applications. Potential applications include (Ref 51, 52):

- High-pressure (firewater) pipes
- Drill pipes, tubing, and risers
- Mooring tendons for tension leg platforms and semisubmersible platforms
- Walls and floors to provide protection against blast and fire

The use of composites is expected to grow as some of these new applications are realized, however, there remain many economic and technical issues that must be resolved before FRP materials are more widely used in offshore platforms (Ref 10, 52). The higher cost of fabricating offshore structures with composites compared with welded steel is a concern to the oil industry. However, there is growing recognition that significant through-life cost savings can be gained with composites due to reduced maintenance and replacement of corroded structures. There is also concern about the lack of design codes and well-established oilfield standards in the use of composites. An important safety concern is that most FRP materials have poor fire- resistant properties, such as short ignition times and high rates of heat release, smoke production, and flame spread. While it is generally recognized that composites have much lower thermal conductivity than metallic materials, these factors make it difficult for composites to meet the stringent fire safety requirements applied to offshore oil and gas platforms.

Civil Infrastructure Applications

Vistasp M. Karbhari, University of California, San Diego

Introduction

CIVIL INFRASTRUCTURE, such as bridges, buildings, waterfront structures, waste treatment facilities, and facilities for transmission and transport of utilities, represents an investment of trillions of dollars worldwide. Increasingly the security of this investment is being questioned. The infrastructure of constructed facilities for the transportation and housing of people, goods, and services, which was developed and rapidly expanded in the middle of the last century, is now reaching a critical age, with widespread signs of deterioration and inadequate functionality. Composites—particularly fiber-reinforced polymer (FRP) materials—are increasingly being adopted or considered as alternatives to conventional materials for infrastructure applications. Within the vast applications area in civil infrastructure, this article concentrates on a few specific examples related to the use of composites in seismic retrofit, component strengthening and repair, and in new structural systems. Reviews of the state- of-the-art as practiced in various regions of the world have been recently published (Ref 1, 2, 3, 4, 5, and 6) and readers are referred to them for further detailed information.

Civil Infrastructure Applications

Vistasp M. Karbhari, University of California, San Diego

The Need for Infrastructure Renewal

The existing infrastructure is in critical need of renewal. For example, deficiencies in the existing bridge inventory include those related to wear, environmental deterioration, and aging of structural components, increased traffic demands and changing traffic patterns, insufficient detailing at the time of original design, the use of substandard materials in initial construction, and inadequate maintenance and rehabilitation measures taken through the life of the structure. In the United States, an estimated 35% of all bridges on the federal inventory are judged to be structurally deficient or functionally obsolete and require repair, strengthening, widening, or replacement. In addition to increasing or changing traffic demands, common deficiencies include:

- Deck deterioration due to wear, deicing salts, temperature gradients, freeze-thaw cycles, and other environmental factors
- Scour at bridge substructures in flowing water
- Corrosion of structural steel members and steel reinforcement in structural concrete
- Problems associated with dynamic response under wind or earthquake conditions

- Physical and chemical aging and deterioration of materials

These deficiencies are not isolated to bridges and other transportation-related structures alone, but are endemic to the built environment, including residential housing, pipelines used for the distribution of water, and industrial structures. This deterioration and inability to provide required services has a tremendous impact on society in terms of socioeconomic losses resulting from delays, accidents, and irregularity in supply.

Within the scope of rehabilitation of civil infrastructure, it is essential to differentiate among *repair, strengthening,* and *retrofit.* These terms often are used interchangeably, but in fact should be used to refer to three different structural conditions (Fig. 1). In "repairing" a structure, the composite material is used to fix a structural or functional deficiency, such as a crack or a severely degraded structural component. In contrast, the strengthening of structures is specific to those situations where the addition or application of the composite would enhance the existing designed performance level, as would be the case in attempting to increase the load rating (or capacity) of a bridge deck through the application of composites to the deck soffit. The term retrofit, although often used as a generic term for rehabilitation, is increasingly being specifically used in relation to the seismic upgrade of facilities, such as in the use of composite jackets for the confinement of columns. The differentiation is important not just on the basis of structural functionality, but also because the specifics related to the use of the material in conjunction with existing conventional materials and its expected life have a significant effect on the selection (or rejection) of fiber-resin combinations from a variety of alternatives.

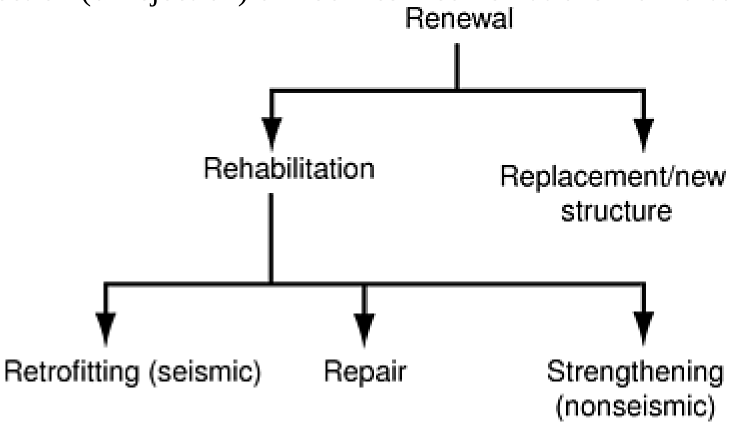

Fig. 1 Types of renewal strategies for civil infrastructure

Vistasp M. Karbhari, University of California, San Diego

Conventional Materials versus Composites

Conventional materials, such as steel, concrete, and wood, have a number of advantages, not the least of which is the relatively low cost of materials and construction. However, it is clear that conventional materials and technologies, although suitable in many situations and with a history of good applicability, lack in longevity in some cases and, in others, are susceptible to rapid deterioration, emphasizing the need for better grades of these materials or newer technologies to supplement the conventional ones used. Also note that design alternatives may be constrained by the current limitations of materials used, for example, in the length of the clear span of a bridge due to weight constraints, or the size of a column due to restrictions on design and minimum dimensions needed. In a similar manner, the use of conventional materials is often not possible in cases of retrofit, or may be deemed as ineffective in terms of functionality. In other situations, restraints such as dead load restrict the widening of current structures or the carriage of higher amounts of traffic over existing lifelines. In all such (and other) cases, there is a critical need for the use of new and emerging materials and technologies, with the end goal of facilitating functionality and greater structural and life-cycle efficiency.

The human race has a long history of attempts to create new materials with enhanced properties for the construction of structural systems. The use of combinations of materials to provide both ease of use and enhanced performance, as in the use of straw reinforcement in mud by the ancient Israelites (800 b.c.), or in the combination of different orientations of veneers of wood, as in plywood, has a long history. The concept of combining materials to create a new system having some of the advantages of each of the constituents can be seen in reinforced concrete (steel, aggregate, sand, and cement) and, to an extent, in the use of special compounds and chemicals in alloys of steel. Fiber-reinforced composites take this concept one step further in civil infrastructure, potentially giving the designer a wide palette of materials choices to fit the specific requirements of the structure and showing immense potential to add to the current range of materials being used. The tailorability of these materials, derived from the inherent anisotropy predicated by the arrangement of the fiber reinforcement in the polymer matrix, as well as the corrosion resistance, light weight, high strength, and stiffness-to-weight ratios permit their use in ways that are not available to conventional materials. These unique characteristics provide significant impetus for their use in rehabilitation and restoration of historic structures without causing significant changes to the aesthetic features or geometric configurations of the original structures. Similarly, the performance attributes, in conjunction with their light weight, enable their use in strengthening severely degraded structural elements, as well as in the modification of existing structures without egress on available headroom or open space. Further, when used in new structural systems, they provide the designer with the ability to truly blend form and function.
Although this article focuses on aspects related to rehabilitation through external application of FRP composites and the development of new structural systems, it needs to be emphasized that composites are also being used in the form of internal reinforcement in structural concrete, as tendons/cables for internal and external prestressing, and as cable stays. In these areas, the primary drivers for the use of composites as replacements for conventional steel members have been corrosion resistance, light weight, and performance attributes. Composite rebar, used for the reinforcement of concrete, is already commercially available in a variety of configurations using carbon, glass, and aramid fibers, and has found application primarily in corrosive regimes, such as coastal and marine structures, and in structures where the magnetic and conductive transparency of composites is advantageous. Design guidelines and specifications for the use of composite rebar have already been developed by associations such as the American Concrete Institute and the Japan Society of Civil Engineers. They have also been included to a level in the Canadian Highway Bridge Design Code. The use of cables and tendons, primarily of carbon and aramid fibers, has been demonstrated on a number of bridges in Europe and Japan. Their application appears to have significant merit, as long as issues related to cost and anchorages can be resolved.

Civil Infrastructure Applications

Seismic Retrofit Applications

Recent earthquakes, such as those in Whittier, CA (1987), Loma Prieta, CA (1989), Northridge, CA (1994), and Kobe, Japan (1995), have repeatedly shown the vulnerability of existing bridge columns built before the 1971 San Fernando, CA, earthquake. For reinforced concrete columns, conventional retrofit measures include the external confinement of the core by heavily reinforced external concrete sections; the use of steel cables wound helically around the existing column at close spacing, which are then covered by concrete; and the use of steel shells or casings that are welded together in the field, confining the existing columns. Although some of these methods are very effective, they are time-consuming, needing days for installation; can cause significant traffic disruption due to access and space requirements for heavy equipment; rely on field welding, the quality and uniformity of which are often suspect; and are susceptible to degradation due to corrosion. Also, due to the isotropic nature of the material in steel casings or jackets, the jacket not only provides the needed confinement, but also causes an increase in stiffness and strength capacity of the retrofitted column. Both of these attributes are not desirable, because higher seismic force levels are typically transmitted to adjacent structural elements.

The use of fiber-reinforced composites not only provides a means for confinement without the attendant increase in stiffness (through the use of hoop reinforcement only, i.e., no axial reinforcement), but also enables the rapid fabrication of cost-effective and durable jackets, with little to no traffic disruption in a large number of cases.

Numerous methods (based on the form of jacketing material or fabrication process) have been tested at large- or full-scale, many of which are now used commercially in Japan and the United States. Generically, fiber-reinforced composite wraps (or jackets) can be classified into six basic categories, as a function of process and/or materials form, as shown in Fig. 2. In the wet lay-up process, fabric is impregnated on-site and wrapped around a column, with cure generally taking place under ambient conditions. In wet winding, the process of fabrication is automated, but essentially follows the same schema, with the difference being that the ensuing jacket has a nominal prestress due to the use of winding tension. The use of prepreg tow presents the opportunity not only for elevated-temperature cure (with the consequent advantages of higher degree of cure, higher glass transition temperature, and greater overall durability associated with moisture and humidity resistance), but also the use of standardized and uniform materials that are easy for the structural designer to specify. In the case of adhesively bonded shells, the concept of uniformity and standardization is carried even further, through the use of prefabricated single- or dual-section jackets that can be assembled in the field through bonding and layering. This process affords a high level of materials quality control due to prefabrication of the elements under factory conditions, but, as in the case of external strengthening, relies on the integrity of the adhesive bond.

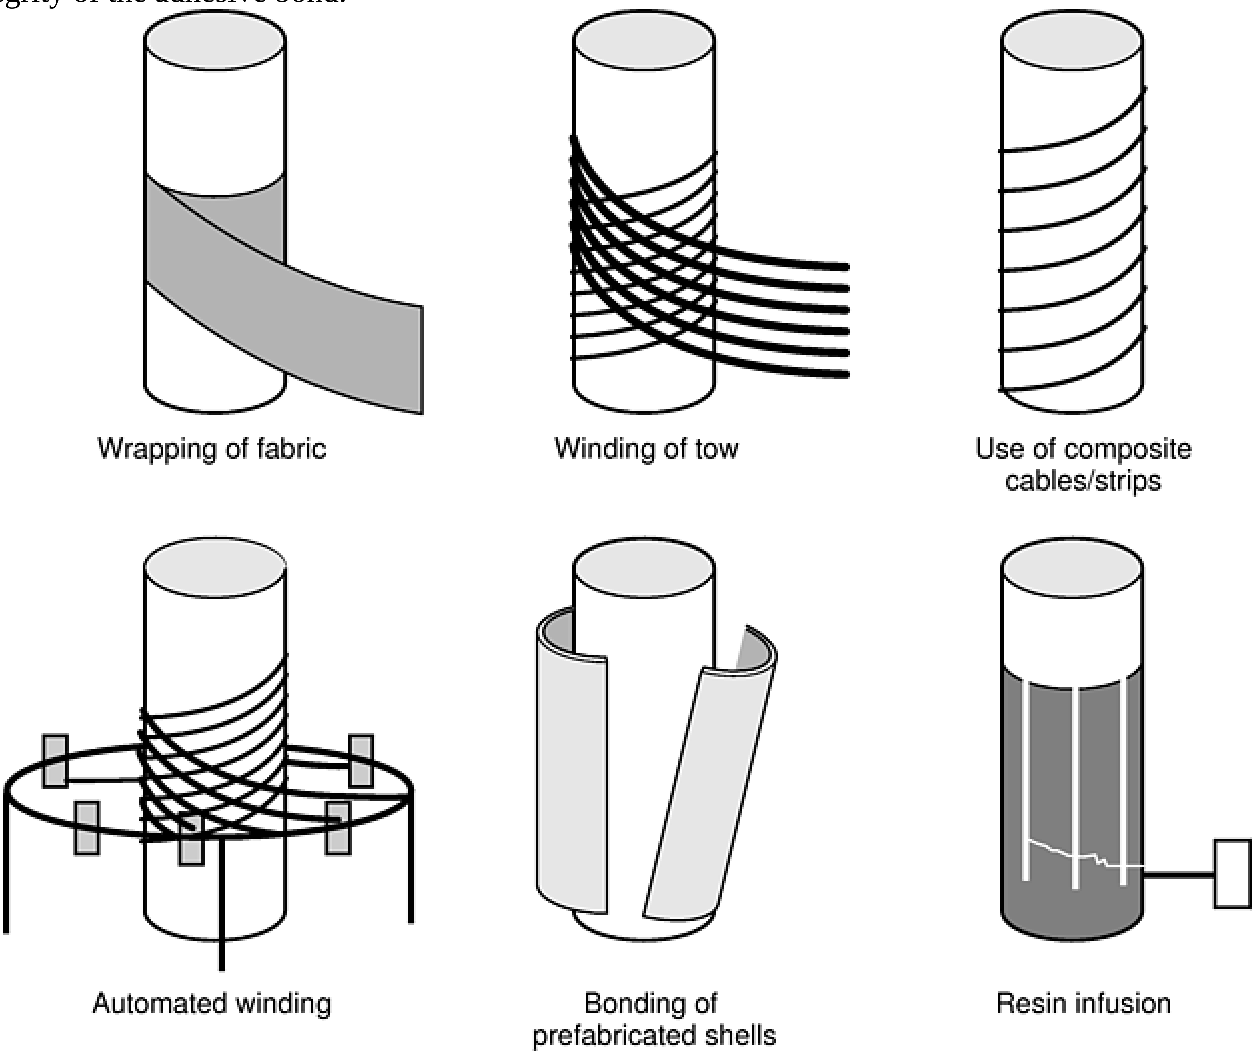

Fig. 2 Schematic of methods of seismic retrofit of columns using composites

The structural effectiveness of composite jackets has been demonstrated through an ample number of large- and full-scale tests (Ref 7, 8), and through demonstration projects in Japan (Ref 5) and the United States (Fig. 3, for example). One of the largest applications of composites in seismic retrofit was conducted using the adhesively bonded shells technique on columns of the Yolo causeway west of Sacramento, California.

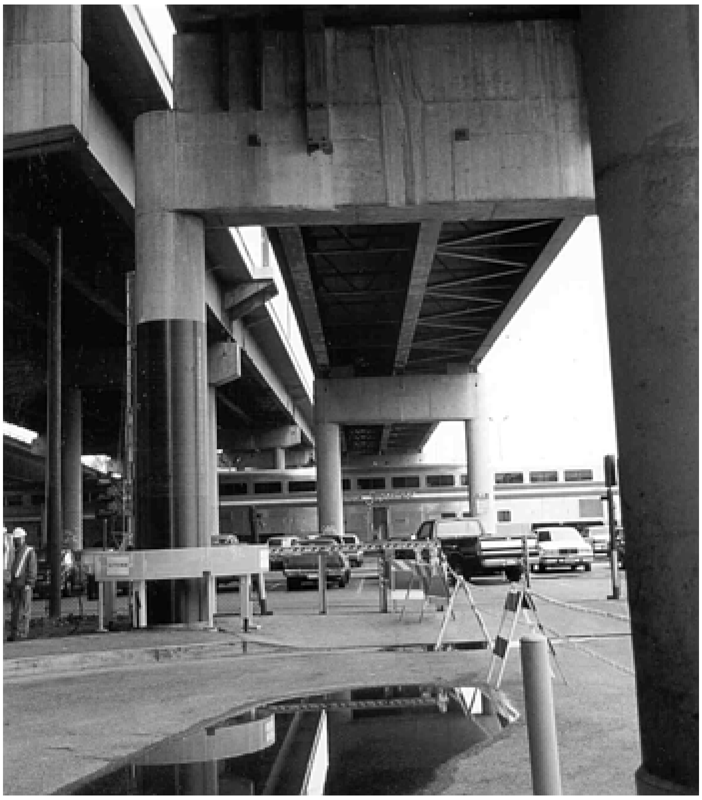

Fig. 3 Columns on the Santa Monica viaduct wrapped with carbon/epoxy prepreg

The use of composites for seismic retrofit is fairly well developed, with established principles for design and analysis of standard column configurations. Design examples and methodology are detailed in Ref 7 and 9. In most cases, the use of composites results in a cost-effective and structurally efficient retrofit scheme that significantly increases structural ductility and, thereby, seismic resistance.

The determination of thickness of the composite retrofit depends on the requirements to correct the failure modes expected under seismic load/deformation, which can be differentiated into four general classes: shear strengthening, plastic hinge confinement, bar-buckling restraint, and lap-splice clamping. A comparison of jacket thicknesses for three typical systems is shown in Table 1, where system A is representative of a tow-preg-based graphite/epoxy composite similar to that used in automated winding, system B is representative of an aramid/epoxy system similar to that used in Japan using wet lay-up, and system C is representative of an E-glass/vinylester similar to that used in prefabricated, adhesively bonded shells. All values in Table 1 are normalized to the thickness values determined for system A. It can be seen that jacket thicknesses for shear, bar-buckling restraint, and lap-splice clamping are driven by the modulus of the jacket in the hoop direction that favors the selection of higher modulus materials (carbon, aramid), whereas the requirements for flexural hinge confinement can be efficiently achieved with a lower modulus, but high- strength and higher strain-capacity material (e.g., E-glass).

Table 1 Comparison of hypothetical jacket thicknesses

Property	**Proportionality relationship**	**System A**	**System B**	System C
Mechanical characteristics of composite jacket in the hoop direction				
Modulus of elasticity (E_j), GPa (10^6 psi)	…	124 (18)	76 (11)	**21 (3)**
Ultimate tensile strength (f_{ju}), MPa (ksi)	…	1380 (200)	1380 (200)	**655 (95)**
Ultimate strain at failure (ϵ_{ju}), %	…	1	1.5	**2.5**
Normalized jacket thickness				
Shear strength	$t_j^v \; \frac{1}{E_j D} C_v$	1	1.6	**6.0**
Plastic hinge confinement	$t_j^c \; \frac{D}{f_{ju} \epsilon_{ju}} C_c$	1	0.7	**0.9**
Bar-buckling restraint	$t_j^b \; \frac{D}{E_j} C_b$	1	1.6	**6.0**

Lap-splice clamping	$t_j^s \frac{D}{E_j} C_s$	**1**	**1.6**	**6.0**

D, diameter of column; t_j, minimum required jacket thickness for indicated parameter; C_v, parameter for shear strength; C_c, parameter for plastic hinge confinement; C_b, parameter for bar buckling restraint; C_s, parameter for lap-splice clamping

Beyond the flexibility afforded by composites for the rapid and cost-effective retrofit of circular and rectangular columns/piers, composites are also invaluable for seismic retrofit of historical structures, such as arch bridges with spandrel columns. (An example is shown in Fig. 4.) Because of historical considerations, the rectangular columns cannot be retrofit using steel jackets without significant changes in the original shape and other architectural considerations. Further, location considerations also make the use of the steel option difficult, in this case emphasizing the overall effectiveness of composites in providing a solution where conventional materials and methods cannot be used easily.

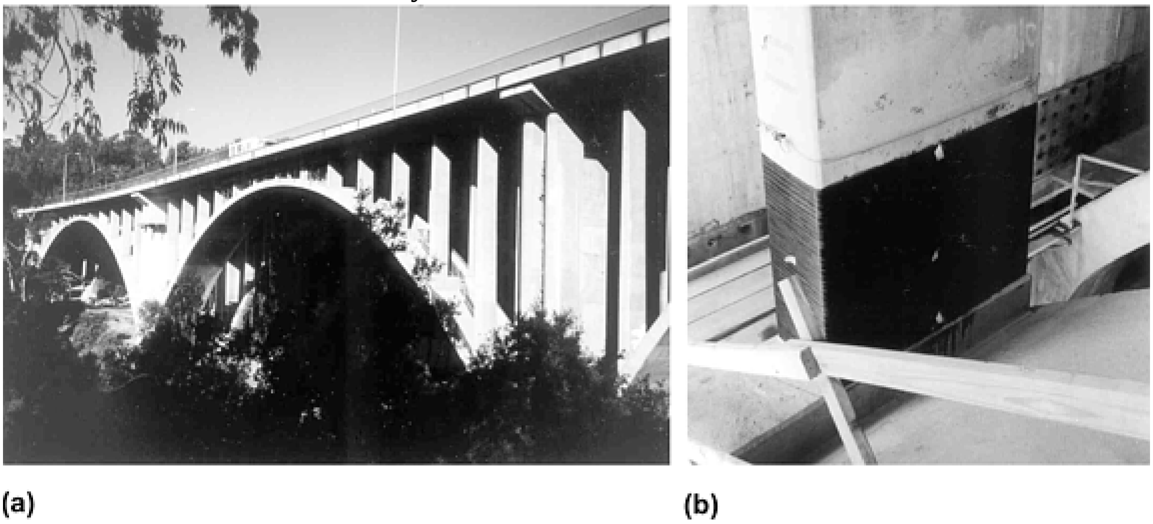

Fig. 4 Seismic retrofit of bridges with spandrel columns. (a) Arch bridge showing spandrel column. (b) Composite jacket on the lower third of a spandrel column

It should be noted that in a number of situations, the method of wrapping has also been used to protect and retard corrosion of steel reinforcement. In addition to the protection afforded by the composites as a barrier to moisture diffusion and penetration, the added confinement also assists in resisting cracking of concrete. Although questions still remain regarding the efficacy of FRP jackets in reducing corrosion in reinforcing steel through encapsulation of the structure after treatment of the concrete, the method has been used in the field to potentially extend the life of bridge columns.

Repair and Strengthening of Beams and Slabs

Degradation due to corrosion of steel reinforcement, spalling of concrete cover, extensive cracking of concrete due to excessive carbonation and/or freeze thaw action, effects of alkali- silica reaction, and rapidly changing traffic needs (both in terms of number of vehicles and load levels) have created a critical need for methods of repair and strengthening of beams and girders, as well as deck soffits and bridge deck slabs. The need for increasing load capacity/rating of bridges due to requirements for uniform postings over a region, such as in Europe, or the need to enhance capacity to ensure safe carriage of increased truck axle weights, as in Australia and Japan, provide significant impetus for the adoption of technology that is capable of achieving this in both a cost-effective manner and without significant distress to traffic. In buildings, materials degradation, changing needs of building occupancy (e.g., residential to office), and upgrades to facilities (e.g., cutting of floor slabs in older buildings to facilitate the construction of shafts for elevator installation) necessitate the strengthening of existing slabs and beams.

Conventional methods for external strengthening range from the use of external post-tensioning to the addition of epoxy-bonded steel plates to the soffit of the deck superstructure. Although the latter technique is simple and has been used in Europe and the United States in the past, it suffers from a number of disadvantages, ranging from difficulty in placement to concerns related to overall durability and corrosion resistance. Steel plates are heavy and unwieldy and thus difficult to handle during erection. At the minimum, jacks, extensive scaffolding, and winches or cranes are needed. The length of individual plates is restricted to a maximum of 6 to 10 m (20 to 30 ft) to facilitate handling, and even at these lengths, it may be difficult to erect them due to preexisting service facilities below the deck slab. Composites fabricated either through wet processes on-site or prefabricated in strips and then adhesively bonded to the concrete surface provide an efficient and easy means of strengthening that can be carried out with no interruptions in traffic flow.

In general, composites can be applied in three ways (as described in Table 2), of which the first two are the most widely used. It should be noted that although the wet lay-up process affords significant flexibility for work on-site, there may be important, technical and psychological advantages in the use of prefabricated, and thus standardized, strips and plates, which are adhesively bonded to the concrete substrate. Regardless of the method of application, it is important to note that the efficacy of the method depends primarily on the appropriate selection of the composite material, based on stiffness and strength requirements, and the efficiency and integrity of the bond between the concrete surface and the composite. The bond between the composite and concrete, whether established through the use of an adhesive or through the use of the same resin system used in the wet lay-up of the composite itself, must be capable of performing under ambient conditions. It must also be capable of providing the required response under extremes of temperature (including temperature gradients between the top and bottom surfaces of concrete), the resulting stress and strain conditions, and in the presence of moisture (which may be absorbed not only from the atmosphere, but could also gather at the adhesive-concrete interface due to moisture collection and ingress through concrete, which itself is a porous material).

Table 2 Methods of application of external composite reinforcement for strengthening

Procedure	**Description**	Time
Adhesive bonding	Composite strip/panel/plate is prefabricated and cured (using wet lay-up, pultrusion, or autoclave cure) and then bonded onto the concrete substrate using an adhesive under pressure	**Very quick application**
Wet lay-up	Resin is applied to the concrete substrate and layers of fabric are then impregnated in place using rollers and/or squeegees. The composite and bond are formed at the same time.	**Slower and needs more set-up**
Vacuum infusion	**Reinforcing fabric is placed over the area under consideration and the entire area is encapsulated in a vacuum bag. Resin is infused into the assembly under vacuum with compaction taking place under vacuum**	**Far slower with significant setup time needed**

	pressure. Unlike the wet lay-up process this is a closed process. In a variant the outer layer of fabric in contact with the vacuum bag is partially cured prior to placement in order to assure a good surface.	

Regardless of the method used, the external application of composites to concrete beams and slabs, if conducted in an appropriate manner, can result in the significant enhancement of load carrying capacity and flexural and shear strength of the original structural element. Test results show that the use of external composite reinforcement (fabric placed using wet lay-up and pultruded strips that were adhesively bonded to the surface), dramatically increase the load-carrying capacity of the slabs, whereas the ductility (or deformation capacity) at initial failure (though at a significantly higher load than possible with a typical reinforced concrete slab) is drastically reduced. Although the procedure provides an efficient means of strengthening, care must be taken to ensure that the rehabilitation design addresses the possibility of elastic failure of the system, with a sudden drop in strength when the composite fails through catastrophic fracture, failure of the composite-concrete bond interphase, limits on capacity increase related to yielding of steel reinforcement, or the use of an appropriately factored, equivalent-energy-based design approach.

Significant research related to the strengthening of beams has already been conducted (Ref 10, 11, and 12) and is being used extensively in the field. The method has found the most applicability in the flexural strengthening of beams and girders through the addition of composite reinforcing strips/plates to the lower surface of beams, or around the entire web area to provide shear strengthening. A carbon-fiber-based strengthening system, consisting of stabilized unidirectional fabric impregnated in the field with an epoxy resin using the wet lay-up process, was used recently for the repair and enhancement of shear capacity of precast, prestressed double-T beam stems at the Pittsburgh airport parking complex. The project consumed over 3400 m^2 (36,600 ft^2) of the fabric, representing one of the largest uses of this material in the United States. It was completed in less than four months, with minimal closure of the garage. In another application, 3000 m (9800 ft) of pultruded carbon/epoxy strips were used at LaGuardia Airport to strengthen runway slabs over Flushing Bay in Queens, NY. The strips were used to restore the ultimate capacity of the slabs and to stiffen them to prevent localized surface cracking and failure initiation from holes that had been cut in the slabs for the installation of additional piling.

The strengthening or repair of slabs is being increasingly considered, but it should be kept in mind that, due to differences in conventional steel reinforcement detailing and structural response between beams and slabs, results derived from the application of composites to beams cannot be directly extrapolated to application of slabs, especially as related to the selection of form and positioning of the external reinforcement (Ref 13). This application is considered to be of significant importance for the future, in terms of buildings, highway infrastructure, piers and waterfront structures, and even tarmacs, not just for purposes of strengthening and increase in load capacity, but also for the repair of deficient structures, such as those where local punching shear failures are seen in bridge decks between longitudinal girders.

Figure 5 shows an area of extensive cracking and punching shear failure in the deck of a bridge (Ref 14). Cracking was initiated in transverse spanning decks in longitudinal bending due to lack of flexural capacity. Subsequently, the effective width in the transverse direction was limited to the spacing between the transverse cracks, resulting in significant flexure and shear overloads. As a consequence, longitudinal cracks develop that spread over the entire deck length due to the moving nature of wheel loads, resulting in the local shear capacity being exceeded over a shear area limited by existing flexural cracks in both directions.

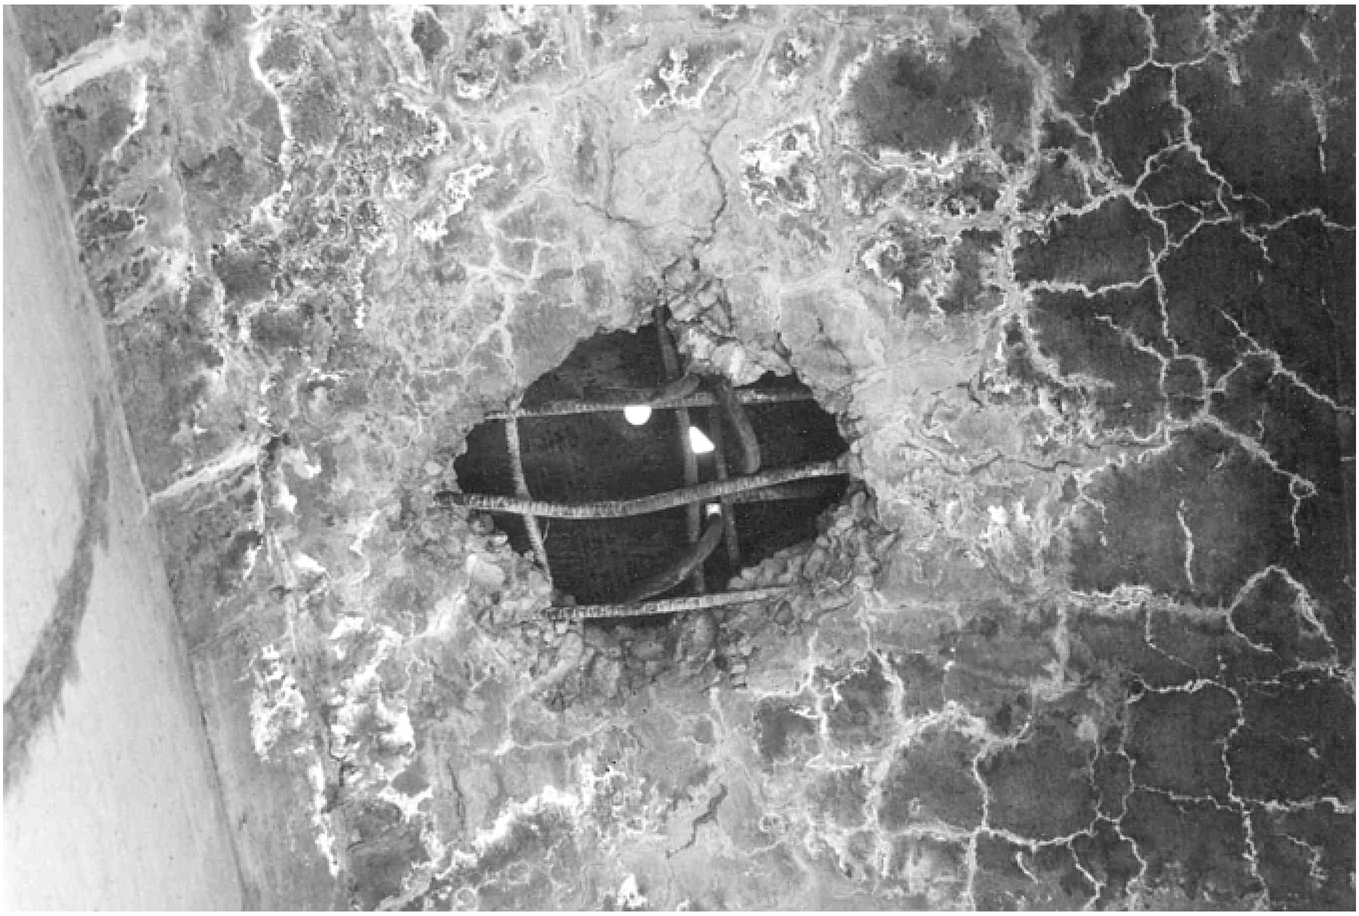

Fig. 5 Extensive cracking and punching shear damage to a bridge deck

A common conventional recourse is the complete reconstruction of the area, often at significant cost and with protracted distress to traffic. In comparison, fiber-reinforced composites can easily be applied without any disruption of traffic. If the repair scheme is designed properly, the external composite reinforcement will not only repair the area that was damaged by punching shear, but will also ensure that existing cracks do not open, causing further deterioration. The repair of this deficiency through the use of adhesively bonded pultruded composite strips and through wet lay-up of unidirectional fabric is shown in Fig. 6. The rehabilitation was conducted under traffic conditions without blocking or otherwise contaminating the aqueduct that carried water underneath it, again exemplifying the significant potential of composites for rehabilitation (Ref 15).

(a)

(b)

Fig. 6 Repair/strengthening of deck using (a) pultruded strips adhesively bonded to the concrete substrate, and (b) unidirectional fabric placed using wet lay-up

Similar schemes can be applied, not just in bridges, but also for the strengthening and repair of floor slabs of parking garages, which often suffer rapid deterioration due to salt-induced cracking, efflorescence of concrete, and corrosion of steel reinforcement. Further, the use of composite strips/bands provides an efficient mechanism for repair where the installation of liftwells and shafts in buildings results in cutting through existing steel reinforcement to form a cutout. Composite strips or bands can be easily applied externally to make up the lost reinforcing capacity, as well as to provide the means for redistribution of loads and resulting stresses. Where preexisting slabs have to be cut for the installation of a liftwell during changes in building use, conventional methods would result in the construction of deep supporting beams, enclosure walls, or columns to support the resulting weaker structure. Not only would all of these alternatives cause valuable space to be used, but significant cost and extended inconvenience to the inhabitants would also result. Composites, as shown in the example in Fig. 7 (Ref 15), thus provide a means not just for strengthening and repair, but also for effecting change in occupancy or use of structures while allowing rapid and nonintrusive reconstruction. Appropriate design can assure that failure is through delamination at the level of cover concrete, with load level decreasing to that of the yield response of the slab with a cutout, thereby ensuring gradual rather than catastrophic failure.

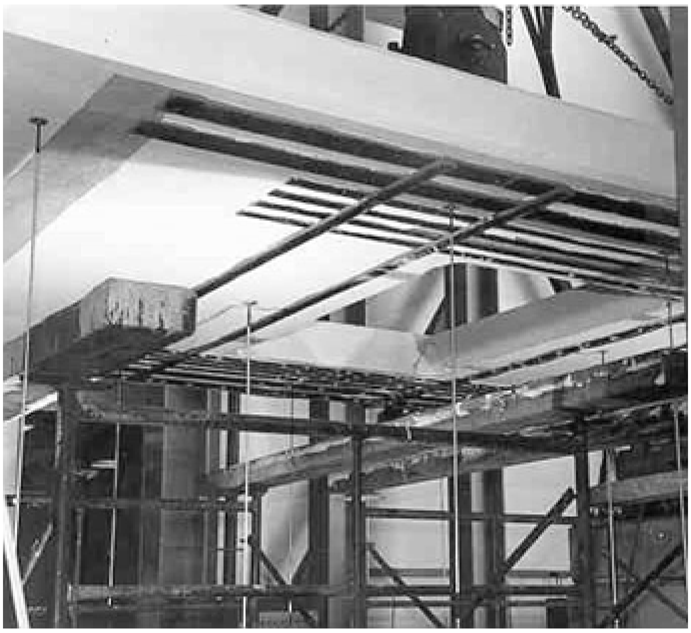

Fig. 7 Placement of composites around cutout in slab to provide external reinforcement for stress redistribution

In addition to the uses described previously, FRP composites have also been used for the repair and strengthening of historical structures or those with local community value, due to the ease of application without causing changes in the overall aesthetics and geometry of the structural components under consideration. In an interesting application in this area, three 65 m (215 ft) tall concrete smoke stacks of a cement plant in San Antonio, TX, were strengthened in 1998 using glass-fiber-reinforced polymer composites over the full height of the stacks to repair them from a structural aspect, while improving the aesthetics of a local landmark. The entire plant, with the smoke stacks as the signature elements, was renovated and converted into a shopping and entertainment complex.

Repair of Large-Diameter Pipes

Prestressed concrete cylinder pipe (PCCP) is widely used for the transportation and distribution of water in municipal, industrial, and agricultural irrigation systems. Pipe diameters range from 1.5 to 6 m (5 to 20 ft), and pressure heads range in height from 15 to 300 m (50 to 1000 ft). Recently, there has been an increasing fear of pipeline ruptures caused by:

- Cracking of the mortar coating or concrete cover, resulting in inadequate protection over a localized portion of prestressing wire, which can then corrode over time and lead to loss of section and ultimate loss in prestress of the pipe
- Defects in the original manufacturing process that could lead to water ingress into the pipe structure, leading to corrosion of the prestressing strands and ultimate loss of prestress
- Defects in the prestressing wire material, leading to accelerated pitting and corrosion

A number of sections have recently failed, with bursts leading to severe structural failure and damage to the surrounding area through cratering (Fig. 8). A number of these pipelines are below roads and in urban areas, leading to realistic fears of severe damage in case of failure, and necessitating the development of in situ repair methods that can be conducted without having to excavate the ground to replace pipe sections.

Fig. 8 Damage due to prestressed concrete cylinder pipe burst (Mojave Desert)

Although repair can be conducted through the use of conventional materials, such as installing an inner steel liner, installation is problematic due to the lack of clear access and the need for welding on-site inside the pipe. Moreover, the use of this method results in significant decreases in pipe cross section, leading to loss in flow. Further, the use of metallic liners necessitates the use of expensive corrosion protection schemes. Taking advantage of the high strength and stiffness of thin cross sections of composite materials, the use of a thin composite liner bonded to the inner surface of the concrete lining (Fig. 9) presents an attractive means to counteract the loss in prestressing due to corrosion of the outer prestressing wire. Recent tests have shown that the use of appropriately designed composite liners having predominant hoop reinforcement can ensure that the full capacity of the pipe can be achieved with very small reduction in inner diameter, thus using composites to effect a rapid and significantly lower cost repair. Similar to the methods of external strengthening described in the previous section, these structural liners can be installed using the wet lay-up process or through the adhesive bonding of prefabricated strips in spiral or hoop fashion. Because the primary need for reinforcement is in a specific direction (along the circumference), materials use can also be optimized in a composite through implementation of predominantly unidirectional (hoop oriented) layers. This method has already been demonstrated in the field as an efficient means of both repair and life-extension, as well as a cost-efficient means of preventive maintenance. Although the application was developed for purposes of repair and strengthening, it could also be used in the fabrication of new large-diameter pipelines to enhance pressure capacity and overall durability.

Replacement Bridge Decks

Of all elements in a bridge superstructure, bridge decks may require the maximum maintenance, for reasons ranging from the deterioration of the wearing surface to the degradation of the deck system itself. Added to the problems of deterioration are issues related to the need for higher load ratings and increased number of lanes on existing bridges to accommodate the constantly increasing traffic flow on major arteries. Beyond the costs and visible consequences associated with continuous retrofit, repair, and upgrade of such structural components are the intangible, but nonetheless important, consequences related to losses in productivity and overall economies related to losses of time and resources caused by delays and detours. Reasons such as those listed previously provide significant impetus for the development of new bridge decks out of materials that are durable, light, and easy to install. Besides the potential savings in life-cycle costs due to increased durability, decks fabricated from composites would be significantly lighter, thereby affecting savings in substructure costs, enabling the use of higher live- load levels by offsetting the higher dead weight of existing conventional decks, and giving

designers the potential of longer unsupported spans and enhanced seismic resistance. These deck structures can either be used as replacements for existing, but deteriorated or substandard concrete/conventional decks, or used as new structural components on conventional or new supporting structural elements.
For use as replacement decks, FRP composite decks have to be designed with four criteria in mind:

- Stiffness developed in the composite deck system (usually through the combination of a core and facesheets) must fall in the range between that of an equivalent uncracked and a cracked concrete deck, and the resulting response must have deformations not exceeding those of the conventional systems.
- Methods of attachment must match those useable on the existing girders and superstructure.
- Factors of safety must be designed in through the use of an appropriately factored equivalent energy approach, so as to offset the initial linear response followed by irreversible cracking/delamination/separation of fabric layers in composite decks.
- Processing methods must enable uniformity at costs comparable with the in-place costs of existing deck systems.

It should be noted that enhanced durability and the consequent lower life-cycle cost, although important, might not be an overriding factor in systems selection at the acquisition stage if cost differences are too high. Thus, it is important that savings arising from faster erection, need for less installation equipment, savings in supporting/foundation structure costs, and significantly reduced disruption of traffic be factored into the systems-level cost.
Fiber-reinforced polymer composite decks have been fabricated using a number of processes, such as wet lay-up (with one of the first vehicular demonstrations being the Miyun Bridge in China, Ref 16), resin-infusion-based processes (Ref 17, 18), pultrusion (Ref 18, 19, 20, and 21), or a combination thereof. The use of modular sections that can "snap" together in the field provide flexibility while satisfying the civil engineer's desire to use standardized sections. Large-scale tests on deck subelements and the use of these in a number of projects in the field have demonstrated that adequate performance levels can be easily achieved at significantly lower weights. It should be noted that because designs are primarily driven by deflection (i.e., stiffness-related) constraints, materials and structural configurations are selected to optimize stiffness, and therefore stress levels in the composite are extremely low under service conditions (generically in the range of 10–15% of ultimate). Although the typical response envelope is linear to failure, it is possible to design for a failure envelope that mimics the overall structural ductility of reinforced concrete by allowing failures at nodes within the composite through mechanisms of delamination and layer separation. Although these modes are irreversible, they do provide a slow degradation of performance with substantial "pseudoductility." Fiber-reinforced polymer bridge decks have already been installed as replacements for existing concrete, steel, and timber decks in a number of cases, and in others have been used as complete replacements for existing superstructure between abutments.

New Structural Systems

The current emphasis on the use of composites in the areas of rehabilitation and replacement can be traced to the greater ease of its introduction in this area due to urgent needs for methods and greater flexibility in accepting technologies without the establishment of standards. However, there is significant long-term potential for the development of new infrastructure systems, using either composites by themselves or in conjunction with existing materials, such as timber, steel, and concrete. The intrinsic light weight and tailorability of composites enable the integration of form and function into civil engineering designs without constraints previously in place due to limitations of conventional materials. Building ecosystems having large, unsupported domes, such as those needed for artificial desert and undersea habitats, long span bridges, such as between Italy and Sicily, or bridges that meld in with environments without upsetting the fragile surrounding ecosystems could all be possible in the 21st century using large and long unsupported prefabricated composite systems, either as full structural elements or as the primary reinforcement. Applications such as floor panels and gratings on offshore platforms are already being used as part of primary structure, both decreasing topside weight (which generically results in a minimum of three times the savings below the waterline) and increasing occupant safety in cases of fire, due to decreased levels of heat conduction as compared with steel and aluminum. Electrical transmission towers fabricated using specially designed interlocking pultruded elements (Ref 22) are already providing immense advantages over metallic incumbent structures due to increased durability and ease of installation, especially in areas that are difficult to access.

The development of new structural concepts and systems that combine the superior mechanical characteristics of directional strength in tension in the direction of the fiber with the dominant characteristics of conventional materials, such as compression in concrete, show great potential for development of new advances in the design and construction of civil infrastructure systems. The concept of using composite tubes as both the formwork and the primary tension reinforcement for columns (Ref 23) provides an efficient means of replacing the reinforcing steel (and the attendant problems related with assemblage in the field and deterioration due to corrosion) while providing a prefabricated reinforcing formwork into which lower strength concrete could be easily and rapidly poured. This provides better seismic response and overall durability, coupled with greater speed of erection. This concept is currently being studied not just for the fabrication of new columns using “stay- in-place” formwork, but also as a framing system for large industrial facilities.

An extension of these concepts is possible for complete bridge systems where both columns and supporting girders for superstructure are prefabricated from hollow shells, assembled on site, and then filled with lightweight, high-flowable concrete under pressure for rapid modular construction. Both composite and reinforced concrete (precast or cast-in-place) decks could be used in this scheme. Prototype systems for slab and girder bridge systems have already been tested (Ref 24) at levels of individual components and large-scale structural subsystems and have shown that performance (both static and fatigue) criteria can readily be reached, with ultimate capacities being significantly in excess of required shear and moment demand for full vehicular operation. A prototype 20.1 m (66 ft) span bridge (Fig. 10) has recently been completed in Palm Desert, CA, using this concept for full vehicular traffic (Ref 25).

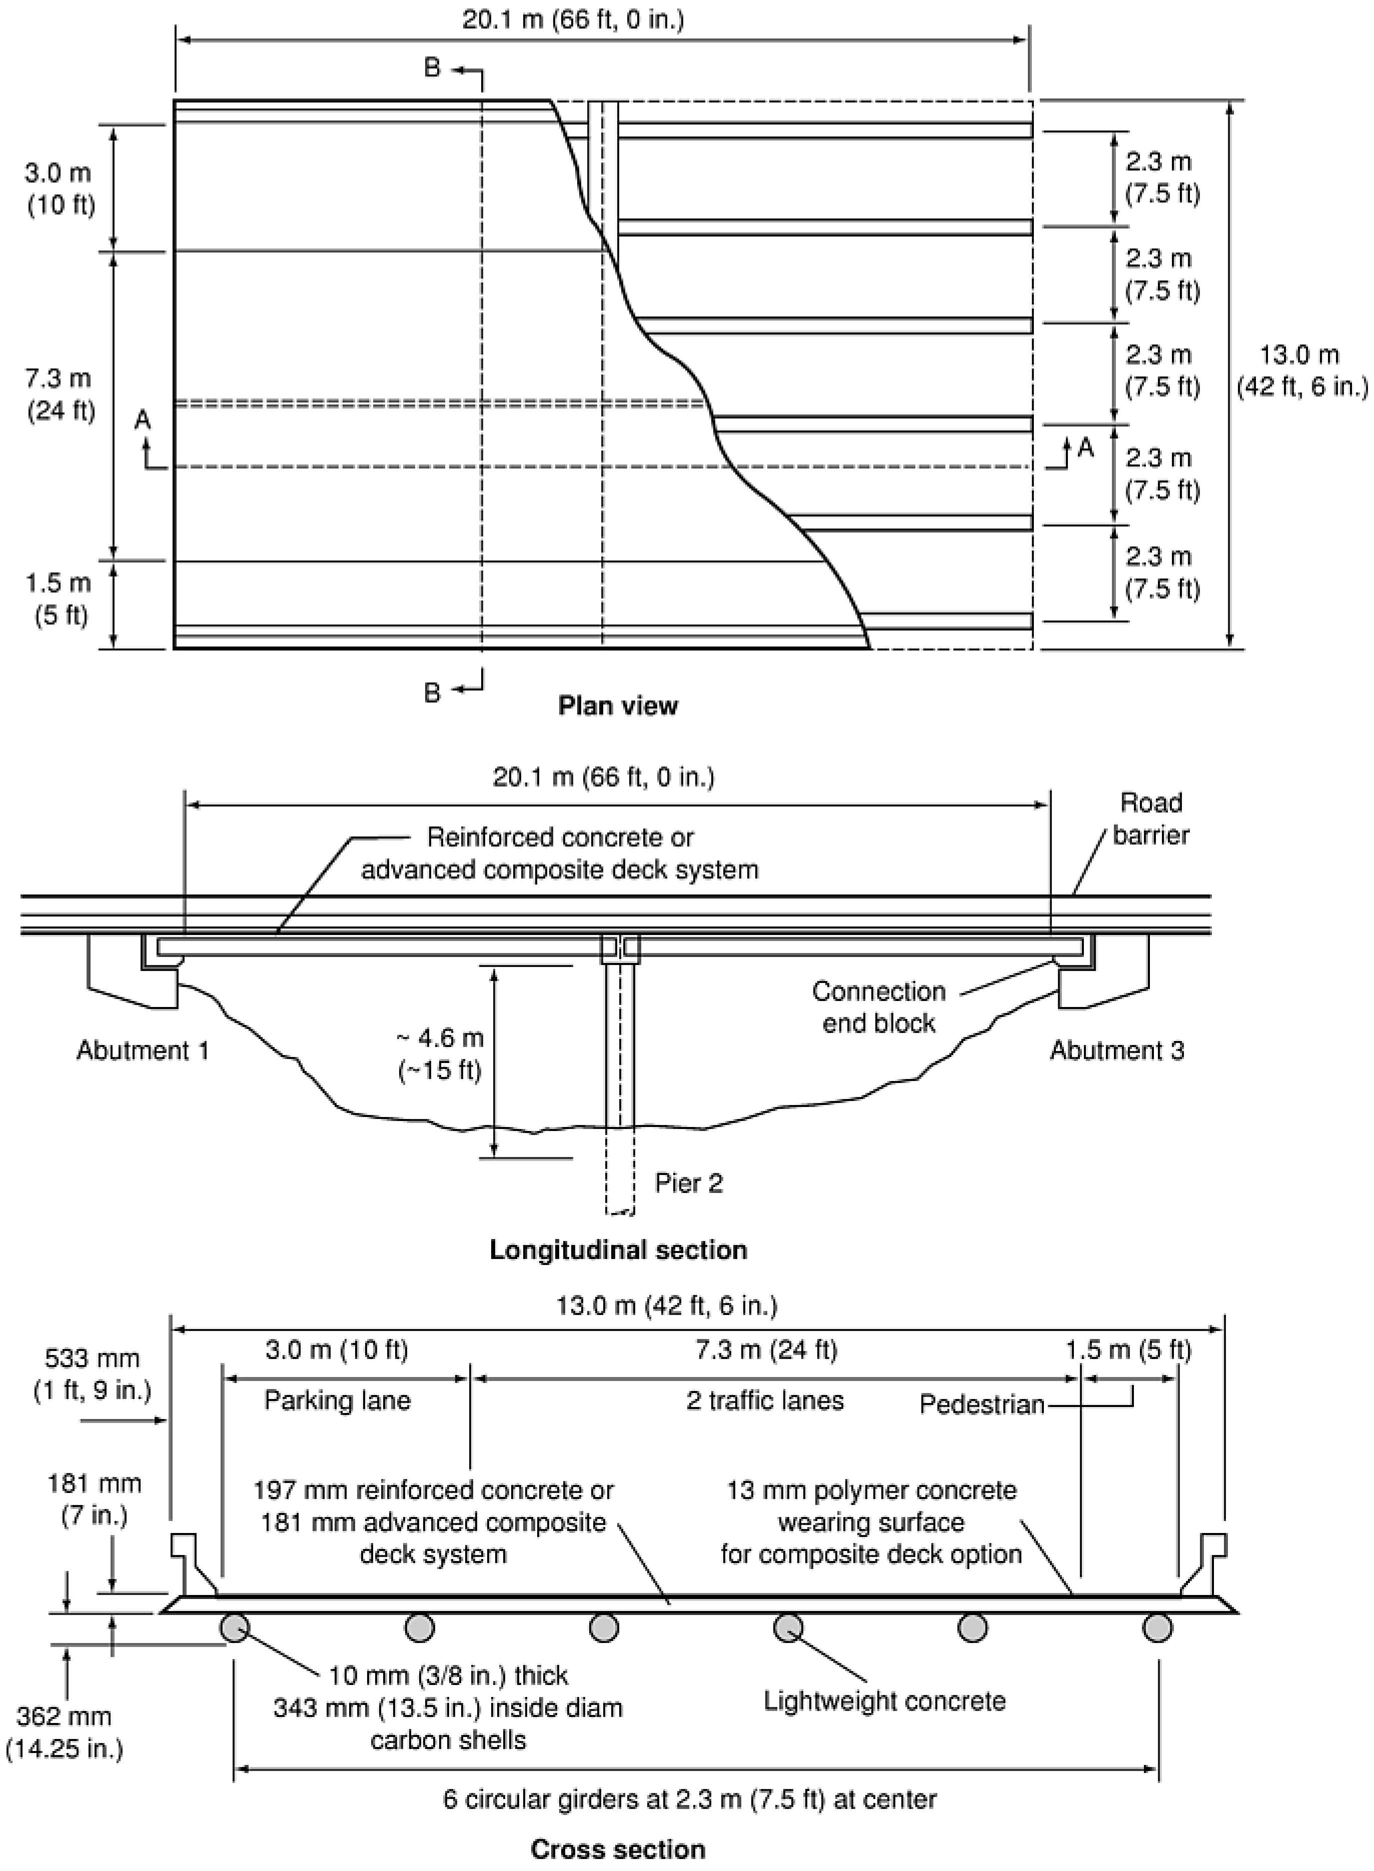

Fig. 10 Geometry of the Kings stormwater channel bridge (Palm Desert, CA)

The use of rectangular and "conrec" shell configurations, such as described in (Ref 26), in place of circular cross sections permits greater optimization of materials usage through hybridization, using both carbon- and

glass-fiber reinforcements, while simultaneously enabling greater ease of construction/assembly using tension-tie-plates to position and hold the assembly together (Fig. 11). Such systems, comprised of composite tube and plate assemblies used synergistically with concrete infill and selective use of conventional embedded connection details, can provide design enhancements that were envisioned earlier with the use of concrete-filled steel tubes, but did not find widespread use due to difficulties associated with steel yielding, corrosion-related degradation, and weight. Such concepts could also conceivably be extended for use in rapid fabrication of large industrial facilities without the use of heavy equipment in areas where labor is either unskilled or not readily available.

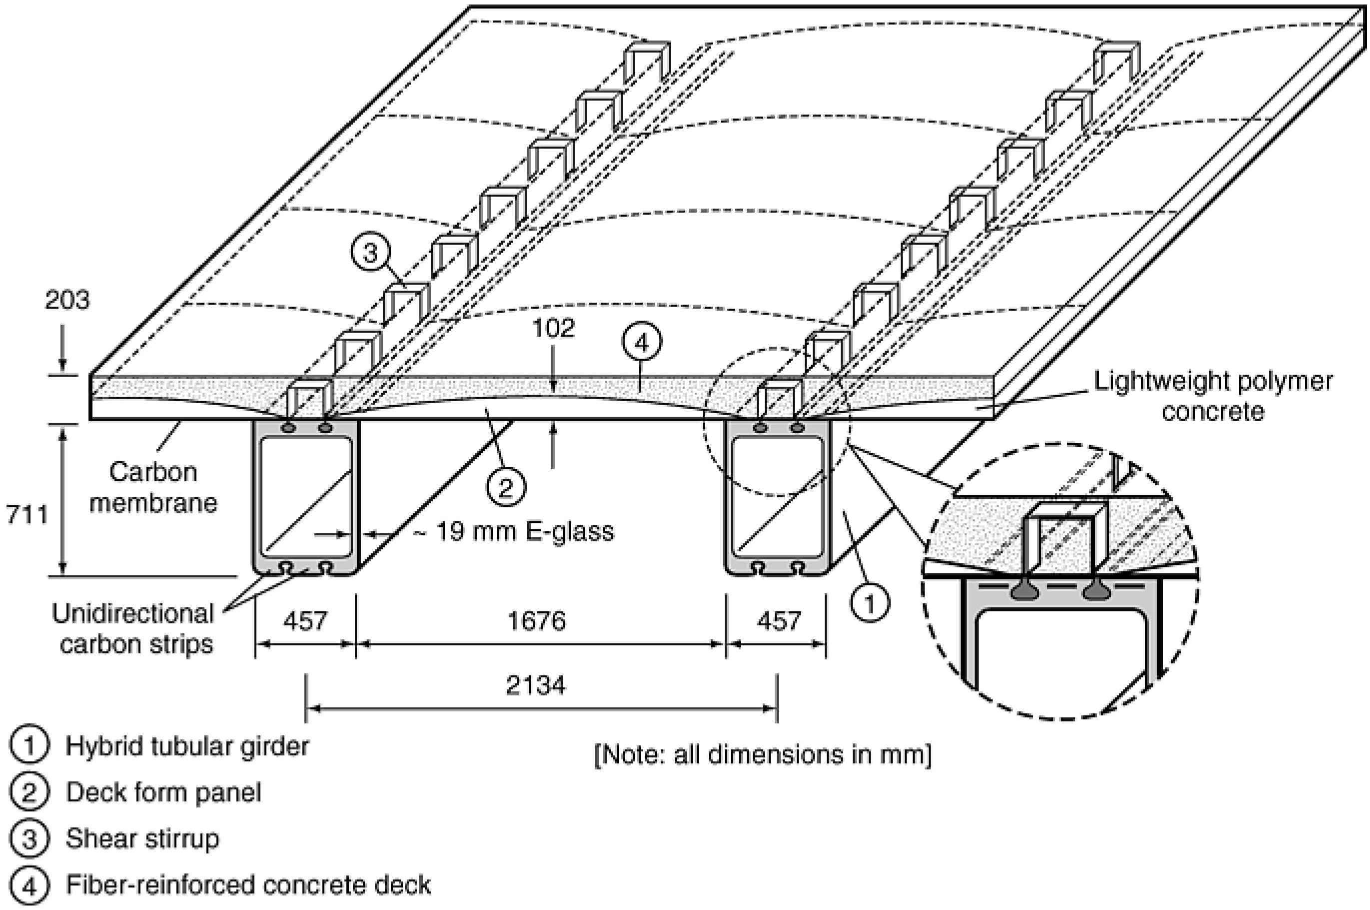

Fig. 11 Modular "snap-in" bridge system

A number of other systems using combinations of deck systems and pultruded beams as girders have already been erected in the field over short spans and are being monitored for performance (Ref 27, 28, and 29). Further developments, such as the envisioned construction of the Interstate 5/Gilman Drive bridge (San Diego, CA) (Fig. 12), which uses concrete-filled carbon/epoxy tubes as the longitudinal girders, E-glass/ vinylester hollow rectangular box-type transverse girders, and a set of structural stiffened deck panel overlaid with fiber–reinforced concrete with steel rebar spanning between the transverse girders (Ref 25, 26), provide additional impetus for the rapid acceptance of composites in civil construction.

Civil Infrastructure Applications

Vistasp M. Karbhari, University of California, San Diego

Outlook

Although the use of polymer-matrix composites is increasing in the area of civil infrastructure, it must be noted that, except in the areas of seismic retrofit and strengthening, most of the other applications are in the realm of demonstrations, rather than in the commercial area. There is no doubt, however, that the intrinsic tailorability and performance attributes of both glass- and carbon-fiber reinforced composites make these materials very attractive for use in civil infrastructure applications, and a welcome addition to the current palette of construction materials. Due to the large volume of material needed, even for niche applications, the civil infrastructure market is expected to provide a significant impetus for further development of new composite material systems (primarily in the area of hybrids and textile structural composites) and new or modified processes capable of fabricating large structural components in a cost-efficient manner.

These developments are likely to range from the production of cheaper carbon fibers and E- glass fibers with greater alkaline resistance, to the greater use of hybrid composites, with hybridization taking place at the level of the tow as well as in textile preform structures. Needs for greater resistance to fires have already spurred the renewed development of phenolic resins with greater flexibility in processing. In an environmentally conscious industry, requirements for the fabrication of large structural components using low-cost processes, such as pultrusion, resin infusion, and resin transfer molding, have lead to the development of low-viscosity, lower-styrene- and volatile-content vinylesters, and phase-transforming resin systems. Field conditions and the intrinsic need for composites that must be able to perform under wide ranges of temperature and humidity levels is leading to intense research in areas related to alternate cure mechanisms capable of achieving rapid cure and higher-than-ambient glass transition temperatures without the use of external heat.

By their very nature, most composite components used in civil infrastructure have to be cost-competitive on an acquisition cost basis, if not at the component level, then at least at the systems level, with incumbents made of conventional materials. Further, the very nature of the applications set almost assures that significant fabrication will be conducted in the field or in partially controlled, but changing environments. The exigencies of size also dictate that, in general, traditional autoclave-based fabrication will not be used widely. The emphasis is increasingly being placed on processes such as wet lay-up, pultrusion, winding, and resin transfer molding, and in the development of newer processes, such as injection pultrusion and resin infusion. It should be noted that these and other developments brought about by the needs of civil infrastructure will not only provide solutions specific to civil infrastructure requirements, but will also have a positive influence on other applications of composites.

In spite of the high level of current interest in this area, the extent and nature of the future use of composites in civil infrastructure will depend on a number of factors, including:

- Resolution of outstanding issues related to durability, fire resistance, and reparability, to the extent of having a good determination of the level of knowledge and assurance of each of these factors
- Development of manufacturing processes and schemes that are amenable to the high-quality, repeatable, and uniform production of primary structural elements in a cost-effective (as related to civil infrastructure economics) manner, both in controlled factory conditions (for prefabricated elements) and in the field (for in situ fabrication)
- Development of validated codes, standards, and guidelines for the use of these materials by the civil engineering community
- Development of low-cost, in situ health- monitoring devices and schemes, especially to provide a level of comfort about the safety of using structures/components fabricated from composites, until a time when an appropriate history of in-field use has been attained
- The synergistic education of both the civil engineering/construction and the composites communities about the needs and methods of development in both areas

Recent advances in materials, manufacturing, mechanics, and design point to the continued development of innovative materials and structural systems that will enable:

- Synthesis of form and function
- Greater emphasis to be paid to aesthetics and blending of the structure into the environment
- Construction of true long-span bridges
- Use of intelligent, self-monitoring structural systems
- Development of very large-scale structural systems, such as large integrated city-structural complexes, built as independent environments on land, in the air/space, or underground

Perhaps in civil infrastructure applications, fiber-reinforced polymer-matrix composites will finally demonstrate their potential as true structural materials and become not just “materials of the future,” but “materials for everyday construction.”

Applications of Ceramic-Matrix Composites

J.R. Davis, Davis & Associates

Introduction

APPLICATIONS for ceramic-matrix composites (CMCs) fall into four major categories:

- Cutting tool inserts
- Wear-resistant parts
- Aerospace and military applications
- Other industrial applications, including engines and energy-related applications

This article reviews application examples in each of these four categories, with emphasis placed on those applications/materials that have achieved commercial viability. Advanced CMCs that are now emerging from laboratories and that show potential for high-performance applications or that are in the prototype stage are also surveyed. An in-depth economic analysis on CMCs, including their processing, new applications, current markets and trends, and U.S. and international companies and institutions involved in CMCs, can be found in Ref 1.

Applications of Ceramic-Matrix Composites

J.R. Davis, Davis & Associates

Applications for Discontinuously Reinforced CMCs

Discontinuous reinforcement involves the addition of particles, platelets, whiskers, or chopped fibers, typically to a polycrystalline ceramic, glass, or glass-ceramic matrix. From an application viewpoint, the most important matrix material is alumina (Al_2O_3), although discontinuously reinforced CMCs have also been produced from silicon carbide (SiC), silicon nitride (Si_3N_4), mullite ($3Al_2O_32SiO_2$), and aluminosilicate matrices. Important reinforcements include SiC, zirconia (ZrO_2), and titanium carbide (TiC). Additional information on discontinuously reinforced CMCs, including their toughening mechanisms and properties, can be found in the article "Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites" in this Volume.

Cutting Tools

Both particulate-reinforced and whisker-reinforced Al_2O_3 have found use as cutting tool inserts. The development of these composite tool materials was partially based on the advances in high-temperature monolithic ceramic materials and processing technology developed for automotive gas turbine and other high-temperature structural applications. Table 1 compares the room-temperature properties of ceramic and cemented carbide tool materials, including several of the CMCs discussed subsequently.

Table 1 Typical property values for cutting tool materials, including discontinuously reinforced CMCs

Tool material	**Transverse rupture strength**		**Hardness, HRA**	Fracture toughness	
	MPa	**ksi**		**MPa** $\sqrt{m}$	ksi $\sqrt{in.}$
Al_2O_3	500–700	70–100	93–94	3.5–4.5	**3.2–4.1**
Al_2O_3-ZrO_2	700–900	100–130	93–94	5.0–8.0	**4.5–7.3**
Al_2O_3-TiC	600–850	90–120	94–95	3.5–4.5	**3.2–4.1**
Al_2O_3-SiC_w	550–750	80–110	94–95	4.5–8.0	**4.1–7.3**
Si_3N_4	700–1050	100–150	92–94	6.0–8.5	**5.5–7.7**
SiAlON	700–900	100–125	93–95	4.5–6.0	**4.1–5.5**
WC-Co alloys	**1250–2100**	**180–300**	**91–93**	**10.0–13.5**	**9.1–11.4**

Source: Ref 2

Al_2O_3-TiC Composites. In the early 1970s, it was discovered that Al_2O_3 admixed with a refractory metal particulate (for example, titanium carbide) could produce a cutting tool with superior hardness and fracture resistance. These hot-pressed or hot isostatically pressed (HIPed) composites consist of approximately 70% Al_2O_3 with 30% TiC particulate. Such composites are referred to as black ceramics due to their color, which results from the presence of TiC. The typical microstructure of an Al_2O_3-TiC composite is shown in Fig. 1.

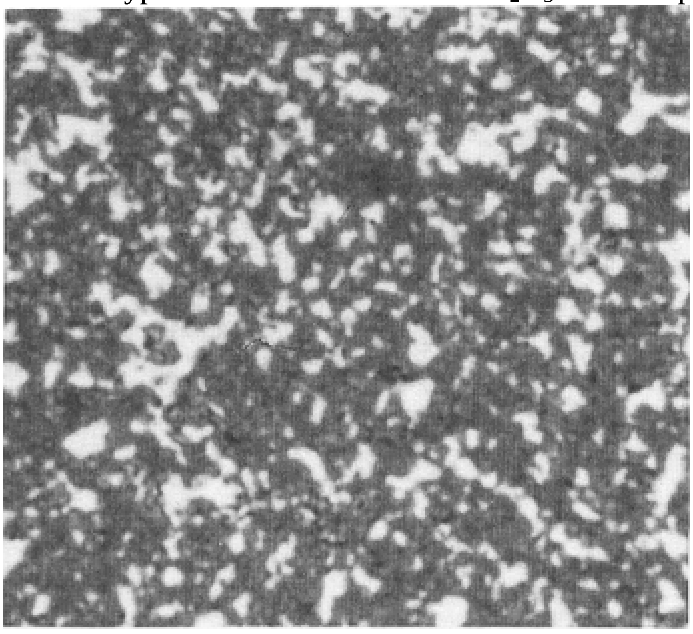

Fig. 1 Microstructure of a hot-pressed Al_2O_3-TiC ceramic tool material. 1500×

The dispersion of hard refractory particles increases the hardness of these composites at temperatures up to 800 °C (1470 °F) when compared to monolithic oxide ceramics (Fig. 2). Simultaneously, the fracture toughness and bending strength is improved through crack impediment, crack deflection, or crack branching caused by the dispersed hard particles. The higher hardness in combination with the higher toughness increases the resistance to abrasive and erosive wear considerably. The lower thermal expansion and higher thermal conductivity of the composites improve thermal-shock resistance when compared to monolithic oxide ceramics. At temperatures exceeding 800 °C (1470 °F), however, the TiC particles oxidize and begin to lose their reinforcing properties and the composite weakens. Thus, this phenomenon must be taken into consideration when selecting cutting conditions such as cutting speed, depth of cut, and feed rate.

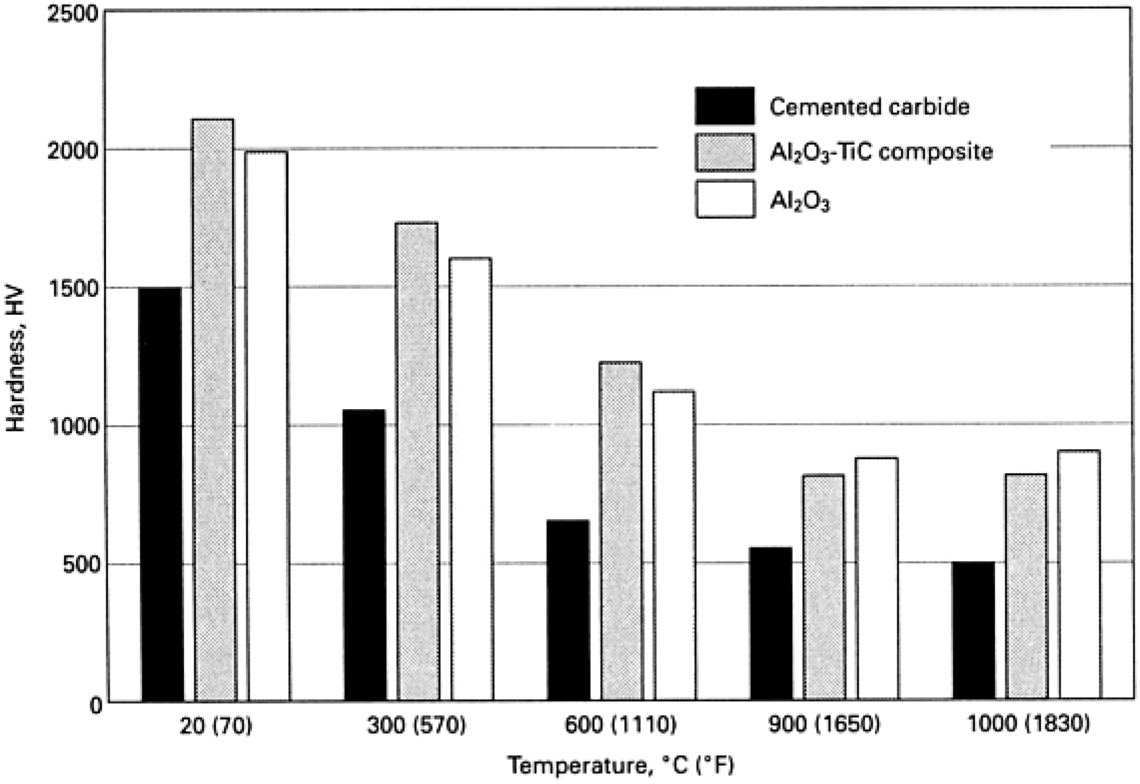

Fig. 2 Hot hardness comparison of monolithic Al_2O_3, Al_2O_3-TiC, and cemented carbide tool materials. Source: Ref 3

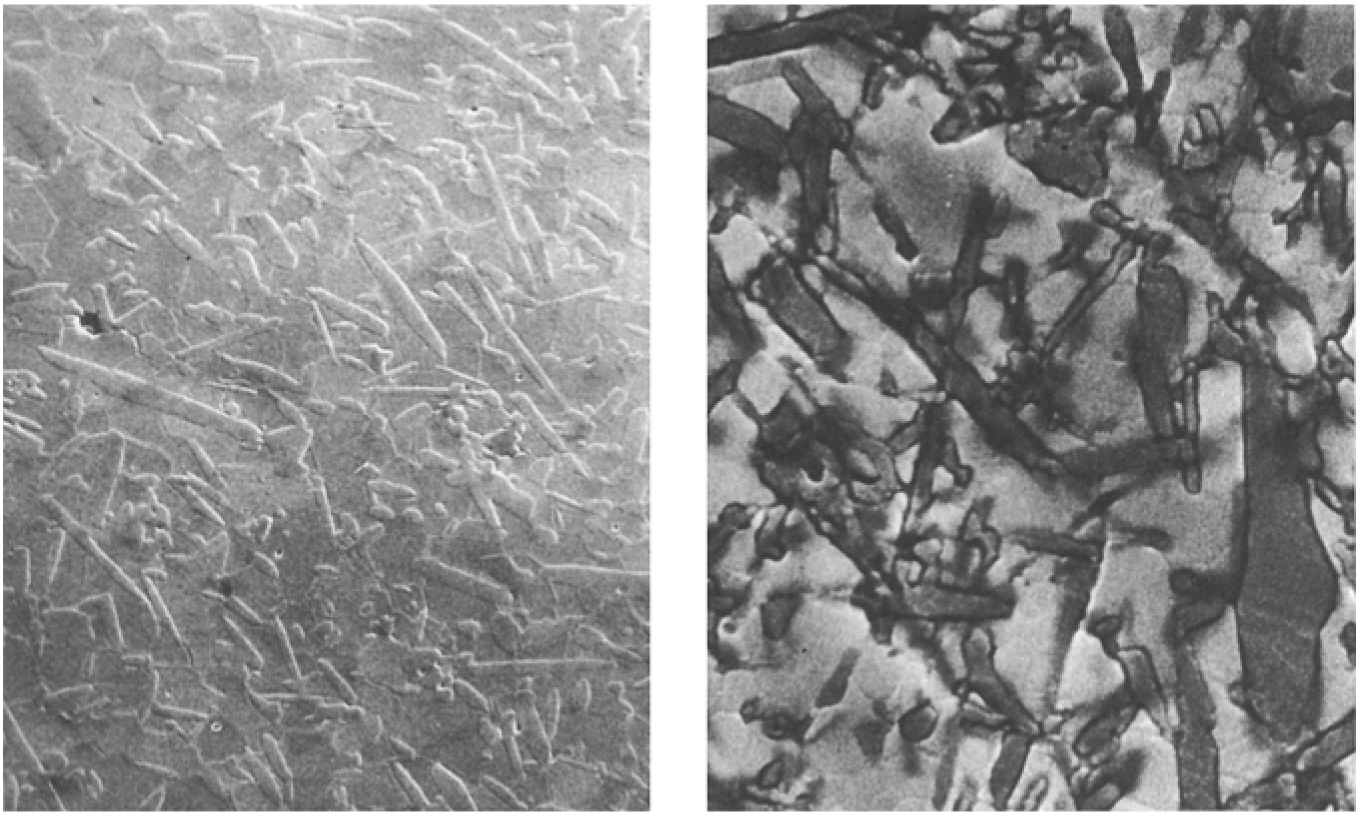
The HIPed Al_2O_3-TiC composite tool grades are used for interrupted cuts, and for roughing and finishing of high-temperature superalloys, hardened steels (30 to 50 HRC), chilled irons (50 to 60 HRC), and gray and ductile cast irons with hardnesses ranging from 140 to 300 HB. Additional information on machining of these materials with Al_2O_3-TiC composite tool inserts can be found in Ref 4.

Silicon carbide whisker-reinforced alumina (Al_2O_3-SiC_w) is the newest Al_2O_3-base tool material. The incorporation of SiC whiskers (20 to 45 vol%) into an Al_2O_3 matrix with subsequent hot pressing results in a composite with significantly improved toughness. Figure 3 shows the microstructure of SiC whisker-reinforced Al_2O_3.



(a) (b)

Fig. 3 Microstructure of SiC whisker-reinforced Al_2O_3 composite. (a) 2100×. (b) 5000×

The whiskers, which are small fibers of single- crystal SiC about 0.5 to 1 μm in diameter and 10 to 125 μm long, have a higher thermal conductivity and a lower coefficient of thermal expansion than Al_2O_3. This improves thermal- shock resistance.

The SiC whiskers in the Al_2O_3 matrix also produce a twofold increase in fracture toughness (Table 1). The fracture toughness is enhanced by the occurrence of whisker "pull-out." A close examination of the fracture surface at high magnification will reveal not only a clear indication of the whiskers randomly dispersed throughout the matrix, but also the obvious hexagonal voids where whiskers have actually been pulled out during the fracture process (Fig. 4). A large amount of energy is required to pull the whiskers out, and this greatly inhibits crack propagation. More detailed information on the fracture toughness of Al_2O_3-SiC_w composites can be found in Ref 5, 6, and 7.

Fig. 4 Fracture surface of a SiC whisker-reinforced Al_2O_3 ceramic. Note hexagonal voids or holes due to whisker pull-out upon fracture. 950×

The Al_2O_3-SiC_w composite tool grades are used for rough turning of alloy and hardened steels (32 to 65 HRC), ductile irons (150 to 300 HB), and chilled irons (50 to 65 HRC). Their primary application area, however, is for roughing, finishing, and milling of difficult-to-machine age-hardenable nickel-base superalloys. Much higher cutting speeds and longer tool life can be achieved when machining these materials with whisker-reinforced Al_2O_3 (Fig. 5). Additional information on the use of Al_2O_3-SiC_w ceramic tooling for machining of superalloys can be found in Ref 9.

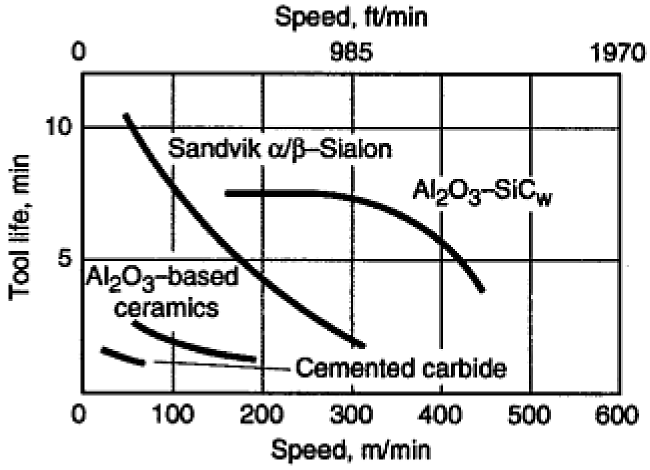


Fig. 5 Tool life of ceramic, CMC, and cemented carbide materials when machining Inconel 718 (feed of 0.2 mm/rev; depth-of-cut of 2 mm). Source: Ref 8

Si_3N_4-Base Composites. A number of particle-reinforced and whisker-reinforced Si_3N_4 composites have also been evaluated as cutting tool materials (Ref 10, 11, 12, 13, and 14). The addition of dispersed phases such as TiC, titanium nitride (TiN), and hafnium carbide (HfC) to a Si_3N_4 matrix results in an increase in hardness. Hot- pressed whisker-reinforced composites, containing from 10 to 30 vol% SiC, exhibit higher fracture

toughness values than do their unreinforced counterparts. Despite these advantages, Si_3N_4-base composite tool materials have not reached commercial viability as have monolithic Si_3N_4 and SiAlON cutting tools.

Wear-Resistant Materials/Applications

Zirconia-Toughened Ceramics. Particulate- toughened ceramics, such as the zirconia-toughened ceramics, are filling applications such as bearings, bushings, precision balls, valve seats, and die inserts where their friction and wear characteristics have improved both performance and cost. One example is zirconia-toughened alumina, or ZTA (Al_2O_3-ZrO_2), where Al_2O_3 is considered the primary or continuous (70 to 95%) phase. Zirconia particulate additions from 5 to 30% (either as pure ZrO_2 or stabilized ZrO_2) represent the second phase (Fig. 6). The ZrO_2 is present either in the tetragonal or monoclinic symmetry. Zirconia-toughened Al_2O_3 is a material of interest primarily because it has a significantly higher strength and fracture toughness than monolithic Al_2O_3 (Table 1).

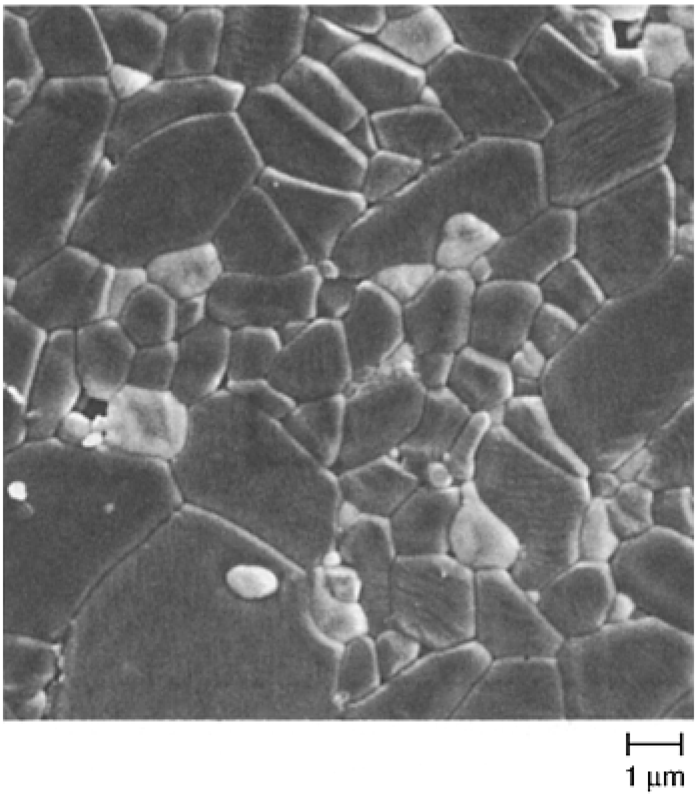

Fig. 6 Scanning electron micrograph of high-purity zirconia-toughened alumina (ZTA) showing dispersed ZrO_2 phase (white) within an Al_2O_3 matrix

The microstructure and subsequent mechanical properties can be tailored to specific applications. Higher ZrO_2 contents lead to increased fracture toughness and strength values, with little reduction in hardness and elastic modulus, provided most of the ZrO_2 can be retained in the tetragonal phase. Strengths up to 1050 MPa (152 ksi) and fracture toughness values as high as 8.0 MPa $\sqrt{m}$(7.3 ksi $\sqrt{in.}$) have been measured (Table 1). Wear properties in some applications may also improve due to mechanical property enhancement compared to alumina. These types of ZTA compositions have been used in transportation equipment where they need to withstand corrosion, erosion, abrasion, and thermal shock (see subsequent discussion). Other applications for ZTA include cutting tool inserts and its use as an abrasive grinding medium.

Zirconia-toughened alumina has also seen some use in thermal shock applications. Extensive use of monoclinic ZrO_2 can result in a severely microcracked ceramic body. This microstructure allows thermal stresses to be distributed throughout a network of microcracks where energy is expended opening and/or extending microcracks, leaving the bulk ceramic body intact (Ref 15).

SiC Particle-Reinforced Al_2O_3 Matrix Composites. An Al_2O_3 matrix composite reinforced with coarse SiC particles has been optimized for applications requiring slurry erosion resistance (Ref 16, 17). Processing was carried out by directed metal oxidation (see the article “Processing of Ceramic-Matrix Composites” in this Volume for details). Wear test data for the Al_2O_3-SiC_p composite and other ceramic and metallic materials are

compared in Fig. 7. Silicon carbide particle-reinforced Al_2O_3 composites of this type are being used successfully in a range of applications including slurry pump components, hydrocyclone liners, chute liners, and materials handling systems. Figure 8 shows several examples of wear components that are available commercially. A similar composite has been commercialized for armor applications.

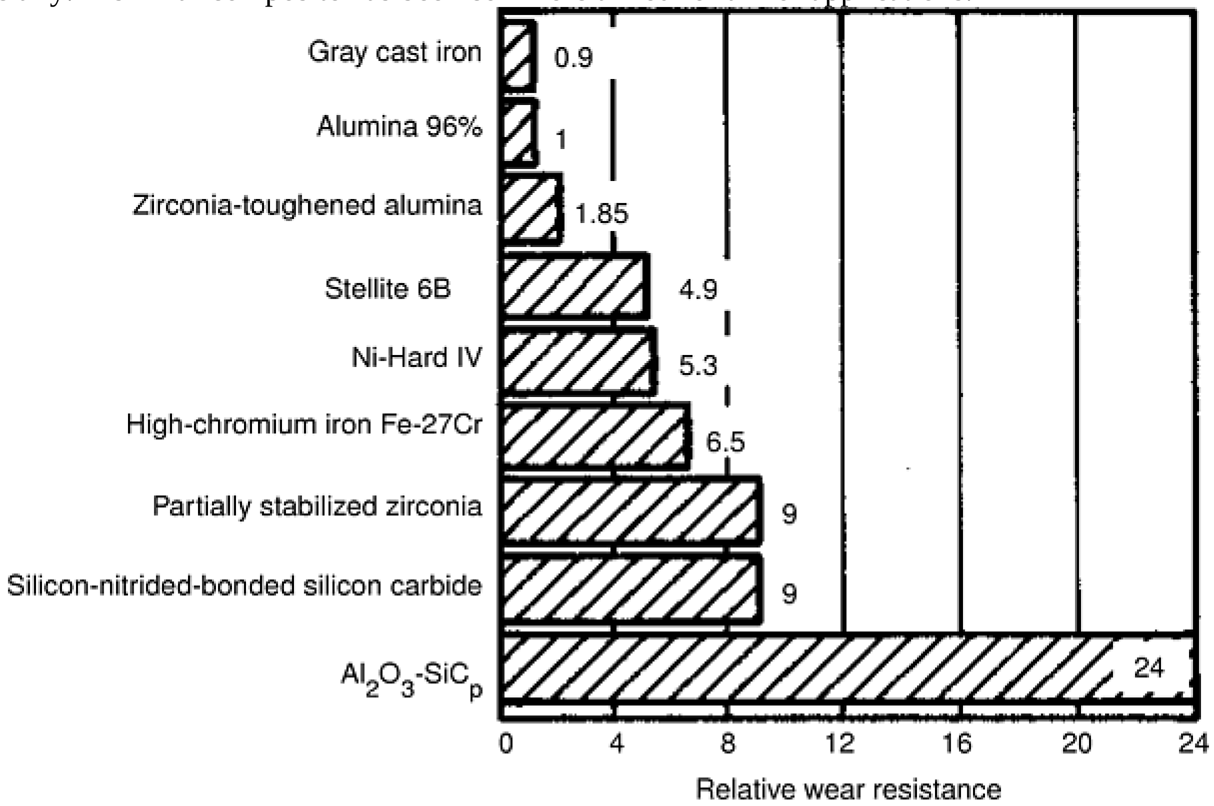

Fig. 7 Relative slurry erosion wear performance of metallic, ceramic, and CMC (Al_2O_3-SiC_p) materials. This evaluation compared measured material losses in a slurry pot test in which 14 mm (0.54 in.) diam by 60 mm (2.4 in.) long test pins were rotated at 10 m/s (33 ft/s) for 20 h in a slurry of 40 wt% 300 to 600 μm SiO_2 particles in neutral water. Source: Ref 18

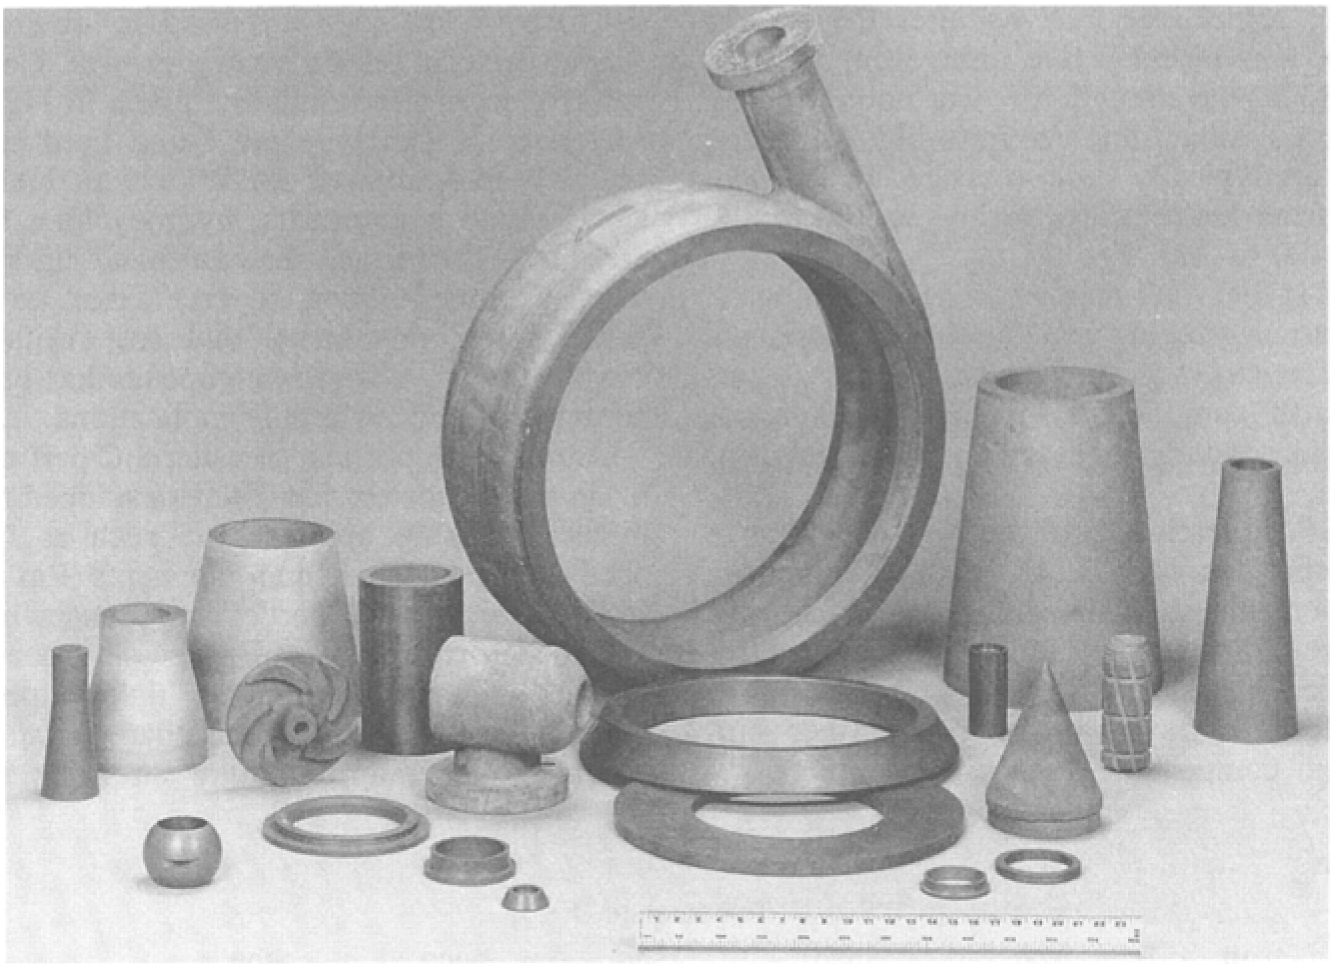

Fig. 8 Examples of wear-resistant Al_2O_3-SiC_p components produced for use in applications requiring resistance to slurry erosion. The pump housing is approximately 640 mm (25 in.) in diameter. Large wear rings are produced up to 1.2 m (48 in.) in diameter.

Another variant of a SiC particle-filled Al_2O_3 matrix composite has been optimized for resistance to sliding and rolling contact wear (Ref 18). This composite uses fine SiC particles with modifications to the residual metal in the Al_2O_3 ceramic matrix. Successful prototype test results have been obtained for piston engine cam follower rollers made of this material.

CMCs for Can-Making Tooling. Ceramic- matrix composites have gained acceptance in aluminum can-making equipment and associated tooling. Products made from CMCs include (Ref 19):

- Punches
- Bodymaker toolpack (redraw dies, ironing dies, pressure rings)
- Domer tooling
- Cupper tooling
- Stripper tooling
- Necker tooling
- Trimmer blades

Materials used for these applications include transformation-toughened zirconia, Al_2O_3-SiC_w, and Si_3N_4-SiC_w. The latter material has the least affinity for aluminum metal pickup during two- piece can-making operations. Figure 9 shows an exploded view of a ceramic can-making tool assembly. Such assemblies are generally made from the same material, with Si_3N_4-SiC_w the most commonly used.

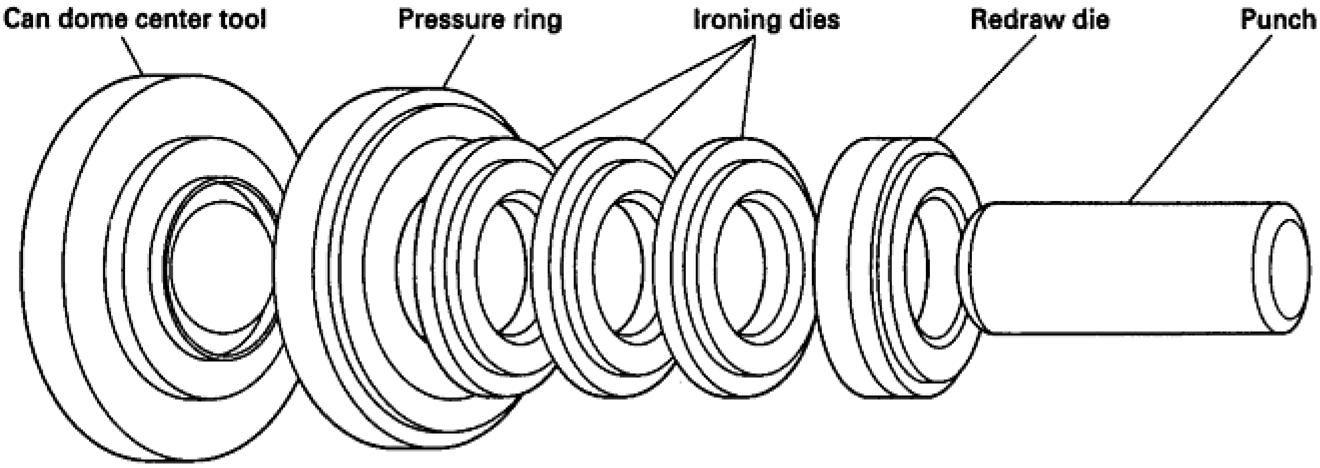

Fig. 9 Exploded view of a Si_3N_4-SiC_w can-making tooling assembly. Source: Ref 19

Aerospace Applications

Although most CMCs under development for aerospace structural applications are the continuous fiber CMCs discussed later in this article, there have been attempts to develop discontinuously reinforced CMCs for such applications. One example is the zirconium diboride (ZrB_2) platelet-reinforced zirconium carbide (ZrC) composite described subsequently. This is another example of CMC processing by direct metal oxidation.

ZrB_2 Platelet-Reinforced ZrC Composites. To form this composite, molten zirconium is directionally reacted with B_4C powder in a graphite mold at temperatures of about 1850 to 2000 °C (3350 to 3630 °F) (Ref 20). The B_4C is completely reacted to form the two ceramic phases ZrB_2 and ZrC. The ZrB_2 takes the form of hexagonal platelets in a ZrC matrix containing controlled amounts of free zirconium, as illustrated by the microstructure shown in Fig. 10.

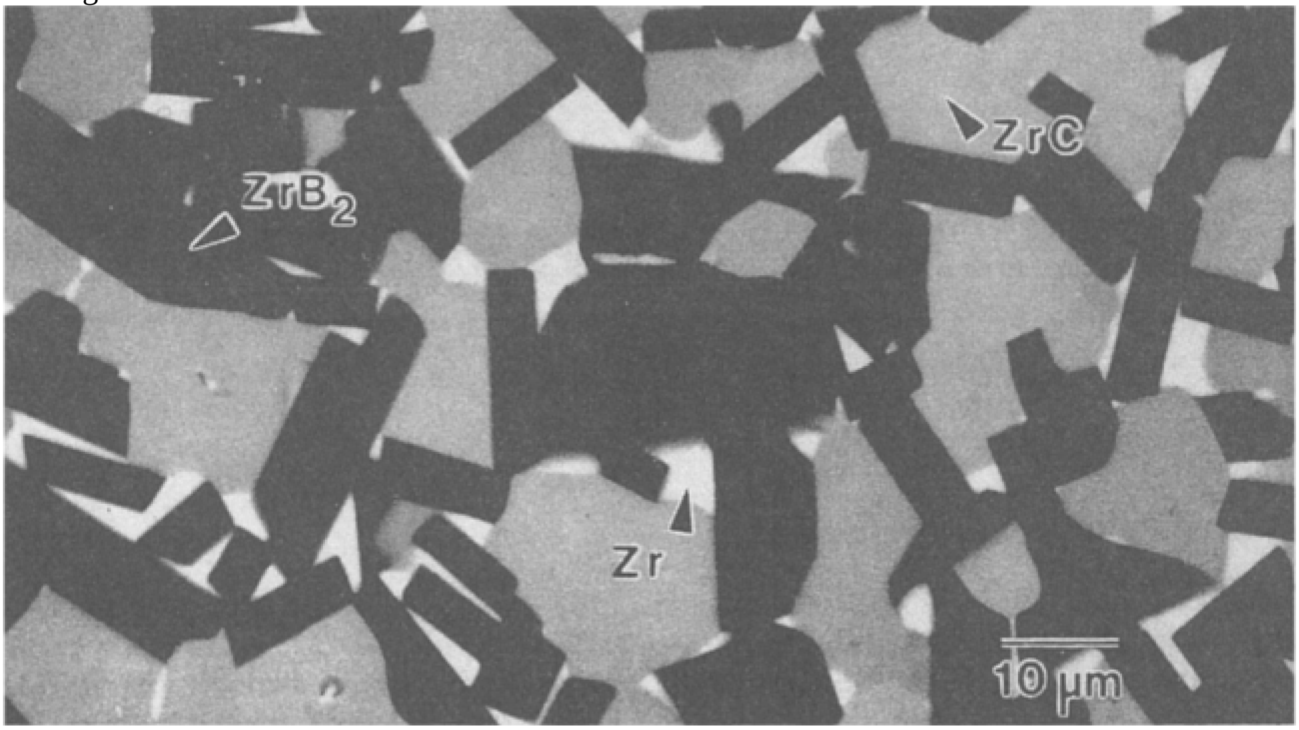

Fig. 10 Microstructure of a ZrB_2 platelet-reinforced composite with a ZrC matrix that also contains controlled amounts of zirconium metal. Source: Ref 18

Typical room-temperature mechanical properties for composites in the 3 to 12 vol% Zr range include flexural strengths of 800 to 900 MPa (116 to 130 ksi), Weibull moduli of 20 to 30, and fracture toughnesses (chevron notch method) of 12 to 15 $MPa\sqrt{m}$ (11 to 14 $ksi\sqrt{in.}$) (Ref 21). The fracture toughness values depend on the metal content. Toughness values of 10 to 12 $MPa\sqrt{m}$ (9 to 11 $ksi\sqrt{in.}$) at very low metal contents

result from platelet toughening mechanisms (that is, crack deflection and crack bridging/platelet pull-out). As the metal content increases, the toughness increases due to an additional contribution from ductile rupturing of metal ligaments during crack propagation.

This composite has been successfully tested in very high temperature (> 2700 °C, or 4900 °F), short time applications in rocket engines. These results derive from the highly refractory nature of the ZrB_2 and ZrC phases and the excellent thermal shock resistance of the composite. Longer-term structural applications at high temperatures may not be possible, because of the limited resistance of these materials to high-temperature oxidation and creep.

This composite is also being evaluated for applications in prosthetic devices based on its strength, fracture toughness, wear resistance, and biocompatibility. Mechanical seals and other special wear parts are additional promising application areas for these materials.

Space Shuttle Thermal Protection System

A key to the success of the space shuttle orbiter is the development of a fully reusable thermal protection system (TPS) capable of being used for up to 100 missions. The key element of the TPS is the thousands of ceramic tiles that protect the shuttle during reentry. Figure 11 shows the orbiter and the temperatures reached during reentry in a typical trajectory. During reentry of the shuttle into the earth's atmosphere, its surface reaches 1260 °C (2300 °F) where the ceramic tiles are used. Even hotter regions (up to 1650 °C, or 3000 °F) occur at the nose tip and the wing leading edges, where reinforced carbon-carbon (RCC) composites must be employed. Figure 12 indicates the materials chosen for various areas of the TPS.

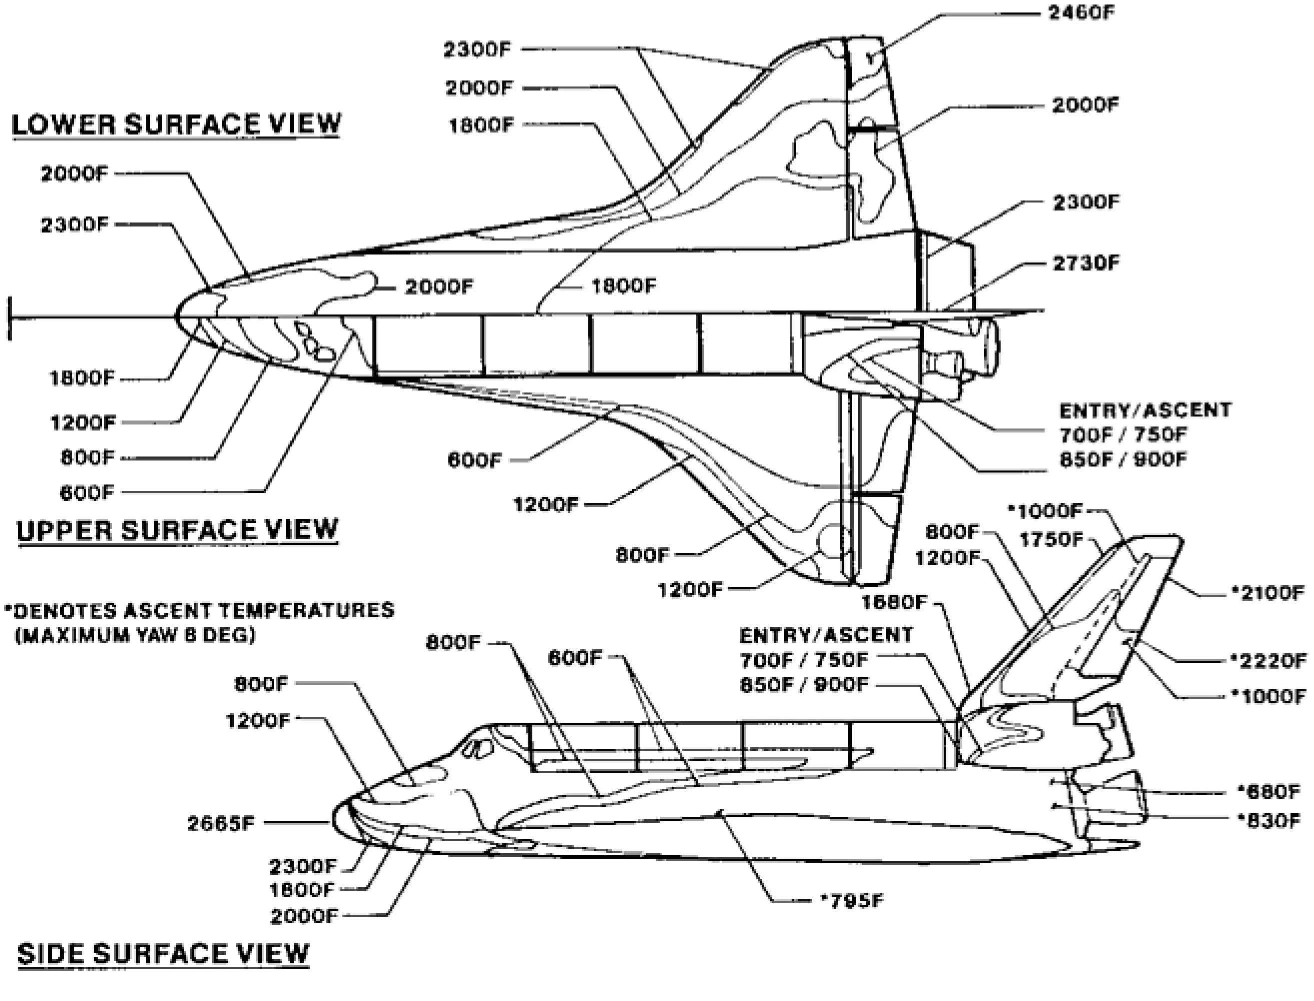

Fig. 11 Space shuttle orbiter isotherms for a typical trajectory. Source: Ref 22

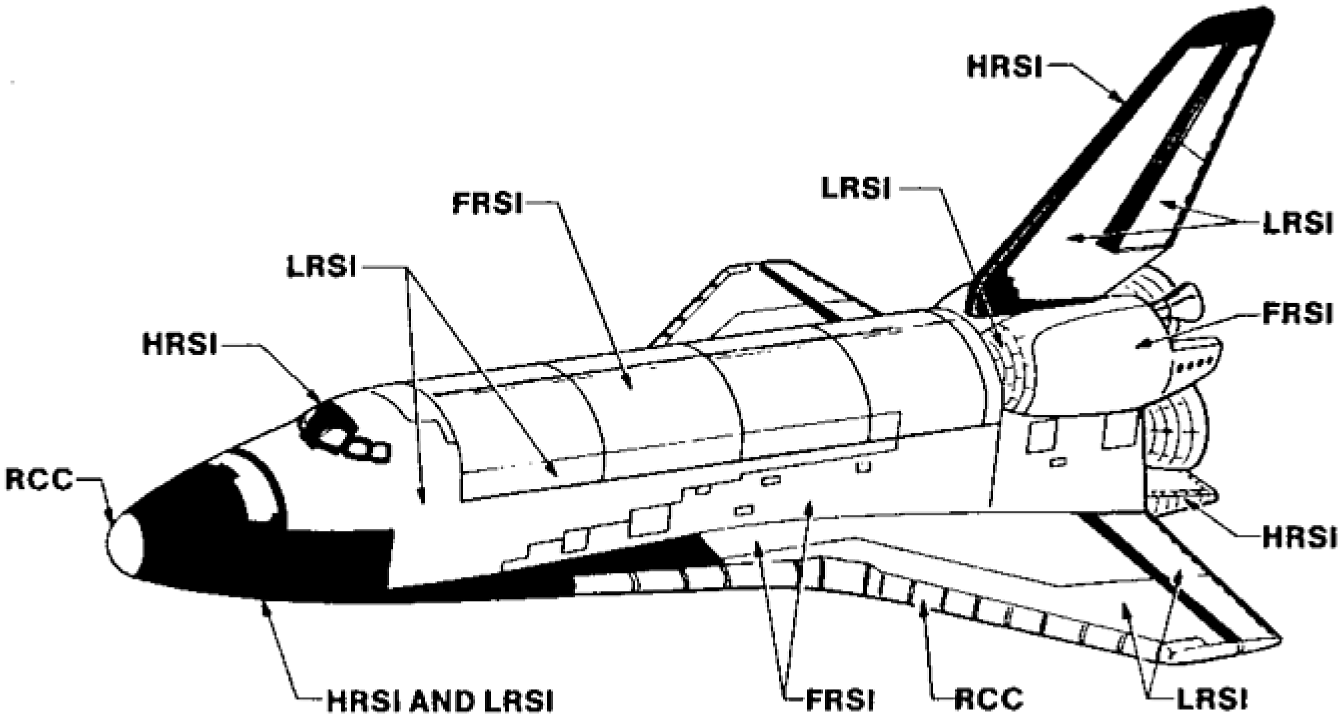

Material generic name	**Material temperature capability, °C (°F)[a]**	**Material composition**	Areas of orbiter
Reinforced carbon-carbon (RCC)	to 1650 (3000)	Pyrolized carbon-carbon, coated with SiC	**Nose cone, wing leading edges, forward external tank separation panel**
High-temperature reusable surface insulation (HRSI)	650–1260 (1200–2300)	SiO_2 tiles, borosilicate glass coating with SiB_4 added	**Lower surfaces and sides, tail leading and trailing edges, tiles behind RCC**
Low-temperature reusable surface insulation (LRSI)	400–650 (750–1200)	SiO_2 tiles, borosilicate glass coating	**Upper wing surfaces, tail surfaces, upper vehicle sides, OMS[b] pods**
Felt reusable surface insulation (FRSI)	**to 400 (750)**	**Nylon felt, silicone rubber coating**	**Wing upper surface, upper sides, cargo bay doors, sides of OMS[b] pods**

(a) 100 missions; higher temperatures are acceptable for a single mission.
(b) Orbital maneuvering system (OMS) engines

Fig. 12 Thermal protection system materials for the U.S. space shuttle. More than 30,000 ceramic tiles are included in the system. Other materials making up the system are reinforced carbon-carbon composites (44 panels and the nose cap) and 333 m^2 (3581 ft^2) of felt reusable surface insulation. Source: Ref 12 Source: Ref 22

The basic tile system is composed of four key elements: a ceramic tile, a nylon felt mounting pad, a filler bar, and a room-temperature vulcanizing (RTV) silicone adhesive. The tile, coated with a high emittance layer of glass, functions as both radiator (to dissipate heat) and insulator (to block heating to the structure). The felt mounting pad, called a strain isolator pad (SIP), isolates the tile from the thermal and mechanical strains of the substructure. The filler bar, also a nylon felt material coated with silicone rubber, protects the structure under the tile- to-tile gap from overheating. The RTV adhesive bonds the tile to the SIP and the SIP and filler bar to the substructure (Fig. 13). The substructure (tile substrate) consists of aluminum alloys or graphite-epoxy composites. More detailed information on the tile system can be found in Ref 22.

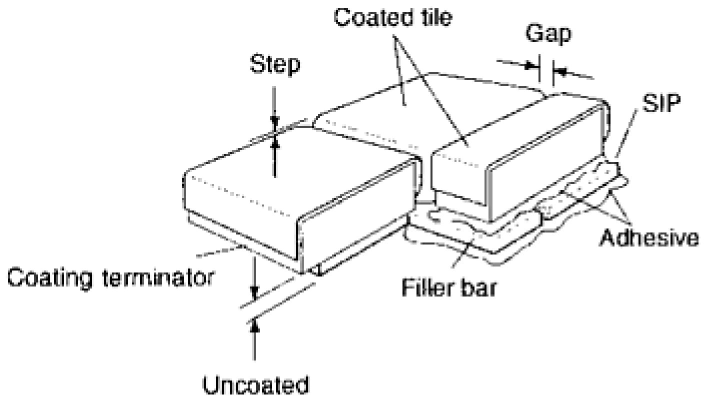

Fig. 13 The silica-silica tile thermal protection system configuration. SIP, strain isolator pad. Source: Ref 22

The ceramic tiles are made from very-high- purity amorphous silica fibers ~1.2 to 4 μm in diameter and 0.32 cm (0.125 in.) long, which are felted from a slurry and pressed and sintered at ~1370 °C (2500 °F) into blocks. Two tile densities are used: 144 kg/m^3 (9 lb/ft^3) (LI-900) and 352 kg/m^3 (22 lb/ft^3) (LI-2200). The LI-900 depends on a colloidal silica binder to achieve a fiber-to-fiber bond, whereas LI-2200 depends entirely on fiber-to-fiber sintering.

Most of the tiles are made from LI-900; however, in areas where higher strength is required, LI-2200 is used. All tiles have a borosilicate glass coating on five sides to provide the proper thermal properties. Those on the underside of the vehicle appear black because of the addition of silicon tetraboride for high emittance at high temperatures, whereas those on upper surfaces generally are white to limit on-orbit system temperature. The black tiles are usually a 15.2 by 15.2 cm (6 by 6 in.) square planform and typically 1.3 to 8.9 cm (0.5 to 3.5 in.) thick, as required. White tiles are generally a 20.3 by 20.3 cm (8 by 8 in.) square planform, 0.5 (0.2) to ~2.5 cm (1 in.) thick. There are special shapes or sizes—as small as ~4.4 cm (1.75 in.) square—as vehicle geometry dictates in some areas.

The silica tiles offer many advantages. The tile is 93% void; thus, it is an excellent insulator, having conductivities (through the thickness) as low as 0.017 to 0.052 W/m · K (0.01 to 0.03 Btu · ft/h · ft^2·°F). The low coefficient of expansion of amorphous silica, as well as the low modulus of the tile, eliminates thermal-stress and thermal- shock problems. Because of the very high purity (99.62%), devitrification is limited, avoiding the high stresses associated with the expansion or contraction of the crystalline phase (cristobalite). Silica has high temperature resistance; it is capable of exposure above 1480 °C (2700 °F) for a limited time. Since it is an oxide, further protection is unnecessary, whereas RCC and refractory metals must have oxidation-protective coatings. Oxidation of the silicon tetraboride in the coating results in boria and silica, the basic ingredients of the glass itself.

Heat-Resistant Industrial Applications

Another CMC processed by directed metal oxidation also using SiC particles in an Al_2O_3 matrix has been developed for high-temperature applications, such as furnace and heat exchanger components. These composites use very fine SiC particles (<10 μm), and the parent metal and processing conditions are selected to optimize high-temperature stability and mechanical characteristics. Elevated-temperature flexural strengths for three such composites are given in Fig. 14. Tests on similar composites have shown that these high-temperature strengths are unaffected by holding at temperatures at least up to 1500 °C (2730 °F) for a thousand hours or more. Prototype heat exchanger tubes and furnace components have been tested successfully, including a rig test of a burner tube involving temperature cycling to 1530 °C (2790 °F). Figure 15 shows examples of heat exchanger and furnace components made of this composite.

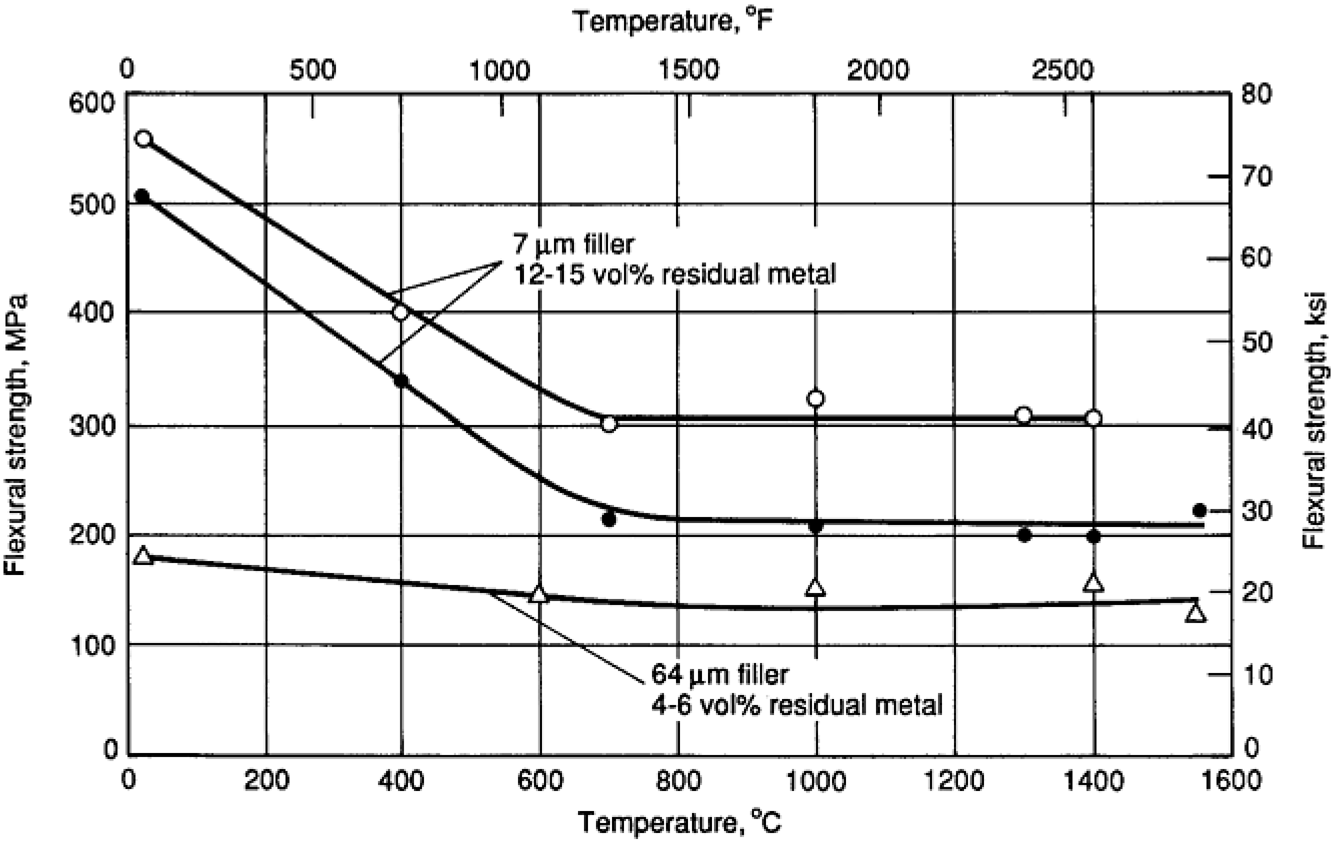

Fig. 14 Four-point flexural strengths of three SiC particle-filled Al_2O_3 matrix composites over a range of temperatures. The upper two curves represent processing differences using the same nominal filler particle size. Source: Ref 18

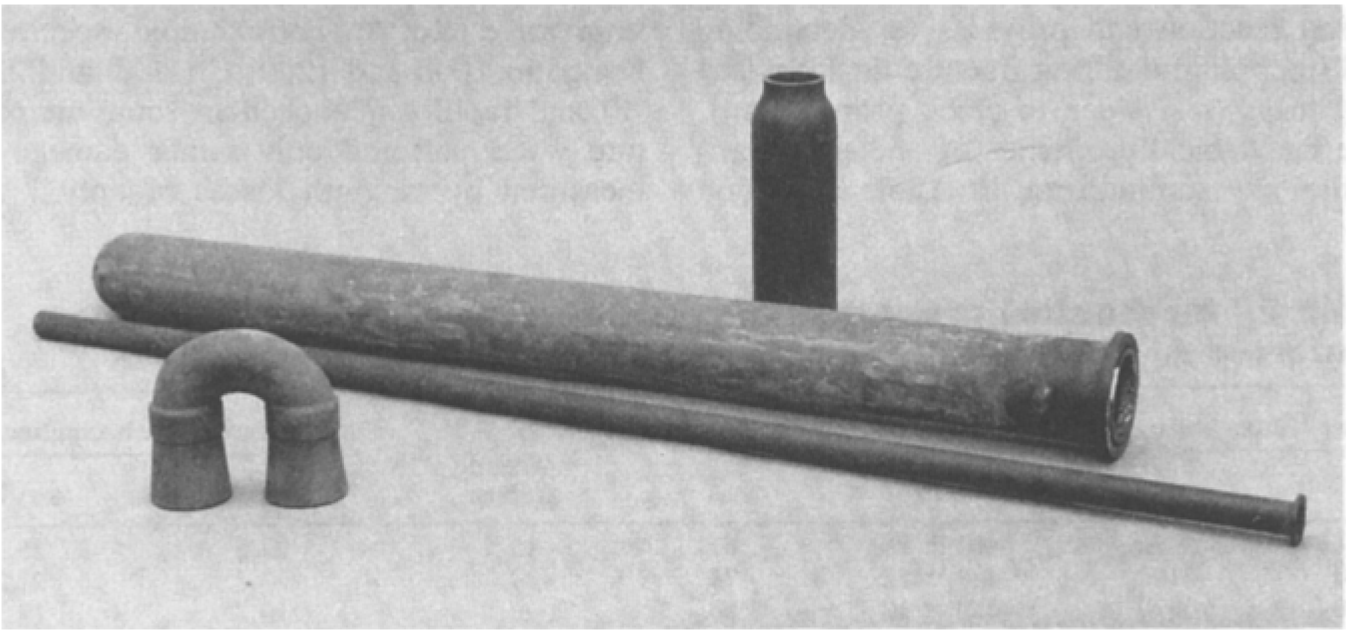

Fig. 15 Heat exchanger and furnace components made from an Al_2O_3-SiC_p composite. Source: Ref 18

Biomedical Applications

A number of ceramics have found use as a biomaterial for surgical implants. For example, monolithic Al_2O_3 is widely used in hip and dental implants, and calcium hydroxyapatite is applied as a coating for orthopedic prostheses. In terms of biocomposites, a number of polymer matrices reinforced with carbon fibers, glass fibers,

or tricalcium phosphate particulate have been studied. One example of a CMC biomedical application is the use of a polymer-reinforced glass-ceramic composite for use as a new bone substitute (Ref 23). Other ceramic-polymer combinations are also under consideration.

Applications of Ceramic-Matrix Composites

J.R. Davis, Davis & Associates

Applications for Continuous Fiber Ceramic Composites

Continuous fiber ceramic composites (CFCCs) are the most recently developed advanced ceramic. The continuous fibers in CFCCs overcome the brittle fracture problem associated with ceramics by providing increased fracture toughness (Fig. 16). The principal mechanisms that toughen CFCC components are:

- Deflection and bridging of cracks by the ceramic fibers
- Fiber pull-out from the ceramic matrix (Fiber pull-out is achieved by applying a coating to the fiber, allowing the fiber to be pulled out under stress.)

As the matrix cracks, the fibers continue to carry the load, thus avoiding the catastrophic behavior that is familiar in ceramic materials. Figure 17 compares the stress-strain behavior of monolithic ceramics and CFCCs.

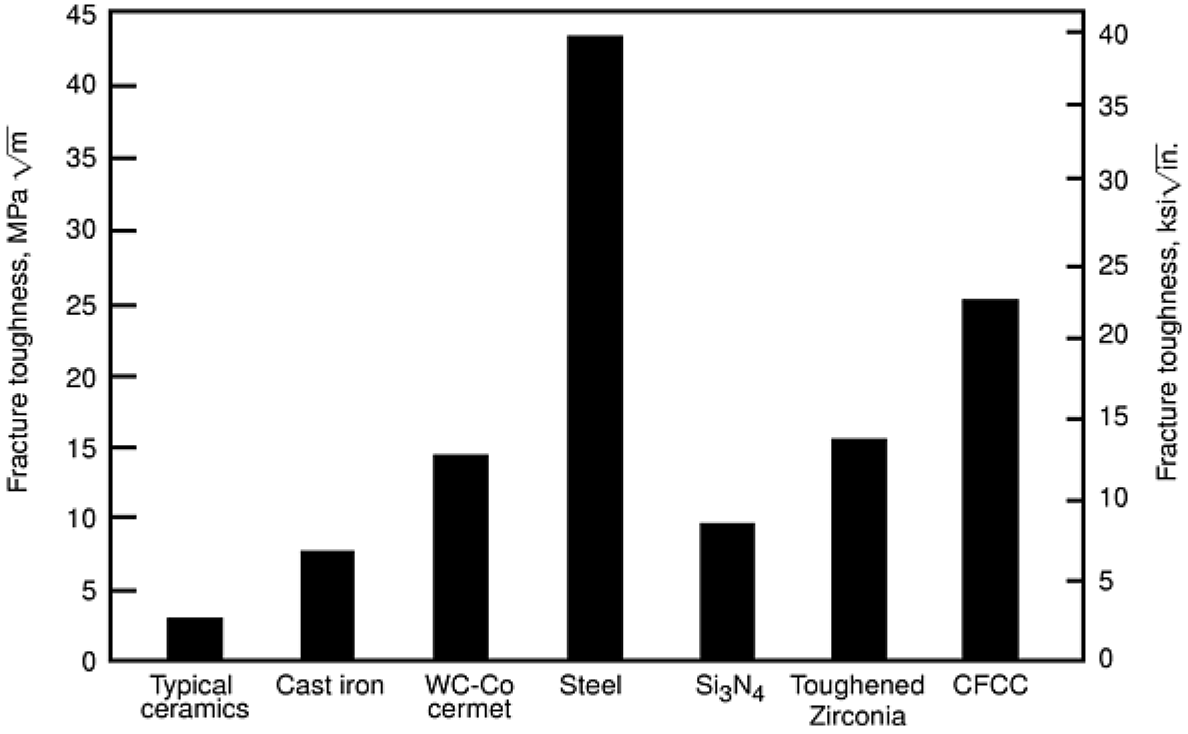

Fig. 16 Fracture toughness comparison for various materials, including CFCCs. Source: Ref 24

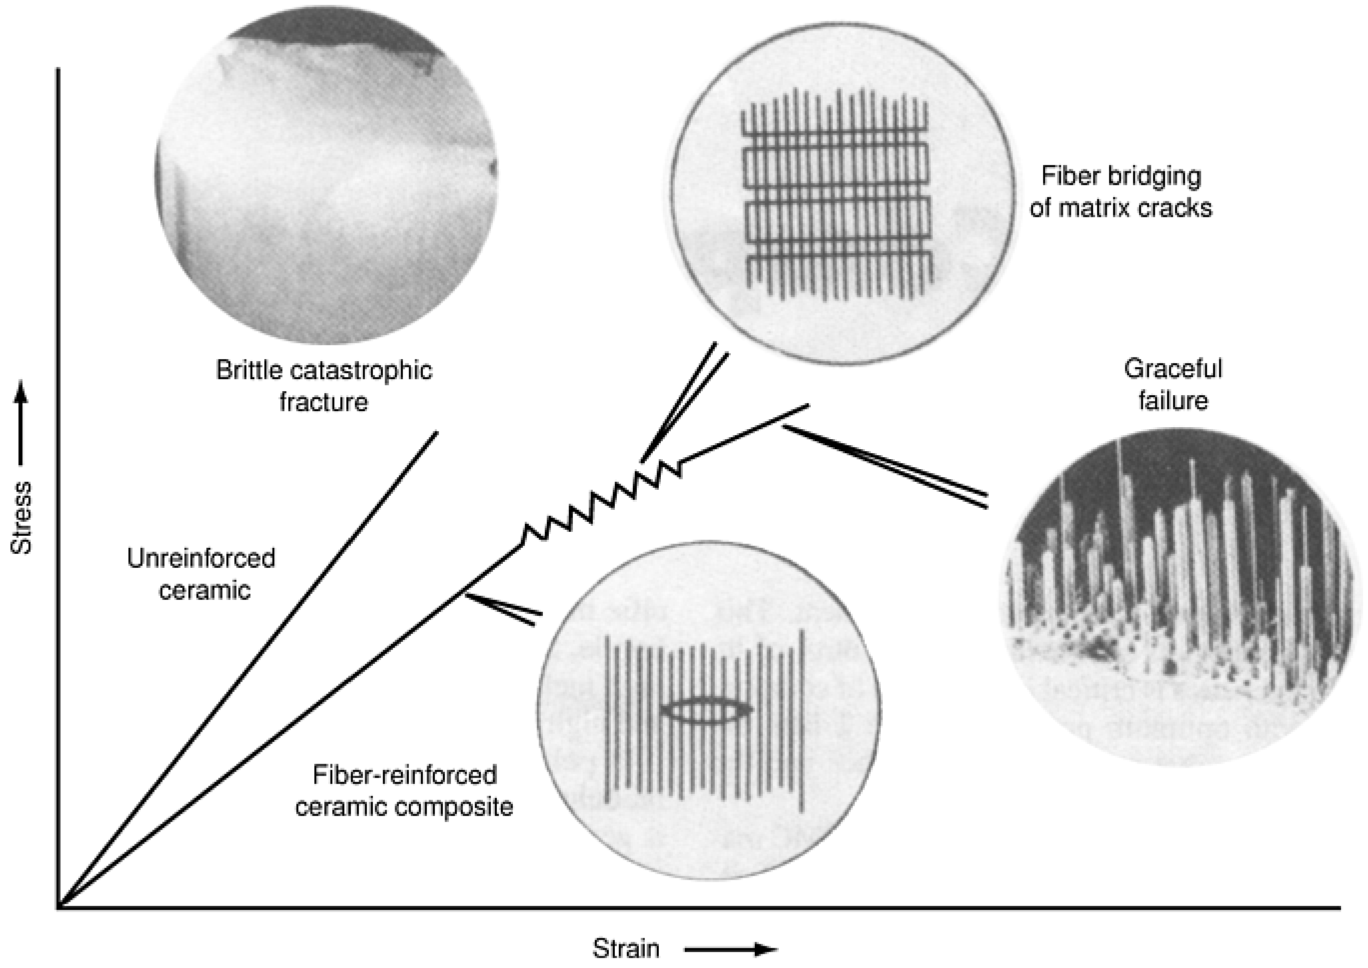

Fig. 17 Stress-strain behavior of reinforced and unreinforced ceramics. Fiber reinforcement of CMCs avoids the brittle catastrophic fracture characteristic of monolithic materials.

Processing. As shown in Table 2, CFCCs are processed by various methods, including chemical vapor infiltration (CVI), polymer impregnation pyrolysis (PIP), melt infiltration, reaction bonding (also referred to as “nitride bonding”), sol gel infiltration, slurry infiltration, directed metal oxidation, and a combination of cold isostatic pressing and hot isostatic pressing (CIP/ HIP). More detailed information on these methods can be found in the article “Processing of Ceramic-Matrix Composites” in this Volume.

Table 2 Examples of various CFCC materials and processes

Process	**Matrix**	Fiber
Chemical vapor infiltration (CVI)	SiC	**SiC, carbon**
Polymer impregnation pyrolysis (PIP)	SiC, SiOC, SiNC	**SiC**
Melt infiltration	SiC-Si	**SiC**
Reaction bonding	Nitride-bonded SiC	**SiC**
Sol gel	Mullite, Al_2O_3	**SiC, Al_2O_3**
Slurry infiltration	Aluminosilicates	**Al_2O_3**
Directed metal oxidation	Al_2O_3	**SiC, Al_2O_3**
CIP/HIP	**Si_3N_4**	**Carbon**

Source: Ref 25, 26

Matrix-Reinforcement Materials. The most common matrix materials for CFCCs are SiC, Al_2O_3, Si_3N_4, mullite, and aluminosilicates (see Table 2). The predominant fiber material is SiC, although Al_2O_3 and carbon fibers are also used. Fiber loadings are often high, on the order of 35 to 50 vol%.

Property ranges typical for CFCCs are listed in Table 3. Additional property data can be found in the article “Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites” in this Volume.

Table 3 Property ranges typical of CFCCs

Property	Range
Density, g/cm^3	**2.1–3.1**
Open porosity, %	**0–20**
Tensile properties	
Strength, MPa (ksi)	**250–400 (35–60)**
Modulus, GPa (10^6 psi)	**90–250 (13–36)**
Strain-to-failure, %	**0.4–0.8**
Flexure properties	
Strength, MPa (ksi)	**200–480 (29–70)**
Modulus, GPa (10^6 psi)	**83–240 (12–35)**
Compressive strength, MPa (ksi)	**450–1100 (65–160)**
Shear strength, MPa (ksi)	**28–68 (4–10)**
Room-temperature thermal conductivity, W/m · K	**1–40**

Source: Ref 26

Application Examples. The high-temperature stability, corrosion resistance, and toughness of CFCCs make them suitable for a wide range of applications in both the aerospace and industrial sectors. Many of the subsequent applications surveyed were brought about by The Continuous Fiber Ceramic Composite (CFCC) Program supported by the Department of Energy (DOE) Office of Industrial Technologies (OIT). This was a collaborative effort between industry, national laboratories, universities, and the U.S. government. A summary of this program can be found on the internet at http://www.oit.doe.gov/ cfcc/. Examples of potential applications for CMCs include (Ref 25, 26 , and 27):

- *Turbine engine components:* combustor liners, shrouds, seals, vanes, blades, and other parts used in gas turbines, including utility, industrial, and aeronautical engine applications. Both SiC-SiC and Al_2O_3-SiC composites are under development for such applications. Various processing methods, including melt infiltration, CVI, PIP, and directed metal oxidation, are used to produce these components.
- *Radiant burner screens:* SiC-SiC reverberatory screens for natural gas burners are being produced by CVI. These burners are used in industrial applications, such as paper or paint drying, chemical

processing, metal treating, and glass forming. The single-layer porous mesh screen is mounted directly above the burner surface.

- *Immersion heater tubes:* SiC-SiC composite burner tubes (Fig. 18) have been developed for melting aluminum in casting foundries. The CFCC is not wetted or chemically attacked by the molten aluminum. The processing approach involves the application of a water-based ceramic slurry onto a mandrel that is filament wound with SiC fiber. The green preform is nitride bonded (thermally treated in a nitrogen atmosphere), which results in a material composed of SiC fibers in a matrix of SiC and Si_3N_4.
- *Hot gas filters:* Al_2O_3-Al_2O_3 composites are being evaluated for use as hot gas filters in advanced coal-fired energy applications. Removing coal-ash particles from the exhaust gas of a coal-fired pressurized fluidized-bed combustor protects the downstream equipment, such as gas turbine engines, from damage, enabling the generation of energy with reduced emissions and with higher efficiency. Sol gel and slurry infiltration methods are used to produce these filters.
- *Turbine disks for rocket engines:* Integrally bladed disks ("blisks") for rocket engine turbopumps have been produced from carbon- fiber-reinforced SiC. Figure 19 shows the Fastrac engine developed by the National Aeronautics and Space Administration (NASA) and the locations of the turbopump and blisk. The blisks were produced by CVI of a woven preform, which was subsequently machined and thermally treated to complete densification. Figure 20 shows the final turbopump assembly.

Other potential applications for CFCCs include heat exchanger tubes, armor, pipe hangers for petroleum refining, submersible pump housings for chemical processing, parts for ethylene cracking reformers, parts exposed to methyl chloride and dimethylchlorosilane, heat treating furnace fans, hot particle separators in municipal waste incinerators, and low-heat-rejection diesel engine exhaust valve guides that are self-lubricating.

Glossary of Terms

A

A-basis
: The "A" mechanical property value is the value above which at least 99% of the population of values is expected to fall, with a confidence of 95%. Also called A-allowable. See also B-basis, S-basis, and typical-basis.

abhesive
: A material that resists adhesion. A film or coating applied to surfaces to prevent sticking, heat sealing, and so on, such as a parting agent or mold release agent.

ablation
: The degradation, decomposition, and erosion of a material caused by high temperature, pressure, time, percent oxidizing species, and velocity of gas flow. A controlled loss of material to protect the underlying structure.

ablative plastic
: A material that absorbs heat (with a low material loss and char rate) through a decomposition process (pyrolysis) that takes place at or near the surface exposed to the heat.

abrasive waterjet
: Similar to a conventional water jet except that a fine grit (usually garnet) is mixed into the high-pressure water stream. Useful for cutting cured organic-matrix and metal-matrix composite materials. The main cutting action is an accelerated erosion process.

absorption
: (1) The penetration into the mass of one substance by another. (2) The process whereby energy is dissipated within a specimen placed in a field of radiant energy. (3) The capillary or cellular attraction of adherend surfaces to draw off the liquid adhesive film into the substrate.

accelerated test
: A test procedure in which conditions are increased in magnitude to reduce the time required to obtain a result. To reproduce in a short time the deteriorating effect obtained under normal service conditions.

accelerator
: A material that, when mixed with a catalyst or a resin, speeds up the chemical reaction between the catalyst and the resin (either in the polymerizing of resins or vulcanization of rubbers). Also called promoter.

accuracy
: The agreement of an experimental or calculated value to an accepted recognized standard or specified value. Compare with precision.

acoustic emission
: A measure of integrity of a material, as determined by sound emission when a material is stressed. Ideally, emissions can be correlated with defects and/or incipient failure.

acrylic plastic
: A thermoplastic polymer made by the polymerization of esters of acrylic acid and its derivatives. Its full name is polymethyl methacrylate. See also polymethyl methacrylate.

activation
: The (usually) chemical process of making a surface more receptive to bonding to a coating or an encapsulating material.

activator
: See accelerator.

addition polymerization
: A chemical reaction in which simple molecules (monomers) are added to each other to form long-chain molecules (polymers) without forming by-products.

additive

Any substance added to another substance, usually to improve properties, such as plasticizers, initiators, light stabilizers, and flame retardants. See also filler.

adherend

A body that is held to another body, usually by an adhesive. A detail or part prepared for bonding.

adhesion

The state in which two surfaces are held together at an interface by mechanical or chemical forces, interlocking action, or both.

adhesion, mechanical

See mechanical adhesion.

adhesion promoter

A coating applied to a substrate, before it is coated with an adhesive, to improve the adhesion of the plastic. Also called primer.

adhesive

A substance capable of holding two materials together by surface attachment. Adhesive can be in film, liquid, or paste form.

adhesive, anaerobic

See anaerobic adhesive.

adhesive assembly

A group of materials or parts, including adhesive, that are placed together for bonding or that have been bonded together.

adhesive bonding

A materials joining process in which an adhesive, placed between facing surfaces, solidifies to bond the surfaces together.

adhesive, cold-setting

See cold-setting adhesive.

adhesive, contact

See contact adhesive.

adhesive failure

Rupture of an adhesive bond such that the separation appears to be at the adhesive-adherend interface.

adhesive film

A synthetic resin adhesive, with or without a film carrier fabric, usually of the thermosetting type, in the form of a thin film of resin, used under heat and pressure as an interleaf in the production of bonded structures.

adhesive, gap-filling

See gap-filling adhesive.

adhesive, heat-activated

See heat-activated adhesive.

adhesive, heat-sealing

See heat-sealing adhesive.

adhesive, hot-melt

See hot-melt adhesive.

adhesive, hot-setting

See hot-setting adhesive.

adhesive, intermediate temperature setting

See intermediate temperature setting adhesive.

adhesive joint

The location at which two adherends or substrates are held together with a layer of adhesive. The general area of contact for a bonded structure.

adhesive, pressure-sensitive

See pressure-sensitive adhesive.

adhesive strength

Strength of the bond between an adhesive and an adherend.

adhesive, structural

See structural adhesive.

admixture

The addition and homogeneous dispersion of discrete components, before cure.

adsorption

(1) The adhesion of the molecules of gases, dissolved substances, or liquids in more or less concentrated form, to the surfaces of solids or liquids with which they are in contact. (2) A concentration of a substance at a surface or interface of another substance.

advanced ceramics

Ceramic materials that exhibit superior mechanical properties, corrosion/oxidation resistance, or electrical, optical, and/or magnetic properties. This term includes many monolithic ceramics as well as particulate-, whisker-, and fiber-reinforced glass, glass-ceramics, and ceramic-matrix composites. Also known as engineering, fine, or technical ceramics.

advanced composites

Composite materials that are reinforced with continuous fibers having a modulus higher than that of fiberglass fibers. The term includes metal-matrix and ceramic- matrix composites, as well as carbon-carbon composites.

afterbrake

See postcure.

aggregate

A hard, coarse material usually of mineral origin used with an epoxy binder (or other resin) in plastic tools. Also used in flooring or as a surface medium.

aging

(1) The effect on materials of exposure to an environment for an interval of time. (2) The process of exposing materials to an environment for an interval of time.

air-bubble void

Air entrapment within and between the plies of reinforcement or within a bondline or encapsulated area; localized, noninterconnected, spherical in shape.

air vent

Small outlet to prevent entrapment of gases in a molding or tooling fixture.

alkyd plastic

Thermoset plastic based on resins composed principally of polymeric esters, in which the recurring ester groups are an integral part of the main polymer chain, and in which ester groups occur in most cross links that may be present between chains.

allotropy

The existence of a substance, especially an element, in two or more forms (for example, crystals). See also graphite.

alloy

(1) In plastics, a blend of polymers or copolymers with other polymers or elastomers under selected conditions; for example, styrene-acrylonitrile. Also called polymer blend. (2) In metals, a substance having metallic properties and being composed of two or more chemical elements of which at least one is a metal.

allyl plastic

A thermoset plastic based on resins made by addition polymerization of monomers containing allyl groups; for example, diallyl phthalate (DAP).

alternating stress

A stress varying between two maximum values that are equal but with opposite signs, according to a law determined in terms of the time.

alternating stress amplitude

A test parameter of a dynamic fatigue test; one-half the algebraic difference between the maximum and minimum stress in one cycle.

ambient

The surrounding environmental conditions, such as pressure, temperature, or relative humidity.

amorphous plastic (amorphous phase)

A plastic that has no crystalline component. There is no order or pattern to the distribution of the molecules.

anaerobic adhesive

An adhesive that cures only in the absence of air after being confined between assembled parts.

anelasticity

A characteristic exhibited by certain materials in which strain is a function of both stress and time, such that while no permanent deformations are involved, a finite time is required to establish equilibrium between stress and strain in both the loading and unloading directions.

angle-ply laminate

A laminate having fibers of adjacent plies, oriented at alternating angles.

angle wrap

Tape fabric wrapped on a starter dam mandrel at an angle to the centerline.

anisotropic

Not isotropic. Exhibiting different properties when tested along axes in different directions. See also anisotropy of laminates.

anisotropic laminate

One in which the properties are different in different directions.

anisotropy of laminates

The difference of the properties along the directions parallel to the length or width of the lamination planes and perpendicular to the lamination.

annealing

In plastics, heating to a temperature at which the molecules have significant mobility, permitting them to reorient to a configuration having less residual stress.

antioxidant

A substance that, when added in small quantities to the resin during mixing, prevents its oxidative degradation and contributes to the maintenance of its properties.

antistatic agents

Agents that, when added to a molding material or applied to the surface of the molded object, make it less conductive, thus hindering the fixation of dust or the buildup of electrical charge.

aramid

A type of highly oriented organic material derived from polyamide (nylon) but incorporating aromatic ring structure. Used primarily as a high-strength, high-modulus fiber. Kevlar and Nomex (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) are examples of aramids.

arc resistance

Ability to withstand exposure to an electric voltage. The total time in seconds that an intermittent arc may play across a plastic surface without rendering the surface conductive.

areal weight

The weight of fiber per unit area (width × length) of tape or fabric.

aromatic

Unsaturated hydrocarbon with one or more benzene ring structures in the molecule.

artificial weathering

The exposure of plastics to cyclic laboratory conditions, consisting of high and low temperatures, high and low relative humidities, and ultraviolet radiant energy, with or without direct water spray and moving air (wind), in an attempt to produce changes in their properties similar to those observed in long-term continuous exposure outdoors. The laboratory exposure conditions are usually intensified beyond those encountered in actual outdoor exposure in an attempt to achieve an accelerated effect. Also called accelerated aging.

ash content

Proportion of the solid residue remaining after a reinforcing substance has been incinerated (charred or intensely heated).

aspect ratio

(1) In essentially two-dimensional rectangular structures such as panels, the ratio of the long dimension to the short dimension. (2) In compressive loading, the ratio of the dimension in the load direction to the dimension in the transverse direction. (3) In fiber micromechanics, the ratio of length to diameter.

assembly time

The time interval between the spreading of the adhesive on the adherend and the application of pressure and/or heat to the assembly.

A-stage

An early stage in the preparation of certain thermosetting resins in which the material is still soluble in certain liquids, and may be liquid or capable of becoming liquid upon heating. See also B-stage and C-stage.

attenuation

The diminution of vibrations or energy over time or distance. The process of making thin and slender, as applied to the formation of fiber from molten glass.

autoclave

A closed vessel for conducting and completing a chemical reaction or other operation, such as cooling, under pressure and with or without heat.

autoclave molding

A process in which, after lay-up, winding, or wrapping, an entire assembly is placed in a heated autoclave, usually at 340 to 1380 kPa (50 to 200 psi). Additional pressure permits higher density and improved removal of volatiles from the resin. Lay-up is usually vacuum bagged with a bleeder and release cloth.

automated tape laying

A fabrication process in which prepreg material, typically unidirectional tape, is laid across the surface of a mold in multiple layers and directions by an automated tape-application machine to form a structure.

automatic mold

A mold for injection or compression molding that repeatedly goes through the entire cycle, including ejection, without human assistance.

automatic press

A hydraulic press for compression molding or an injection machine that operates continuously, being controlled mechanically, electrically, hydraulically, or by a combination of any of these methods.

axial strain

The linear strain in a plane parallel to the longitudinal axis of the specimen.

axial winding

In filament-wound reinforced plastics, a winding with the filaments parallel to, or at a small angle to, the axis (0° helix angle). See also polar winding.

B

back pressure

Resistance of a material, because of its viscosity, to continued flow when mold is closing.

bagging

Applying an impermeable layer of film over an uncured part and sealing the edges so that a vacuum can be drawn.

bag molding

A method of molding or laminating that involves the application of fluid pressure, usually by means of air, steam, water, or vacuum, to a flexible barrier material that transmits the pressure to the material being molded or bonded.

bag side

The side of the part that is cured against the vacuum bag.

balanced construction

Equal parts of warp and fill in fiber fabric. Construction in which reactions to tension and compression loads result in extension or compression deformations only and in which flexural loads produce pure bending of equal magnitude in axial and lateral directions.

balanced design

In filament-wound reinforced plastics, a winding pattern so designed that the stresses in all filaments are equal.

balanced in-plane contour

In a filament- wound part, a head contour in which the filaments are oriented within a plane and the radii of curvature are adjusted to balance the stresses along the filaments with the pressure loading.

balanced laminate

A composite laminate in which all laminae at angles other than 0° and 90° occur only in ± pairs (not necessarily adjacent). See also symmetrical laminate.

balanced twist

An arrangement of twists in a combination of two or more strands that does not cause kinking or twisting on themselves when the yarn produced is held in the form of an open loop.

band density

In filament winding, the quantity of fiberglass reinforcement per inch of band width, expressed as strands (or filaments) per inch.

band thickness

In filament winding, the thickness of the reinforcement as it is applied to the mandrel.

band width

In filament winding, the width of the reinforcement as it is applied to the mandrel.

Barcol hardness

A hardness value obtained by measuring the resistance to penetration of a sharp steel point under a spring load. The instrument, called the Barcol impressor, gives a direct reading on a 0 to 100 scale. The hardness value is often used as a measure of the degree of cure of a plastic.

bare glass

Glass, such as yarns, rovings, and fabrics, from which the sizing or finish has been removed. Also, such glass before the application of sizing or finish.

barrier coat

An exterior coating applied to a composite wound structure to provide protection.

barrier film

The layer of film used during cure to permit removal of air and volatiles from a composite lay-up while minimizing resin loss.

barrier plastics

A general term applied to a group of lightweight, transparent, impact-resistant plastics, usually rigid copolymers of high acrylonitrile content. Barrier plastics are generally characterized by gas, aroma, and flavor barrier characteristics approaching those of metal and glass.

batch

In general, a quantity of materials formed during the same process or in one continuous process and having identical characteristics throughout. Also called a lot.

batt

Felted fabrics. Structures built by the interlocking action of compressing fibers, without spinning, weaving, or knitting.

B-basis

The “B” mechanical property value is the value above which at least 90% of the population of values is expected to fall, with a confidence of 95%. See also A-basis, S-basis, and typical-basis.

bearing area

The diameter of the hole times the thickness of the material. The cross-section area of the bearing load member on the sample.

bearing strain

The ratio of the deformation of the bearing hole, in the direction of the applied force, to the pin diameter. Also, the stretch or deformation strain for a sample under bearing load.

bearing strength

The maximum bearing stress that can be sustained. Also, the bearing stress at that point on the stress-strain curve where the tangent is equal to the bearing stress divided by *n*% of the bearing hole diameter.

bearing stress

The applied load in pounds divided by the bearing area. Maximum bearing stress is the maximum load in pounds sustained by the specimen during the test, divided by the original bearing area.

bending-twisting coupling

A property of certain classes of laminates that exhibit twisting curvatures when subjected to bending moments.

bias fabric

Warp and fill fibers at an angle to the length of the fabric.

biaxial load

A loading condition in which a laminate is stressed in two different directions in its plane. A loading condition of a pressure vessel under internal pressure and with unrestrained ends.

biaxial winding

In filament winding, a type of winding in which the helical band is laid in sequence, side by side, with crossover of the fibers eliminated.

bidirectional laminate

A reinforced plastic laminate with the fibers oriented in two directions in its plane. A cross laminate. See also unidirectional laminate.

binder

The resin or cementing constituent (of a plastic compound) that holds the other components together. The agent applied to fiber mat or preforms to bond the fibers before laminating or molding.

bismaleimide (BMI)

A type of polyimide that cures by an addition rather than a condensation reaction, thus avoiding problems with volatiles formation, and which is produced by a vinyl-type polymerization of a prepolymer terminated with two maleimide groups. Intermediate in temperature capability between epoxy and polyimide.

bisphenol “A.”

A condensation product formed by the reaction of two molecules of phenol with acetone. This polyhydric phenol is the standard intermediate resin that is reacted with epichlorohydrin in the production of epoxy resins.

bladder

An elastomeric lining for the containment of hydroproof or hydroburst pressurization medium in filament-wound structures.

blanket

Fiber or fabric plies that have been laid up in a complete assembly and placed on or in the mold all at one time (flexible bag process). Also, the type of bag in which the edges are sealed against the mold.

bleeder cloth

A woven or nonwoven layer of material used in the manufacture of composite parts to allow the escape of excess gas and resin during cure. The bleeder cloth is removed after the curing process and is not part of the final composite.

bleeding

The removal of excess resin from a laminate during cure. The diffusion of color out of a plastic part into the surrounding surface or part.

bleedout

The excess liquid resin that migrates to the surface of a winding. Primarily occurs in filament winding.

blister

An imperfection, a rounded elevation of the surface of a plastic, with boundaries that may be more or less sharply defined, somewhat resembling in shape a blister on the human skin.

bloom

A visible local exudation or finish change on the surface of a plastic. Bloom can be caused by a lubricant or plasticizer or by atmospheric contamination.

BMC

See bulk molding compound.

BMI

See bismaleimide.

body putty

A pastelike mixture of plastic resin (polyester or epoxy) and talc used in repair of metal surfaces, such as auto bodies.

bond

To unite materials by means of an adhesive.

bond line

The layer of adhesive that attaches two adherends.

bond strength

The unit load applied to tension, compression, flexure, peel, impact, cleavage, or shear required to break an adhesive assembly with failure occurring in or near the plane of the bond.

boron fiber

A fiber produced by vapor deposition of elemental boron, usually onto a tungsten filament core, to impart strength and stiffness.

boss

See polar boss.

braid

A system of three or more yarns that are interwoven in such a way that no two yarns are twisted around each other.

braiding

(1) Weaving of fibers into a tubular shape instead of a flat fabric, as for graphite- fiber-reinforced golf club shafts. (2) Textile process where two or more strands, yarns, or tapes are intertwined in the bias direction to form an integral structure.

branched polymer

In molecular structure of polymers, a main chain with attached side chains, in contrast to a linear polymer.

breaking extension

The elongation necessary to cause rupture of a test specimen. The tensile strain at the moment of rupture.

breaking factor

The breaking load divided by the original width of a test specimen, expressed in lb/in.

breaking length

A measure of the breaking strength of yarn. The length of a specimen whose weight is equal to the breaking load.

breakout

Fiber separation or break on surface plies at drilled or machined edges.

breather

A loosely woven material that serves as a continuous vacuum path over a part but is not in contact with the resin.

breathing

The opening and closing of a mold to allow gas to escape early in the molding cycle. Also called degassing; sometimes called bumping, in phenolic molding.

bridging

(1) Condition in which fibers do not move into or conform to radii and corners during molding, resulting in voids and dimensional control problems. (2) In the fracture mechanics of composites, the toughening mechanism of the reinforcing fibers behind the crack tip, before these fibers fail.

broad goods

Fiber woven to form fabric up to 1270 mm (50 in.) wide. It may or may not be impregnated with resin and is usually furnished in rolls of 25 to 140 kg (50 to 300 lb).

B-stage

An intermediate stage in the reaction of certain thermosetting resins in which the material softens when heated and is plastic and fusible but may not entirely dissolve or fuse. Also called resistol. The resin in an uncured prepreg or premix is usually in this stage. See also A-stage and C-stage.

buckling (composite)

A mode of failure generally characterized by an unstable lateral material deflection due to compressive action on the structural element involved.

bulk density

The density of a molding material in loose form (granular, nodular, and so forth), expressed as a ratio of weight to volume.

bulk factor

The ratio of the volume of a raw molding compound or powdered plastic to the volume of the finished solid piece produced therefrom. The ratio of the density of the solid plastic object to the apparent or bulk density of the loose molding powder.

bulk modulus

The ratio of the hydrostatic pressure to the volume strain.

bulk molding compound (BMC)

Thermosetting resin mixed with strand reinforcement, fillers, and so on, into a viscous compound for compression or injection molding. See also premix and sheet molding compound.

bundle

A general term for a collection of essentially parallel filaments or fibers.

burned

Showing evidence of thermal decomposition or charring through some discoloration, distortion, destruction, or conversion of the surface of the plastic, sometimes to a carbonaceous char.

burst strength (bursting strength)

Measure of the ability of a material to withstand internal hydrostatic or gas dynamic pressure without rupture. Hydraulic pressure required to burst a vessel of given thickness.

bushing

(1) An electrically heated alloy container encased in insulating material, used for melting and feeding glass in the forming of individual fibers or filaments. (2) A special extraheavy load-carrying short cylinder inserted in bolt or pin holes.

butt joint

A type of edge joint in which the edge faces of the two adherends are at right angles to the other faces of the adherends.

C

calender

To produce a smooth finish and a desired dimensional thickness for sheet material by passing it between sets of pressure rollers.

carbon

The element that provides the backbone for all organic polymers. Graphite is a more ordered form of carbon. Diamond is the densest crystalline form of carbon.

carbon-carbon

A composite material consisting of carbon or graphite fibers in a carbon or graphite matrix.

carbon fiber

Fiber produced by the pyrolysis of organic precursor fibers, such as rayon, polyacrylonitrile (PAN), and pitch, in an inert environment. The term is often used interchangeably with the term graphite; however, carbon fibers and graphite fibers differ. The basic differences lie in the temperature at which the fibers are made and heat treated, and in the amount of elemental carbon produced. Carbon fibers typically are carbonized in the region of 1315 °C (2400 °F) and assay at 93 to 95% carbon, while graphite fibers are graphitized at 1900 to 2480 °C (3450 to 4500 °F) and assay at more than 99% elemental carbon. See also pyrolysis (of fibers).

carbonization

The process of pyrolyzation in an inert atmosphere at temperatures ranging from 800 to 1600 °C (1470 to 2910 °F) and higher, usually at about 1315 °C (2400 °F). Range is influenced by precursor, individual manufacturer's process, and properties desired.

catalyst

(1) A substance that changes the rate of a chemical reaction without itself undergoing permanent change in composition or becoming a part of the molecular structure of the product. (2) A substance that markedly speeds up the cure of a compound when added in minor quantity, compared to the amounts of primary reactants. See also accelerator, curing agent, hardener, inhibitor, and promoter.

catastrophic failures

Totally unpredictable failures of a mechanical, thermal, or electrical nature.

catenary

(1) A measure of the difference in length of the strands in a specified length of roving as a result of unequal tension. (2) The tendency of some strands in a taut, horizontal roving to sag more than the others.

caul plates

Smooth metal plates, free of surface defects, the same size and shape as a composite lay-up, used immediately in contact with the lay-up during the curing process to transmit normal pressure and temperature, and to provide a smooth surface on the finished laminate.

cavity

(1) The space inside a mold in which a resin or molding compound is poured or injected. (2) The female portion of a mold. (3) That portion of the mold that encloses the molded article (often referred to as the die). Depending on the number of such depressions, molds are designated as single cavity or multiple cavity.

cell

In honeycomb core, a cell is a single honeycomb unit, usually in a hexagonal shape.

cell size

The diameter of an inscribed circle within a cell of honeycomb core.

cellular plastic

A plastic containing numerous cells, interconnecting or not, distributed throughout the mass. Also called expanded plastic or foamed plastic.

ceramic

A rigid, frequently brittle material made from clay and other inorganic, nonmetallic substances and fabricated into articles by sintering, that is, cold molding followed by fusion of the part at high temperature.

ceramic-matrix composites

Advanced composites that consist of fibers or whiskers in a ceramic matrix. Typical reinforcing materials include carbon fibers and silicon carbide fibers or whiskers. Matrix materials commonly used are glass, glass-ceramics, alumina, and silicon nitride. Ceramic-matrix composites are resistant to both oxidation and wear. See also continuous fiber ceramic composite, discontinuous fiber-reinforced composite, and particulate reinforced ceramic-matrix composite.

cermet

Composite materials consisting of two constituents, one being either an oxide, carbide, boride, or similar inorganic compound, and the other a metallic binder.

CFCC

See continuous fiber ceramic composite.

C-glass

A glass with a soda-lime-borosilicate composition that is used for its chemical stability in corrosive environments.

chain length

The length of the stretched linear macromolecule, most often expressed by the number of identical links.

chalking

Dry, chalklike appearance of deposit on the surface of a plastic.

Charpy impact test

A test for shock loading in which a centrally notched sample bar is held at both ends and broken by striking the back face in the same plane as the notch.

charring

The heating of a composite in air to reduce the polymer matrix to ash, allowing the fiber content to be determined by weight.

chemical vapor deposited (CVD) carbon

Carbon deposited on a substrate by pyrolysis of a hydrocarbon, such as methane.

chemical vapor deposition (CVD)

Process used in manufacture of several composite reinforcements, especially boron and silicon carbide, in which desired reinforcement material is deposited from vapor phase onto a continuous core, for example, boron on tungsten wire (core).

chopped strand mat
A mat formed of strands cut to a short length, randomly distributed, without intentional orientation, and held together by a binder.

chopped strands
Short strands cut from continuous filament strands, not held together by any means.

circuit
In filament winding, one complete traverse of a winding band from one arbitrary point along the winding path to another point on a plane through the starting point and perpendicular to the axis.

circumferential (“circ”) winding
In filament- wound reinforced plastics, a winding with the filaments essentially perpendicular to the axis (90° or level winding).

clamping pressure
In injection molding and transfer molding, the pressure that is applied to the mold to keep it closed in opposition to the fluid pressure of the compressed molding material.

closure
The complete coverage of a mandrel with one layer (two plies) of fiber. When the last tape circuit that completes mandrel coverage lays down adjacent to the first without gaps or overlaps, the wind pattern is said to have “closed.”

cloth
See woven fabric and nonwoven fabric.

co-curing
The act of curing a composite laminate and simultaneously bonding it to some other prepared surface, or curing together an inner and outer tube of similar or dissimilar fiber-resin combination after each has been wound or wrapped separately. See also secondary bonding.

coefficient of elasticity
The reciprocal of Young's modulus in a tension test. See also compliance.

coefficient of expansion
A measure of the change in length or volume of an object, specifically measured by the increase in length or volume of an object per unit length or volume.

coefficient of friction
A measure of the resistance to sliding of one surface in contact with another surface.

coefficient of thermal expansion (CTE)
The change in length or volume per unit length or volume produced by a 1° change in temperature.

cohesion
(1) The propensity of a single substance to adhere to itself. (2) The internal attraction of molecular particles toward each other. (3) The ability to resist partition of itself. (4) The force holding a single substance together.

cohesive failure
Failure of an adhesive joint occurring primarily in an adhesive layer.

cohesive strength
Intrinsic strength of an adhesive.

coin test
Using a coin to tap a laminate in different spots, listening for a change in sound, which would indicate the presence of a defect. A surprisingly accurate test in the hands of experienced personnel.

coke
Carbonaceous residue resulting from the pyrolysis of pitch.

cold flow
The distortion that takes place in materials under continuous load at temperatures within the working range of the material without a phase or chemical change. See also creep.

cold-setting adhesive
A synthetic resin adhesive capable of hardening at normal room temperature in the presence of a hardener.

collet

A rigid, lateral container for the mold- forming material. A dam, a restriction box. The drive wheel that pulls glass fibers from the bushing. A forming tube is placed on the collet, and a package of strand is wound up on the tube. A metal band, ferrule, collar, or flange, often used to hold a tool or workpiece.

collimated

Rendered parallel.

collimated roving

Roving that has been made using a special process (usually parallel wound), so that the strands are more parallel than in standard roving.

colloidal

A state of suspension in a liquid medium in which extremely small particles are suspended and dispersed but not dissolved.

compaction

The application of a temporary vacuum bag and vacuum to remove trapped air and compact the lay-up.

compatibility

The ability of two or more substances combined with one another to form a homogeneous composition of useful plastic properties; for example, the suitability of a sizing or finish for use with certain general resin types. Nonreactivity or negligible reactivity between materials in contact.

complex dielectric constant

The vectorial sum of the dielectric constant and the loss factor.

complex shear modulus

The vectorial sum of the shear modulus and the loss modulus.

complex Young's modulus

The vectorial sum of Young's modulus and the loss modulus. Analogous to the complex dielectric constant.

compliance

Tensile compliance: the reciprocal of Young's modulus. Shear compliance: the reciprocal of shear modulus. Also, a term used in the evaluation of stiffness and deflection.

composite material

A combination of two or more materials (reinforcing elements, fillers, and composite matrix binder), differing in form or composition on a macroscale. The constituents retain their identities; that is, they do not dissolve or merge completely into one another although they act in concert. Normally, the components can be physically identified and exhibit an interface between one another. Composite materials are usually man-made and created to obtain properties that cannot be achieved by any of the components acting alone.

compound

The intimate admixture of a polymer with other ingredients, such as fillers, softeners, plasticizers, reinforcement, catalysts, pigments, or dyes. A thermoset compound usually contains all the ingredients necessary for the finished product, while a thermoplastic compound may require subsequent addition of pigments, blowing agents, and so forth.

compression molding

Technique for molding in which a part is shaped by placing the fiber and resin into an open mold cavity, closing the mold, and applying heat and pressure until the material has cured or achieved its final form. Compression molding can be used for making parts from glass mat thermoplastics, long-fiber thermoplastics, and short-fiber reinforced sheet molding compounds (thermosets).

compressive modulus

Ratio of compressive stress to compressive strain below the proportional limit. Theoretically equal to Young's modulus determined from tensile experiments.

compressive strength

The ability of a material to resist a force that tends to crush or buckle. The maximum compressive load sustained by a specimen divided by the original cross-sectional area of the specimen.

compressive stress

The normal stress caused by forces directed toward the plane on which they act.

condensation polymerization

A chemical reaction in which two or more molecules combine, with the separation of water or some other simple substance. If a polymer is formed, the process is called polycondensation. See also polymerization.

conditioning

Subjecting a material to a prescribed environmental and/or stress history before testing.

conductivity

Reciprocal of volume resistivity. The measure of the ability of a material to transfer heat or electric current from one face of a unit cube to the opposite face (conductivity per unit volume).

consolidation

In metal-matrix or thermoplastic composites, a processing step in which fiber and matrix are compressed by one of several methods to reduce voids and achieve desired density.

constituent

In general, an element of a larger grouping. In advanced composites, the principal constituents are the fibers and the matrix.

contact adhesive

An adhesive that is apparently dry to the touch and that will adhere to itself simultaneously upon contact. An adhesive applied to both adherends and allowed to become dry, which develops a bond when the adherends are brought together without sustained pressure.

contact molding

A process for molding reinforced plastics in which reinforcement and resin are placed on a mold. Cure is either at room temperature using a catalyst-promoter system or by heating in an oven, without additional pressure.

contact pressure molding

A method of molding or laminating in which the pressure, usually less than 70 kPa (10 psi), is only slightly more than necessary to hold the materials together during the molding operation.

contact pressure resins

Liquid resins that thicken or polymerize on heating, and, when used for bonding laminates, require little or no pressure.

contaminant

An impurity or foreign substance present in a material or environment that affects one or more properties of the material, particularly adhesion.

continuous fiber ceramic composite (CFCC)

A ceramic-matrix composite in which the reinforcing phase(s) consists of continuous filaments, fibers, yarn, or knitted or woven fabrics.

continuous filament yarn

Yarn formed by twisting two or more continuous filaments into a single, continuous strand.

copolymer

A long-chain molecule formed by the reaction of two or more dissimilar monomers. See also polymer.

core

(1) The central member, usually foam or honeycomb, of a sandwich construction to which the faces of the sandwich are attached or bonded. (2) The central member of a plywood assembly. (3) A channel in a mold for circulation of heat transfer media. (4) A device on which prepreg is wound.

core crush

A collapse, distortion, or compression of the core.

core depression

A localized indentation or gouge in the core.

cored mold

A mold incorporating passages for electrical heating elements, steam, or water.

core separation

A partial or complete breaking of the core node bond.

core splicing

The joining of segments of a core by bonding, or by overlapping each segment and then driving them together.

corrosion resistance

The ability of a material to withstand contact with ambient natural factors or those of a particular, artificially created atmosphere, without degradation or change in properties. For metals, this could be pitting or rusting; for organic materials, it could be crazing.

count
: For fabric, number of warp and filling yarns per inch in woven cloth. For yarn, size based on relation of length and weight.

coupling agent
: Any chemical substance designed to react with both the reinforcement and matrix phases of a composite material to form or promote a stronger bond at the interface.

coupon
: Usually, a specimen for a specific test, such as a tensile coupon.

crack
: An actual separation of material, visible on opposite surfaces of the part, and extending through the thickness. A fracture.

crack growth
: Rate of propagation of a crack through a material due to a static or dynamic applied load.

crazing
: Region of ultrafine cracks, which may extend in a network on or under the surface of a resin or plastic material. May appear as a white band. Often found in a filament-wound pressure vessel or bottle.

creel
: A device for holding the required number of roving balls (spools) or supply packages in desired position for unwinding onto the next processing step, that is, weaving, braiding, or filament winding.

creep
: (1) The change in dimension of a material under load over a period of time, not including the initial instantaneous elastic deformation. (Creep at room temperature is called cold flow.) (2) The time-dependent part of strain resulting from an applied stress.

creep, rate of
: The slope of the creep-time curve at a given time. Deflection with time under a given static load.

crimp
: The waviness of a fiber or fabric, which determines the capacity of fibers to cohere under light pressure. Measured by the number of crimps or waves per unit length.

critical length
: The minimum fiber length required for shear loading to its ultimate strength by the matrix.

critical longitudinal stress
: (1) Applied to fibers, the longitudinal stress necessary to cause internal slippage and separation of a spun yarn. (2) The stress necessary to overcome the interfiber friction developed as a result of twist.

critical strain
: The strain at the yield point.

cross laminate
: A laminate in which some of the layers of material are oriented approximately at right angles to the remaining layers with respect to the grain, or strongest direction in tension. See also parallel laminate.

cross-linking
: Applied to polymer molecules, the setting-up of chemical links between the molecular chains. When extensive, as in most thermosetting resins, cross-linking makes one infusible supermolecule of all the chains.

cross-linking, degree of
: The fraction of cross- linked polymeric units in the entire system.

cross-ply laminate
: (1) A laminate with plies usually oriented at 0° and 90° only. (2) Any filamentary laminate that is not uniaxial.

crosswise direction
: Crosswise refers to the cutting of specimens and to the application of load. For rods and tubes, crosswise is any direction perpendicular to the long axis. For other shapes or materials that are stronger in one direction than in another, crosswise is the direction that is weaker. For materials that are equally

strong in both directions, crosswise is an arbitrarily designated direction at right angles to the lengthwise direction.

crystalline plastic
: A polymeric material having an internal structure in which the atoms are arranged in an orderly three-dimensional configuration.

C-scan
: The back-and-forth scanning of a specimen with ultrasonics. A nondestructive testing technique for finding voids, delaminations, defects in fiber distribution, and so forth.

C-stage
: The final stage in the reaction of certain thermosetting resins in which the material is practically insoluble and infusible. Sometimes referred to as resite. The resin in a fully cured thermoset molding is in this stage. See also A- stage and B-stage.

cure
: To irreversibly change the properties of a thermosetting resin by chemical reaction, that is, condensation, ring closure, or addition. Cure may be accomplished by addition of curing (cross linking) agents, with or without heat and pressure.

cure cycle
: The time/temperature/pressure cycle used to cure a thermosetting resin system or prepreg.

cure monitoring, electrical
: Use of electrical techniques to detect changes in the electrical properties and/or mobility of the resin molecules during cure. A measuring of resin cure.

cure stress
: A residual internal stress produced during the curing cycle of composite structures. Normally, these stresses originate when different components of a wet lay-up have different thermal coefficients of expansion.

curing agent
: A catalytic or reactive agent that, when added to a resin, causes polymerization. Also called hardener.

CVD carbon
: See chemical vapor deposited (CVD) carbon.

cyanate ester resins
: Thermosetting resins that are derived from bisphenols or polyphenols, and are available as monomers, oligomers, blends, and solutions.

cycle time
: In molding, the total time used to carry out a complete sequence of operations making up the molding cycle.

D

dam
: Boundary support or ridge used to prevent excessive edge bleeding or resin runout of a laminate and to prevent crowning of the bag during cure.

damage tolerance
: A design measure of crack growth rate. Cracks in damage tolerant designed structures are not permitted to grow to critical size during expected service life.

damping
: The decay, with time, of the amplitude of free vibrations of a specimen. See also hysteresis and attenuation.

daylight
: The distance, in the open position, between the moving and fixed tables or the platens of a hydraulic press. In the case of a multiplaten press, daylight is the distance between adjacent platens. Daylight provides space for removal of the molded part from the mold.

debond

(1) A deliberate separation of a bonded joint or interface, usually for repair or rework purposes. (2) An unbonded or nonadhered region; a separation at the fiber-matrix interface due to strain incompatibility. See also disbond and delamination.

debulking
: Compacting of a thick laminate under moderate heat and pressure and/or vacuum to remove most of the air, to ensure seating on the tool, and to prevent wrinkles.

deep-draw mold
: A mold having a core that is long in relation to the wall thickness.

deflashing
: A finishing technique used to remove the flash (excess, unwanted material) on a plastic molding.

deflection temperature under load
: The temperature at which a simple cantilever beam deflects a given amount under load. Formerly called heat distortion temperature.

deformation under load
: The dimensional change of a material under load for a specified time following the instantaneous elastic deformation caused by the initial application of the load. See also cold flow and creep.

degassing
: See breathing.

degradation
: A deleterious change in the chemical structure, physical properties, or appearance of a plastic.

degree of polymerization
: Number of structural units, or mers, in the average polymer molecule in a sample measure of molecular weight.

delamination
: Separation of the layers of material in a laminate, either local or covering a wide area. Can occur in the cure or subsequent life.

denier
: A yarn and filament numbering system in which the yarn number is numerically equal to the weight in grams of 9000 meters. Used for continuous filaments. The lower the denier, the finer the yarn.

densification process
: Consolidation of a loose or bulky material.

density, apparent
: The weight in air of a unit volume of a material.

density, bulk
: The weight per unit volume of a material, including voids inherent in material as tested.

deposition
: The process of applying a material to a base by means of vacuum, electrical, chemical, screening, or vapor methods, often with the assistance of a temperature and pressure container.

design allowables
: Statistically defined (by a test program) material property allowable strengths, usually referring to stress or strain. See also A-basis, B-basis, S-basis, and typical basis.

desizing
: (1) The process of eliminating sizing, which is generally starch, from gray (also greige) goods before applying special finishes or bleaches (for yarn such as glass or cotton). (2) Removing lubricant size following weaving of a cloth.

desorption
: A process in which an absorbed material is released from another material. Desorption is the reverse of absorption, adsorption, or both.

devitrification
: The formation of crystals (seeds) in a glass melt, usually occurring when the melt is too cold. These crystals can appear as defects in glass fibers.

D-glass
: A high boron content glass made especially for laminates requiring a precisely controlled dielectric constant.

diaphragm forming

A method of simultaneously consolidating and forming thermoplastic composites in which the lay-up is sandwiched between two heat-formable sheets (often superplastic aluminum sheets) and placed under gas pressure in a press to form and consolidate the desired shape.

dielectric

(1) A nonconductor of electricity. (2) The ability of a material to resist the flow of an electrical current.

dielectric constant

The ratio of the capacitance of an assembly of two electrodes separated solely by a plastic insulating material to its capacitance when the electrodes are separated by air. See also complex dielectric constant.

dielectric curing

The curing of a synthetic thermosetting resin by the passage of an electric charge (produced from a high-frequency generator) through the resin.

dielectric heating

The heating of materials by dielectric loss in a high-frequency electrostatic field.

dielectric loss

A loss of energy evidenced by the rise in heat of a dielectric placed in an alternating electric field.

dielectric monitoring

A means of tracking the cure of thermosets by changes in their electrical properties during material processing.

dielectric strength

(1) The property of an insulating material that enables it to withstand electric stress. (2) The average potential per unit thickness at which failure of the dielectric material occurs.

dielectrometry

Use of electrical techniques to measure the changes in loss factor (dissipation) and in capacitance during cure of the resin in a laminate.

differential scanning calorimetry (DSC)

Measurement of the energy absorbed (endotherm) or produced (exotherm) as a resin system is cured. Also detects loss of solvents and other volatiles.

differential thermal analysis (DTA)

An experimental analysis technique in which a specimen and a control are heated simultaneously and the difference in their temperatures is monitored. The difference in temperature provides information on relative heat capacities, presence of solvents, changes in structure (that is, phase changes, such as melting of one component in a resin system), and chemical reactions. See also differential scanning calorimetry.

diluent

An ingredient added to an adhesive, usually to reduce the concentration of bonding materials.

dimensional stability

Ability of a plastic part to retain the precise shape to which it was molded, cast, or otherwise fabricated.

disbond

(1) An area within a bonded interface between two adherends in which an adhesion failure or separation has occurred. (2) An area of separation between two laminae in the finished laminate (in this case, the term delamination is normally preferred). See also debond.

discontinuous fiber-reinforced composite

A ceramic-matrix composite material reinforced by chopped fibers.

displacement angle

In filament winding, the advancement distance of the winding ribbon on the equator after one complete circuit.

dissipation factor, electrical

See electrical dissipation factor.

distortion

(1) In fabric, the displacement of fill fiber from the 90° angle (right angle) relative to the warp fiber. (2) In a laminate, the displacement of the fibers (especially at radii), relative to their idealized location, due to motion during lay-up and cure.

doctor blade or bar
: A straight piece of material used to spread resin, as in application of a thin film of resin for use in hot melt prepregging or for use as an adhesive film. Also called paste metering blade.

dolly
: In filament winding, the planar reinforcement applied to a local area between windings to provide extra strength in an area where a cut-out is to be made, for example, port openings. Usually placed at the knuckle joints of cylinder to dome.

dome
: In filament winding, the portion of a cylindrical container that forms the spherical or elliptical shell ends of the container.

doubler
: Localized areas of extra layers of reinforcement, usually to provide stiffness or strength for fastening or other abrupt load transfer. See also tabs.

draft
: The taper or slope of the vertical surfaces of a mold designed to facilitate removal of molded parts.

draft angle
: The angle of a taper on a mandrel or mold that facilitates removal of the finished part.

drape
: The ability of a fabric or prepreg to conform to a contoured surface.

drawn fiber
: Fiber with a certain amount of orientation imparted by the drawing process by which it was formed.

dry laminate
: A laminate containing insufficient resin for complete bonding of the reinforcement. See also resin-starved area.

dry lay-up
: Construction of a laminate by the layering of preimpregnated reinforcement (partly cured resin) in a female mold or on a male mold, usually followed by bag molding or autoclave molding.

dry winding
: A term used to describe filament winding using preimpregnated roving, as differentiated from wet winding, where unimpregnated roving is pulled through a resin bath just before being wound onto a mandrel. See also wet winding.

DSC
: See differential scanning calorimetry.

DTA
: See differential thermal analysis.

ductility
: The amount of plastic strain that a material can withstand before fracture. Also, the ability of a material to deform plastically before fracturing.

dwell
: (1) A pause in the application of pressure or temperature to a mold, made just before it is completely closed, to allow the escape of gas from the molding material. In filament winding, the time that the traverse mechanism is stationary while the mandrel continues to rotate to the appropriate point for the traverse to begin a new pass. (2) In a standard autoclave cure cycle, an intermediate step in which the resin matrix is held at a temperature below the cure temperature for a specified period of time sufficient to produce a desired degree of staging. Used primarily to control resin flow.

dynamic modulus
: The ratio of stress to strain under vibratory conditions (calculated from data obtained from either free or forced vibration tests, in shear, compression, or elongation).

E

edge distance ratio
: The distance from the center of the bearing hole to the edge of the specimen in the direction of the principal stress, divided by the diameter of the hole.

edge joint
: A joint made by bonding the edge faces of two adherends.

EEW
: See epoxide equivalent weight.

E-glass
: A family of glasses with a calcium aluminoborosilicate composition and a maximum alkali content of 2.0%. A general-purpose fiber that is most often used in reinforced plastics, and is suitable for electrical laminates because of its high resistivity. Also called electric glass.

elastic deformation
: The part of the total strain in a stressed body that disappears upon removal of the stress.

elasticity
: That property of materials by virtue of which they tend to recover their original size and shape after removal of a force causing deformation. See also viscoelasticity.

elastic limit
: The greatest stress a material is capable of sustaining without permanent strain remaining after the complete release of the stress. A material is said to have passed its elastic limit when the load is sufficient to initiate plastic, or nonrecoverable, deformation.

elastic recovery
: The fraction of a given deformation that behaves elastically. A perfectly elastic material has an elastic recovery of 1; a perfectly plastic material has an elastic recovery of 0.

elastomer
: A material that substantially recovers its original shape and size at room temperature after removal of a deforming force.

elastomeric tooling
: A tooling system that uses the thermal expansion of rubber materials to form composite parts during cure.

electrical dissipation factor
: The ratio of the power loss in a dielectric material to the total power transmitted through it; thus, the imperfection of the dielectric. Equal to the tangent of the loss angle.

electric glass
: See E-glass.

electroformed molds
: A mold made by electroplating metal on the reverse pattern of the cavity. Molten steel may then be sprayed on the back of the mold to increase its strength.

elongation
: Deformation caused by stretching. The fractional increase in length of a material stressed in tension. (When expressed as percentage of the original gage length, it is called percentage elongation.)

elongation at break
: Elongation recorded at the moment of rupture of the specimen, often expressed as a percentage of the original length.

encapsulation
: The enclosure of an item in plastic. Sometimes used specifically in reference to the enclosure of capacitors or circuit board modules.

end
: A strand of roving consisting of a given number of filaments gathered together. The group of filaments is considered an “end” or strand before twisting, a “yarn” after twist has been applied. An individual warp yarn, thread, fiber, or roving.

end count
: An exact number of ends supplied on a ball of roving.

endurance limit
: See fatigue limit.

engineered plastic
: A material that has been made by specific design and through use of particular monomers and monomer sequences to produce a plastic with desired properties, possibly for a specific application.

engineering plastics

Those plastics and polymeric compositions for which well-defined properties are available such that engineering rather than empirical methods can be used for the design and manufacture of products that require definite and predictable performance in structural applications over a substantial temperature range.

environment

The aggregate of all conditions (such as contamination, temperature, humidity, radiation, magnetic and electric fields, shock, and vibration) that externally influence the performance of an item.

environmental stress cracking

The susceptibility of a thermoplastic resin to crack or craze when in the presence of surface-active agents or other environments.

epichlorohydrin

The basic epoxidizing resin intermediate in the production of epoxy resins. It contains an epoxy group and is highly reactive with polyhydric phenols such as bisphenol A.

epoxide

Compound containing the oxirane structure, a three-member ring containing two carbon atoms and one oxygen atom. The most important members are ethylene oxide and propylene oxide.

epoxide equivalent weight (EEW)

The weight of a resin (in grams) that contains one gram equivalent of epoxy.

epoxy plastic

A polymerizable thermoset polymer containing one or more epoxide groups and curable by reaction with amines, alcohols, phenols, carboxylic acids, acid anhydrides, and mercaptans. An important matrix resin in composites and structural adhesive.

equator

In filament winding, the line in a pressure vessel described by the junction of the cylindrical portion and the end dome. Also called tangent line or point.

even tension

The process whereby each end of roving is kept in the same degree of tension as the other ends making up that ball of roving. See also catenary.

exotherm

The liberation or evolution of heat during the curing of a plastic product.

expanded plastic

See cellular plastic.

extend

To add fillers or low-cost materials in an economy-producing endeavor. To add inert materials to improve void-filling characteristics and reduce crazing.

extenders

Low-cost materials used to dilute or extend high-cost resins without extensive lessening of properties. See also filler.

extensibility

The ability of a material to extend or elongate upon application of sufficient force, expressed as percent of the original length.

extensional-bending coupling

A property of certain classes of laminates that exhibit bending curvatures when subjected to extensional loading.

extensional-shear coupling

A property of certain classes of laminates that exhibit shear strains when subjected to extensional loading.

extensometer

A mechanical or optical device for measuring linear strain due to mechanical stress.

F

fabric

(1) A material made of woven fibers or filaments. (2) A planar textile also known as cloth.

fabricating (fabrication)
: The manufacture of products from molded parts, rods, tubes, sheeting, extrusions, or other form by appropriate operations, such as punching, cutting, drilling, and tapping. Fabrication includes fastening parts together or to other parts by mechanical devices, adhesives, heat sealing, welding, or other means.

fabric fill face
: That side of the woven fabric where the greatest number of the yarns are perpendicular to the selvage.

fabric, nonwoven
: See nonwoven fabric.

fabric prepreg batch
: Prepreg containing fabric from one fabric batch, impregnated with one batch of resin in one continuous operation.

fabric warp face
: That side of the woven fabric where the greatest number of the yarns are parallel to the selvage.

fabric, woven
: See woven fabric.

facings
: (1) Skins and doublers in any lay-up. (2) The outermost layer or composite component of a sandwich construction, generally thin and of high density, which resists most of the edgewise loads and flatwise bending moments, synonymous with face, skin, and facesheet.

fairing
: A member or structure, the primary function of which is to streamline the flow of a fluid by producing a smooth outline and to reduce drag, as in aircraft frames and boat hulls.

fatigue
: The failure or decay of mechanical properties after repeated applications of stress. Fatigue tests give information on the ability of a material to resist the development of cracks, which eventually bring about failure as a result of a large number of cycles.

fatigue life
: The number of cycles of deformation required to bring about failures of the test specimen under a given set of oscillating conditions (stresses or strains). Also known as safe life.

fatigue limit
: The stress level below which a material can be stressed cyclically for an infinite number of times without failure.

fatigue ratio
: The ratio of fatigue strength to tensile strength. Mean stress and alternating stress must be stated.

fatigue strength
: The maximum cyclical stress a material can withstand for a given number of cycles before failure occurs. The residual strength after being subjected to fatigue.

faying surface
: The surfaces of materials in contact with each other and joined or about to be joined together.

felt
: A fibrous material made up of interlocked fibers by mechanical or chemical action, moisture, or heat. Made from fibers such as asbestos, cotton, glass, and so forth. See also batt.

fiber
: A general term used to refer to filamentary materials. Often, fiber is used synonymously with filament. It is a general term for a filament with a finite length that is at least 100 times its diameter, which is typically 0.10 to 0.13 mm (0.004 to 0.005 in.). In most cases it is prepared by drawing from a molten bath, spinning, or deposition on a substrate. A whisker, on the other hand, is a short, single- crystal fiber or filament made from a wide variety of materials, with diameters ranging from 1 to 25 μm (40 to 1400 μin.) and aspect ratios (a measure of length) between 100 and 15,000. Fibers can be continuous or specific short lengths (discontinuous), normally no less than 3.2 mm (1/8 in.).

fiber content
: The amount of fiber present in a composite. This is usually expressed as a percentage volume fraction or weight fraction of the composite.

fiber count

The number of fibers per unit width of ply present in a specified section of a composite.

fiber diameter

The measurement (expressed in hundred thousandths) of the diameter of individual filaments.

fiber direction

The orientation or alignment of the longitudinal axis of the fiber with respect to a stated reference axis.

fiberglass

An individual filament made by drawing molten glass. A continuous filament is a glass fiber of great or indefinite length. A staple fiber is a glass fiber of relatively short length, generally less than 430 mm (17 in.), the length related to the forming or spinning process used.

fiberglass reinforcement

Major material used to reinforce plastic. Available as mat, roving, fabric, and so forth, it is incorporated into both thermosets and thermoplastics.

fiber pattern

Visible fibers on the surface of laminates or molding. The thread size and weave of glass cloth.

fiber placement

Continuous process for fabricating composite shapes with complex contours and/or cutouts by means of a device that lays preimpregnated fibers (in tow form) onto a nonuniform mandrel or tool. Differs from filament winding in several ways. There is no limit on fiber angles; compaction takes place on-line via heat, pressure, or both; and fibers can be added and dropped as necessary. The process produces more complex shapes and permits a faster put-down rate than filament winding.

fiber-reinforced plastic (FRP)

A general term for a composite that is reinforced with cloth, mat, strands, or any other fiber form.

fiber show

Strands or bundles of fibers that are not covered by plastic and that are at or above the surface of a composite.

fiber wash

Splaying out of woven or nonwoven fibers from the general reinforcement direction. Fibers are carried along with bleeding resin during cure.

filament

The smallest unit of a fibrous material. The basic units formed during drawing and spinning, which are gathered into strands of fiber for use in composites. Filaments usually are of extreme length and very small diameter, usually less than 25 μm (1 mil). Normally, filaments are not used individually. Some textile filaments can function as a yarn when they are of sufficient strength and flexibility.

filamentary composite

A major form of advanced composite in which the fiber constituent consists of continuous filaments. Specifically, a filamentary composite is a laminate comprised of a number of laminae, each of which consists of a nonwoven, parallel, uniaxial, planar array of filaments (or filament yarns) embedded in the selected matrix material. Individual laminae are directionally oriented and combined into specific multiaxial laminates for application to specific envelopes of strength and stiffness requirements.

filament winding

A process for fabricating a composite structure in which continuous reinforcements (filament, wire, yarn, tape, or other), either previously impregnated with a matrix material or impregnated during the winding, are placed over a rotating and removable form or mandrel in a prescribed way to meet certain stress conditions. Generally the shape is a surface of revolution and may or may not include end closures. When the required number of layers is applied, the wound form is cured and the mandrel removed.

fill

Yarn oriented at right angles to the warp in a woven fabric.

filler

A relatively inert substance added to a material to alter its physical, mechanical, thermal, electrical, and other properties, or to lower cost or density. Sometimes the term is used specifically to mean particulate additives. See also inert filler.

fillet

A rounded filling or adhesive that fills the corner or angle where two adherends are joined.

filling yarn

The transverse threads or fibers in a woven fabric. Those fibers running perpendicular to the warp. Also called weft.

film adhesive

A synthetic resin adhesive, usually of the thermosetting type, in the form of a thin, dry film of resin with or without a paper or glass carrier.

finish

Chemical finish applied to glass and other fibers, after sizing has been removed, to facilitate resin wetting, resin bonding, and good environmental performance of the cured laminate. See also size.

first-order transition

A change of state associated with crystallization or melting in a polymer.

flame resistance

Ability of a material to extinguish flame once the source of heat is removed. See also self-extinguishing resin.

flame retardants

Certain chemicals that are used to reduce or eliminate the tendency of a resin to burn.

flammability

Measure of the extent to which a material will support combustion.

flash

That portion of the charge that flows from or is extruded from the mold cavity during the molding. Extra plastic attached to a molding along the parting line, which must be removed before the part is considered finished.

flexibilizer

An additive that makes a finished plastic more flexible or tough. See also plasticizer.

flexible molds

Molds made of rubber or elastomeric plastics, used for casting plastics. They can be stretched to remove cured pieces with undercuts.

flexural modulus

The ratio, within the elastic limit, of the applied stress on a test specimen in flexure to the corresponding strain in the outermost fibers of the specimen.

flexural strength

The maximum stress that can be borne by the surface fibers in a beam in bending. The flexural strength is the unit resistance to the maximum load before failure by bending, usually expressed in force per unit area.

flow

(1) The movement of resin under pressure, allowing it to fill all parts of a mold. (2) The gradual but continuous distortion of a material under continued load, usually at high temperatures; also called creep.

flow line

A mark on a molded piece made by the meeting of two flow fronts during molding. Also called striae, weld mark, or weld line.

flow marks

Wavy surface appearance of an object molded from thermoplastic resins, caused by improper flow of the resin into the mold.

fluoroplastic

A plastic based on polymers made from monomers containing one or more atoms of fluorine, or copolymers of such monomers with other monomers, the fluorine-containing monomer(s) being in greatest amount by mass.

fluted core

An integrally woven reinforcement material consisting of ribs between two skins in a unitized sandwich construction.

foamed plastics

(1) Resins in sponge form, flexible or rigid, with cells closed or interconnected and density over a range from that of the solid parent resin to 0.030 g/cm^3. Compressive strength of rigid foams is fair, making

them useful as core materials for sandwich constructions. (2) A chemical cellular plastic, the structure of which is produced by gases generated from the chemical interaction of its constituents.

foaming agent

Chemicals added to plastics and rubbers that generate inert gases on heating, causing the resin to assume a cellular structure.

foam-in-place

Refers to the deposition of foams when the foaming machine must be brought to the work that is “in place,” as opposed to bringing the work to the foaming machine. Also, foam mixed in a container and poured into a mold, where it rises to fill the cavity.

force

The male half of the mold that enters the cavity, exerting pressure on the resin and causing it to flow. Also called punch.

FP fiber

Polycrystalline alumina fiber (Al_2O_3). A ceramic fiber useful for high-temperature (1370 to 1650 °C, or 2500 to 3000 °F) composites.

fracture

The separation of a body. Defined both as rupture of the surface without complete separation of laminate and as complete separation of a body because of external or internal forces.

fracture stress

The true, normal stress on the minimum cross-sectional area at the beginning of fracture.

fracture toughness

A measure of the damage tolerance of a material containing initial flaws or cracks. Used in aircraft structural design and analysis.

free-radical polymerization

A type of polymerization in which the propagating species is a long-chain free radical initiated by the introduction of free radicals from thermal or photochemical decomposition.

free wall

The portion of a honeycomb cell wall that is not connected to another cell.

friction, coefficient of

See coefficient of friction.

FRP

See fiber-reinforced plastic.

fungus resistance

The resistance of a material to attack by fungi in conditions promoting their growth.

fuzz

Accumulation of short, broken filaments after passing glass strands, yarns, or rovings over a contact point. Often, weighted and used as an inverse measure of abrasion resistance.

G

gage length

Length over which deformation is measured, for a tensile or compressive test specimen. The deformation over the gage length divided by the gage length determines the strain.

gap

(1) In filament winding, the space between successive windings in which windings are usually intended to lay next to each other. (2) Separations between fibers within a filament winding band. (3) The distance between adjacent plies in a lay-up of unidirectional tape materials.

gap-filling adhesive

An adhesive subject to low shrinkage in setting, used as sealant.

gel

The initial jellylike solid phase that develops during the formation of a resin from a liquid. A semisolid system consisting of a network of solid aggregates in which liquid is held.

gelation

The point in a resin cure when the resin viscosity has increased to a point such that it barely moves when probed with a sharp instrument.

gelation time

(1) That interval of time, in connection with the use of synthetic thermosetting resins, extending from the introduction of a catalyst into a liquid adhesive system until the start of gel formation. (2) The time under application of load for a resin to reach a solid state.

gel coat

A quick-setting resin applied to the surface of a mold and gelled before lay-up. The gel coat becomes an integral part of the finished laminate, and is usually used to improve surface appearance and bonding.

gel permeation chromatography (GPC)

A form of liquid chromatography in which the polymer molecules are separated by their ability or inability to penetrate the material in the separation column.

gel point

The stage at which a liquid begins to exhibit pseudoelastic properties. This stage may be conveniently observed from the inflection point on a viscosity time plot.

geodesic

The shortest distance between two points on a surface.

geodesic isotensoid

Constant stress level in any given filament at all points in its path.

geodesic-isotensoid contour

In filament-wound reinforced plastic pressure vessels, a dome contour in which the filaments are placed on geodesic paths so that the filaments will exhibit uniform tensions throughout their length under pressure loading.

geodesic ovaloid

A contour for end domes, the fibers forming a geodesic line: the shortest distance between two points on a surface of revolution. The forces exerted by the filaments are proportioned to meet hoop and meridional stresses at any point.

glass

An inorganic product of fusion that has cooled to a rigid condition without crystallizing. Glass is typically hard and relatively brittle, and has a conchoidal fracture.

glass cloth

Conventionally woven glass fiber material. See also scrim.

glass fiber

A fiber spun from an inorganic product of fusion that has cooled to a rigid condition without crystallizing.

glass filament

A form of glass that has been drawn to a small diameter and extreme length. Most filaments are less than 0.15 mm (0.005 in.) in diameter.

glass filament bushing

The unit through which molten glass is drawn in making glass filaments.

glass finish

A material applied to the surface of a glass reinforcement to improve the bond between the glass and the plastic resin matrix.

glass flake

Thin, irregularly shaped flakes of glass, typically made by shattering a thin- walled tube of glass.

glass former

An oxide that forms a glass easily. Also, one which contributes to the network of silica glass when added to it.

glass mat thermoplastic (GMT)

A semifinished resin-fiber combination supplied as blanks for compression molding.

glass, percent by volume

The product of the specific gravity of a laminate and the percent glass by weight, divided by the specific gravity of the glass.

glass stress

In a filament-wound part, usually a pressure vessel, the stress calculated using the load and the cross-sectional area of the reinforcement only.

glass transition

The reversible change in an amorphous polymer or in amorphous regions of a partially crystalline polymer from, or to, a viscous or rubbery condition to, or from, a hard and relatively brittle one.

glass-transition temperature (T_g)

(1) The approximate midpoint of the temperature range over which the glass transition takes place; glass and silica fiber exhibit a phase change at approximately 955 °C (1750 °F) and carbon/ graphite fibers at 2205 to 2760 °C (4000 to 5000 °F). (2) The temperature at which increased molecular mobility results in significant changes in the properties of a cured resin system. (3) The inflection point on a plot of modulus versus temperature. The measured value of T_g depends to some extent on the method of test.

GMT

See glass mat thermoplastic.

graphite

The crystalline allotropic form of carbon.

graphite fiber

A fiber made from a precursor by an oxidation, carbonization, and graphitization process (which provides a graphitic structure). See also carbon fiber.

graphitization

The process of pyrolyzation in an inert atmosphere at temperatures in excess of 1925 °C (3500 °F), usually as high as 2480 °C (4500 °F), and sometimes as high as 9750 °C (5400 °F), converting carbon to its crystalline allotropic form. Temperature depends on precursor and properties desired.

green strength

The ability of the material (such as urethane elastomer), while not completely cured, to undergo removal from the mold and handling without tearing or permanent distortion.

greige, gray goods

Any fabric before finishing, as well as any yarn or fiber before bleaching or dyeing; therefore, fabric with no finish or size.

H

hand

The softness of a piece of fabric, as determined by the touch (individual judgment).

hand lay-up

The process of placing (and working) successive plies of reinforcing material or resin-impregnated reinforcement in position on a mold by hand.

handling life

The out-of-refrigeration time over which a material retains its handleability.

hardener

A substance or mixture added to a plastic composition to promote or control the curing action by taking part in it.

hardness

The resistance to surface indentation usually measured by the depth of penetration (or arbitrary units related to the depth of penetration) of a blunt point under a given load using a particular instrument according to a prescribed procedure. See also Barcol hardness, Mohs hardness, Rockwell hardness, and Shore hardness.

harness satin

Weaving pattern producing a satin appearance. “Eight-harness” means the warp tow crosses over seven fill tows and under the eighth (repeatedly).

heat-activated adhesive

A dry adhesive that is rendered tacky or fluid by application of heat, or heat and pressure, to the assembly.

heat buildup

The rise in temperature in a part resulting from the dissipation of applied strain energy as heat or from applied mold cure heat. See also hysteresis.

heat cleaned
: A condition in which glass or other fibers are exposed to elevated temperatures to remove preliminary sizings or binders not compatible with the resin system to be applied.

heat distortion temperature
: The temperature at which a standard test bar deflects a specified amount under a stated load.

heat resistance
: The property or ability of plastics and elastomers to resist the deteriorating effects of elevated temperatures.

heat sealing
: A method of joining plastic films by simultaneous application of heat and pressure to areas in contact.

heat-sealing adhesive
: A thermoplastic film adhesive that is melted between the adherend surfaces by heat application to one or both of the adjacent adherend surfaces.

heat sink
: A contrivance for the absorption or transfer of heat away from a critical element or part. Bulk graphite is often used as a heat sink.

heat treating
: Term used to cover annealing, hardening, tempering, and so on.

helical winding
: In filament-wound items, a winding in which a filament band advances along a helical path, not necessarily at a constant angle, except in the case of a cylinder.

heterogeneous
: (1) Descriptive term for a material consisting of dissimilar constituents separately identifiable. (2) A medium consisting of regions of unlike properties separated by internal boundaries. Note that not all nonhomogeneous materials are necessarily heterogeneous.

hexa
: Shortened form of hexamethylenetetramine, a source of reactive methylene for curing novolacs.

high-frequency heating
: The heating of materials by dielectric loss in a high-frequency electrostatic field. The material is exposed between electrodes and is heated quickly and uniformly by absorption of energy from the electrical field.

high-pressure laminates
: Laminates molded and cured at pressures not lower than 6.9 MPa (1.0 ksi), and more commonly in the range of 8.3 to 13.8 MPa (1.2 to 2.0 ksi).

high-pressure spot
: See resin-starved area.

HIP
: See hot isostatic pressing.

homogeneous
: (1) Descriptive term for a material of uniform composition throughout. (2) A medium that has no internal physical boundaries. (3) A material whose properties are constant at every point, that is, constant with respect to spatial coordinates (but not necessarily with respect to directional coordinates).

honeycomb
: Manufactured product of resin-impregnated sheet material (paper, glass fabric, and so on) or metal foil, formed into hexagonal-shaped cells. Used as a core material in sandwich construction. See also sandwich construction.

hoop
: Ply laid onto a mandrel at a 90° angle. Primarily used in reference to filament winding of cylindrically shaped objects.

hoop stress
: The circumferential stress in a material of cylindrical form subjected to internal or external pressure.

hot isostatic pressing

A process for fabricating certain metal-matrix composites. A preform is consolidated under fluid pressure (usually an inert gas) at high temperature and pressure in a pressure vessel.

hot-melt adhesive

An adhesive that is applied in a molten state and forms a bond after cooling to a solid state. A bonding agent that achieves a solid state and resultant strength by cooling, as contrasted with other adhesives that achieve the solid state through evaporation of solvents or chemical cure. A thermoplastic resin that functions as an adhesive when melted between substrates and cooled.

hot-setting adhesive

An adhesive that requires a temperature at or above 100 °C (212 °F) to set.

hot working

Any form of mechanical deformation processing carried out on a metal or alloy above its recrystallization temperature but below its melting point.

hybrid

A composite laminate consisting of at least two distinct types of matrix or reinforcement. Each matrix or reinforcement type can be distinct because of its (1) physical and/or mechanical properties, (2) material form, and (3) chemical composition. See also interply hybrid and intraply hybrid.

hydraulic press

A press in which the molding force is created by the pressure exerted by a fluid.

hydromechanical press

A press in which the molding forces are created partly by a mechanical system and partly by an hydraulic system.

hydrophilic

Capable of absorbing water; easily wetted by water.

hydrophobic

Capable of repelling water; poorly wetted by water.

hygroscopic

Capable of absorbing and retaining atmospheric moisture.

hygrothermal effect

Change in properties due to moisture absorption and temperature change.

hysteresis

The energy absorbed in a complete cycle of loading and unloading. This energy is converted from mechanical to frictional energy (heat).

I

ignition loss

The difference in weight before and after burning. As with glass, the burning off of the binder or size.

impact strength

The ability of a material to withstand shock loading. The work done in fracturing a test specimen in a specified manner under shock loading.

impact test

Measure of the energy necessary to fracture a standard notched bar by an impulse load. See also Izod impact test, reverse impact test, and Charpy impact test.

impregnate

In reinforced plastics, to saturate the reinforcement with a resin.

impregnated fabric

A fabric impregnated with a synthetic resin. See also prepreg.

inclusion

A physical and mechanical discontinuity occurring within a material or part, usually consisting of solid, encapsulated foreign material. Inclusions are often capable of transmitting some structural stresses and energy fields, but in a noticeably different degree from the parent material. See also voids.

induction bonding

A secondary joining process for thermoplastic composite parts in which a metallic susceptor is placed in the bondline and an induction coil is used to heat the joint above the melt temperature of the thermoplastic matrix.

inert filler

A material added to a plastic to alter the end-item properties through physical rather than chemical means.

infrared

Part of the electromagnetic spectrum between the visible light range and the radar range. Radiant heat is in this range, and infrared heaters are frequently used in the thermoforming and curing of plastics and composites. Infrared analysis is used for identification of polymer constituents.

inhibitor

A substance that retards a chemical reaction. Also used in certain types of monomers and resins to prolong storage life.

initial modulus

The slope of the initial straight portion of a stress-strain or load-elongation curve. See also Young's modulus.

initial strain

The strain produced in a specimen by given loading conditions before creep occurs.

initial (instantaneous) stress

The stress produced by force in a specimen before stress relaxation occurs.

initiator

Peroxides used as sources of free radicals. They are used in free-radical polymerizations, for curing thermosetting resins, as cross-linking agents for elastomers and polyethylene, and for polymer modification.

injection molding

Method of forming a plastic to the desired shape by forcing the heat-softened plastic into a relatively cool cavity under pressure.

inorganic

Designating or pertaining to the chemistry of all elements and compounds not classified as organic. Matter other than animal or vegetable, such as earthy or mineral matter. Applies to the chemistry of all elements and compounds not classified as organic.

inorganic pigments

Natural or synthetic metallic oxides, sulfides, and other salts that impart heat and light stability, weathering resistance, color, and migration resistance to plastics.

insert

An integral part of a plastic molding consisting of metal or other material that may be molded or pressed into position after the molding is completed.

insulation resistance

(1) The electrical resistance between two conductors or systems of conductors separated only by insulating material. (2) The ratio of the applied voltage to the total current between two electrodes in contact with a specified insulator. (3) The electrical resistance of an insulating material to a direct voltage.

insulator

A material of such low electrical conductivity that the flow of current through it can usually be neglected. Similarly, a material of low thermal conductivity, such as that used to insulate structural shells.

integral composite structure

Composite structure in which several structural elements, which would conventionally be assembled together by bonding or mechanical fasteners after separate fabrication, are instead laid up and cured as a single, complex, continuous structure, for example, spars, ribs, and one stiffened cover of a wing box fabricated as a single integral part. The term is sometimes applied more loosely to any composite structure not assembled by mechanical fasteners. All or some parts of the assembly may be co-cured.

integrally heated

A term referring to tooling that is self-heating, through use of electrical heaters such as cal rods. Most hydroclave tooling is integrally heated. Some autoclave tooling is integrally heated to compensate for thick sections, to provide high heat-up rates, or to permit processing at a higher temperature than is otherwise possible with the autoclave.

integral skin foam

Urethane foam with a cellular core structure and a relatively nonporous skin.

interface

(1) The boundary or surface between two different, physically distinguishable media. (2) On fibers, the contact area between fibers and sizing or finish. (3) In a laminate, the contact area between the reinforcement and the laminating resin.

interference fits

A joint or mating of two parts in which the male part has an external dimension larger than the internal dimension of the mating female part. Distension of the female by the male creates a stress, which supplies the bonding force for the joint.

interlaminar

Descriptive term pertaining to an object (for example, voids), event (for example, fracture), or potential field (for example, shear stress) referenced as existing or occurring between two or more adjacent laminae.

interlaminar shear

Shearing force tending to produce a relative displacement between two laminae in a laminate along the plane of their interface.

intermediate temperature setting adhesive

An adhesive that sets in the temperature range from 30 to 100 °C (87 to 211 °F).

interpenetrating polymer network

A combination of two polymers in a network in which at least one (or both) is crosslinked around the other. Interpenetrating polymer networks are frequently used to toughen epoxy matrices where the epoxy is continuous and a thermoplastic polymer is discontinuous.

interphase

The boundary region between a bulk resin or polymer and an adherend in which the polymer has a high degree of orientation to the adherend on a molecular basis. It plays a major role in the load transfer process between the bulk of the adhesive and the adherend or the fiber and the laminate matrix resin.

interply cracks

Through-cracking of individual layers within a composite lay-up, perpendicular to the ply interfaces.

interply hybrid

A composite in which adjacent laminae are composed of different materials.

intralaminar

Descriptive term pertaining to an object (for example, voids), event (for example, fracture), or potential field (for example, temperature gradient) existing entirely within a single lamina without reference to any adjacent laminae.

intraply hybrid

A composite in which different materials are used within a specific layer or band.

irradiation

As applied to plastics, the bombardment with a variety of subatomic particles, usually alpha-, beta-, or gamma-rays. Used to initiate polymerization and copolymerization of plastics and in some cases to bring about changes in the physical properties of a plastic.

irreversible

Not capable of redissolving or remelting. Chemical reactions that proceed in a single direction and are not capable of reversal (as applied to thermosetting resins).

isocyanate plastics

Plastics based on resins made by the condensation of organic isocyanates with other compounds. Generally reacted with polyols on a polyester or polyether backbone molecule, with the reactants being joined through the formation of the urethane linkage. See also polyurethane and urethane plastics.

isostatic pressing

Pressing powder under a gas or liquid so that pressure is transmitted equally in all directions, for example, in sintering.

isotropic

Having uniform properties in all directions. The measured properties of an isotropic material are independent of the axis of testing.

Izod impact test

A test for shock loading in which a notched specimen bar is held at one end and broken by striking, and the energy absorbed is measured.

J

joint, adhesive

See adhesive joint.

joint, butt

See butt joint.

joint, edge

See edge joint.

joint, lap

See lap joint.

joint, scarf

See scarf joint.

K

Kapton

Trade name (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) for a polyimide film that emits low smoke and flame, resists hydraulic fluids, and has good low- and elevated-temperature performance.

kerf

The width of a cut made by a saw blade, torch, waterjet, laser beam, and so forth.

Kevlar

Trade name (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) for an organic polymer composed of aromatic polyamides having a para-type orientation (parallel chain extending bonds from each aromatic nucleus).

K-factor

The coefficient of thermal conductivity. The amount of heat that passes through a unit cube of material in a given time when the difference in temperature of two opposite faces is 1°.

knitted fabrics

Fabrics produced by interlooping chains of yarn.

knuckle area

The area of transition between sections of different geometry in a filament- wound part, for example, where the skirt joins the cylinder of the pressure vessel. Also called Y-joint.

L

lamina

A single ply or layer in a laminate made up of a series of layers (organic composite). A flat or curved surface containing unidirectional fibers or woven fibers embedded in a matrix (metal-matrix composite).

laminae

Plural of lamina.

laminate

(1) To unite laminae with a bonding material, usually with pressure and heat (normally used with reference to flat sheets, but also rods and tubes). (2) A product made by such bonding. See also bidirectional laminate and unidirectional laminate.

laminate coordinates

A reference coordinate system (used to describe the properties of a laminate), generally in the direction of principal axes, when they exist.

laminate orientation

The configuration of a cross-plied composite laminate with regard to the angles of cross-plying, the number of laminae at each angle, and the exact sequence of the lamina lay-up.

laminate ply

One fabric-resin or fiber-resin layer of a product that is bonded to adjacent layers in the curing process.

lap

In filament winding, the amount of overlay between successive windings, usually intended to minimize gapping. In bonding, the distance one adherend covers another adherend.

lap joint

A joint made by placing one adherend partly over another and bonding the overlapped portions.

lattice pattern

A pattern of filament winding with a fixed arrangement of open voids.

lay-up

(1) The reinforcing material placed in position in the mold. (2) The process of placing the reinforcing material in position in the mold. (3) The resin-impregnated reinforcement. (4) A description of the component materials, geometry, and so on, of a laminate. (5) A fabrication process involving the assembly of successive layers of resin-impregnated material.

L-direction

The ribbon direction, that is, the direction of the continuous sheets of honeycomb.

level winding

See circumferential winding.

linear expansion

The increase of a given dimension, measured by the expansion or contraction of a specimen or component subject to a thermal gradient or changing temperature. See also coefficient of thermal expansion.

liner

In a filament-wound pressure vessel, the continuous, usually flexible coating on the inside surface of the vessel, used to protect the laminate from chemical attack or to prevent leakage under stress.

liquid crystal polymer

A thermoplastic polymer that is melt processable and develops high orientation in molding, with resultant tensile strength and high-temperature capability that is notably improved. First commercial availability was as an aromatic polyester. With or without fiber reinforcement.

liquid metal infiltration

Process for immersion of metal fibers in a molten metal bath to achieve a metal-matrix composite; for example, graphite fibers in molten aluminum.

liquid shim

Material used to position components in an assembly where dimensional alignment is critical. For example, epoxy adhesive is introduced into gaps after the assembly is placed in the desired configuration.

load-deflection curve

A curve in which the increasing tension, compression, or flexural loads are plotted on the ordinate axis and the deflections caused by those loads are plotted on the abscissa axis.

longos

Low-angle helical or longitudinal windings.

loop tenacity

The tenacity or strength value obtained by pulling two loops, as two links in a chain, against each other in order to demonstrate the susceptibility that a fibrous material has for cutting or crushing itself; loop strength.

loss factor

The product of the dissipation factor and the dielectric constant of a dielectric material.

loss modulus

A damping term describing the dissipation of energy into heat when a material is deformed.

loss on ignition

Weight loss, usually expressed as percent of total, after burning off an organic sizing from glass fibers, or an organic resin from a glass fiber laminate.

loss tangent

See electrical dissipation factor.

lot

A specific amount of material produced at one time using the same process and the same conditions of manufacture, and offered for sale as a unit quantity.

low-pressure laminates

In general, laminates molded and cured in the range of pressures from 2760 kPa (400 psi) down to and including pressure obtained by the mere contact of the plies.

lubricant

A material added to most sizings to improve the handling and processing properties of textile strands, especially during weaving.

M

macerate

To chop or shred fabric for use as a filler for a molding resin.

macro

In relation to composites, denotes the gross properties of a composite as a structural element but does not consider the individual properties or identity of the constituents.

mandrel

The core tool around which resin-impregnated paper, fabric, or fiber is wound to form pipes, tubes, or structural shell shapes.

mat

(1) A fibrous material for reinforced plastic consisting of randomly oriented chopped filaments, short fibers (with or without a carrier fabric), or swirled filaments loosely held together with a binder. Available in blankets of various widths, weights, and lengths. (2) A sheet formed by filament winding a single- hoop ply of fiber on a mandrel, cutting across its width and laying out a flat sheet.

matched metal molding

A reinforced plastics manufacturing process in which matching male and female metal molds are used (similar to compression molding) to form the part, with time, pressure, and heat.

matrix

The essentially homogeneous material in which the fiber system or reinforcing particles of a composite are embedded. Both thermoplastic and thermoset resins may be used, as well as metals, ceramics, and glasses.

mechanical adhesion

Adhesion between surfaces in which the adhesive holds the parts together by interlocking action.

mechanical properties

(1) The properties of a material, such as compressive and tensile strengths and modulus, that are associated with elastic and inelastic reaction when force is applied. (2) The individual relationship between stress and strain.

melt

A charge of molten metal or plastic. See also liquid metal infiltration.

mer

The repeating structural unit of any polymer.

mesophase

An intermediate phase in the formation of carbon from a pitch precursor. This is a liquid crystal phase in the form of microspheres, which, upon prolonged heating above 400 °C (750 °F), coalesce, solidify, and form regions of extended order. Heating to above 2000 °C (3630 °F) leads to the formation of graphite structure.

mesoscopic

Pertaining to the size range between microscopic and macroscopic.

metallic fiber

Manufactured fiber composed of metal, plastic-coated metal, metal-coated plastic, or a core completely covered by metal.

metal-matrix composites

Advanced composites that consist of a nonmetallic reinforcement incorporated into a metallic matrix. Reinforcements may constitute from 10 to 60 vol% of the composite. Continuous fiber or filament reinforcements include graphite, silicon carbide, boron, alumina, and refractory metals. Matrix materials include aluminum (the most common), titanium, magnesium, copper, and ordered intermetallic compounds (NiAl and Ti_3Al).

M-glass

A high beryllia (BeO_2) content glass designed especially for high modulus of elasticity.

micro

In relation to composites, denotes the properties of the constituents, that is, matrix, reinforcement, and interface only, and their effects on the composite properties.

microcracking

Cracks formed in composites when thermal stresses locally exceed the strength of the matrix. Since most microcracks do not penetrate the reinforcing fibers, microcracks in a cross-plied tape laminate or in a laminate made from cloth prepreg are usually limited to the thickness of a single ply.

micromechanics

Analysis of the structural behavior of composites on a constituent (matrix, reinforcement, interface) level.

microstructure

A structure with heterogeneities that can be seen through a microscope.

mil

A unit of length used in measuring the diameter of glass fiber strands, wire, and so on (1 mil = 0.001 in., or 0.0254 mm).

milled fiber

Continuous glass strands hammer milled into very short glass fibers. Useful as inexpensive filler or anticrazing reinforcing fillers for adhesives.

modulus, initial

See initial modulus.

modulus of elasticity

The ratio of the stress or load applied to the strain or deformation produced in a material that is elastically deformed. If a tensile strength of 13.8 MPa (2.0 ksi) results in an elongation of 1%, the modulus of elasticity is 13.8 MPa (2.0 ksi) divided by 0.01, or 1380 MPa (200 ksi). Also called Young's modulus. See also offset modulus and secant modulus.

modulus, offset

See offset modulus.

modulus of resilience

The energy that can be absorbed per unit volume without creating a permanent distortion. Calculated by integrating the stress-strain curve from zero to the elastic limit and dividing by the original volume of the specimen.

modulus of rigidity

The ratio of stress to strain within the elastic region for shear or torsional stress. Also called shear modulus or torsional modulus.

modulus of rupture, in bending

The maximum tensile or compressive stress value (whichever causes failure) in the extreme fiber of a beam loaded to failure in bending.

modulus of rupture, in torsion

The maximum shear stress in the extreme fiber of a member of circular cross section loaded to failure in torsion.

modulus, secant

See secant modulus.

modulus, tangent

See tangent modulus.

Mohs hardness

A measure of the scratch resistance of a material. The higher the number, the greater the scratch resistance (No. 10 being termed diamond).

moisture absorption

The pickup of water vapor from air by a material. It relates only to vapor withdrawn from the air by a material and must be distinguished from water absorption, which is the gain in weight due to the take-up of water by immersion.

moisture content

The amount of moisture in a material determined under prescribed conditions and expressed as a percentage of the mass of the moist specimen, that is, the mass of the dry substance plus the moisture present.

moisture equilibrium

The condition reached by a sample when it no longer takes up moisture from, or gives up moisture to, the surrounding environment.

moisture vapor transmission

A rate at which water vapor passes through a material at a specified temperature and relative humidity (g/mil/24 h/100 $in.^2$).

mold

(1) The cavity or matrix into or on which the plastic composition is placed and from which it takes form. (2) To shape plastic parts or finished articles by heat and pressure. (3) The assembly of all the parts that function collectively in the molding process.

molded edge

An edge that is not physically altered after molding for use in final form, and particularly one that does not have fiber ends along its length.

molded net

Description of a molded part that requires no additional processing to meet dimensional requirements.

molding

The forming of a polymer or composite into a solid mass of prescribed shape and size by the application of pressure and heat for given times. Sometimes used to denote the finished part.

molding cycle

(1) The period of time required for the complete sequence of operations on a molding press to produce one set of moldings. (2) The operations necessary to produce a set of moldings without reference to the total time taken.

molding powder or compound

Plastic material in varying stages of pellets or granulation, and consisting of resin, filler, pigments, reinforcements, plasticizers, and other ingredients, ready for use in the molding operation.

molding pressure

The pressure applied to the ram of an injection machine, compression press, or transfer press to force the softened plastic to fill the mold cavities completely.

mold-release agent

A lubricant, liquid, or powder (often silicone oils and waxes) used to prevent sticking of molded articles in the cavity.

mold shrinkage

(1) The immediate shrinkage that a molded part undergoes when it is removed from a mold and cooled to room temperature. (2) The difference in dimensions, expressed in inches per inch, between a molding and the mold cavity in which it was molded (at normal-temperature measurement). (3) The incremental difference between the dimensions of the molding and the mold from which it was made, expressed as a percentage of the mold dimensions.

mold surface

The side of a laminate that faced the mold (tool) during cure in an autoclave or hydroclave.

molecular weight

The sum of the atomic weights of all the atoms in a molecule. A measure of the chain length for the molecules that make up the polymer.

monofilament

A single fiber or filament of indefinite length, strong enough to function as a yarn in commercial textile operations.

monolayer

The basic laminate unit from which cross-plied or other laminate types are constructed. Also, a “single” layer of atoms or molecules adsorbed on or applied to a surface.

monomer

A single molecule that can react with like or unlike molecules to form a polymer. The smallest repeating structure of a polymer (mer). For addition polymers, this represents the original unpolymerized compound.

morphology

The overall form of a polymer structure, that is, crystallinity, branching, molecular weight, and so on.

multicircuit winding

In filament winding, a winding that requires more than one circuit before the band repeats by laying adjacent to the first band.

multifilament yarn

A large number (500 to 2000) of fine, continuous filaments (often 5 to 100 individual filaments), usually with some twist in the yarn to facilitate handling.

MVT

See moisture vapor transmission.

Mylar

A trade name (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) for a polyester film used as a release sheet in adhesive and composite bonding. Also used as food packaging.

N

NDE

See nondestructive evaluation.

NDI

See nondestructive inspection.

NDT

See nondestructive testing.

neat resin

Resin to which nothing (additives, reinforcements, and so on) has been added.

necking

The localized reduction in cross section that may occur in a material under tensile stress.

needled mat

A mat formed of strands cut to a short length, then felted together in a needle loom with or without a carrier.

nesting

In reinforced plastics, the placing of plies of fabric so that the yarns of one ply lie in the valleys between the yarns of the adjacent ply (nested cloth).

net resin content prepreg

A prepreg product form that contains the final desired resin content and does not require resin bleeding (removal) during the cure process.

netting analysis

The analysis of filament- wound structures that assumes the stresses induced in the structure are carried entirely by the filaments, and the strength of the resin is neglected, and assumes also that the filaments possess no bending or shearing stiffness and carry only the axial tensile loads.

node

The connected portion of adjacent ribbons of honeycomb.

NOL ring

A parallel filament- or tape-wound hoop test specimen developed by the Naval Ordnance Laboratory (NOL) (now the Naval Surface Weapons Laboratory) for measuring various mechanical strength

properties of the material, such as tension and compression, by testing the entire ring or segments of it. Also known as a parallel fiber reinforced ring.

Nomex

A trade name (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) for an aramid fiber or paper used for honeycomb construction.

nominal stress

The stress at a point calculated on the net cross section without taking into consideration the effect on stress of geometric discontinuities, such as holes, grooves, fillets, and so on. The calculation is made by simple elastic theory.

nominal value

A value assigned for the purpose of a convenient designation. A nominal value exists in name only. It is often an average number with a tolerance so as to fit together with adjacent parts.

nondestructive evaluation (NDE)

Broadly considered synonymous with nondestructive inspection (NDI). More specifically, the analysis of NDI findings to determine whether the material will be acceptable for its function.

nondestructive inspection (NDI)

A process or procedure, such as ultrasonic or radiographic inspection, for determining the quality or characteristics of a material, part, or assembly, without permanently altering the subject or its properties. Used to find internal anomalies in a structure without degrading its properties.

nondestructive testing (NDT)

Broadly considered synonymous with nondestructive inspection (NDI).

nonhygroscopic

Lacking the property of absorbing and retaining an appreciable quantity of moisture (water vapor) from the air.

nonwoven fabric

A planar textile structure produced by loosely compressing together fibers, yarns, rovings, and so on, with or without a scrim cloth carrier. Accomplished by mechanical, chemical, thermal, or solvent means, and combinations thereof.

normal stress

The stress component that is perpendicular to the plane on which the forces act.

notched specimen

A test specimen that has been deliberately cut or notched, usually in a V-shape, to induce and locate point of failure.

notch factor

Ratio of the resilience determined on a plain specimen to the resilience determined on a notched specimen.

notch sensitivity

The extent to which the sensitivity of a material to fracture is increased by the presence of a surface nonhomogeneity, such as a notch, a sudden change in section, a crack, or a scratch. Low notch sensitivity is usually associated with ductile materials, and high notch sensitivity is usually associated with brittle materials.

novolac

A linear, thermoplastic, B-staged phenolic resin, which, in the presence of methylene or other cross-linking groups, reacts to form a thermoset phenolic.

nylon

The generic name for all synthetic polyamides.

nylon plastics

Plastics based on a resin composed principally of a long-chain synthetic polymeric amide that has recurring amide groups as an integral part of the main polymer chain. Numerical designations (nylon 6, nylon 6/6, and so on) refer to the monomeric amides of which they are made. Characterized by great toughness and elasticity.

O

off-axis laminate

A laminate whose principal axis is oriented at an angle (θ) other than 0 or 90° with respect to a reference direction, usually related to principal load or stress direction.

offset modulus

The ratio of the offset yield stress to the extension at the offset point.

offset yield strength

The stress at which the strain exceeds by a specific amount (the offset) an extension of the initial, approximately linear, proportional portion of the stress-strain curve. It is expressed in force per unit area.

olefin

A group of unsaturated hydrocarbons of the general formula C_nH_{2n} named after the corresponding paraffins by the addition of “-ene” or “-ylene” to the root, for example, ethylene, propylene, and pentene.

open-cell foam

Foamed or cellular material with cells that are generally interconnected. Closed cell refers to cells that are not interconnected.

orange peel

An uneven surface somewhat resembling that of an orange peel; said of injection moldings that have unintentionally ragged surfaces.

organic

Matter originating in plant or animal life, or composed of chemicals of hydrocarbon origin, either natural or synthetic.

orientation

The alignment of the crystalline structure in polymeric materials in order to produce a highly aligned structure. Orientation can be accomplished by cold drawing or stretching in fabrication.

oriented materials

Materials, particularly amorphous polymers and composites, whose molecules and/or macroconstituents are aligned in a specific way. Oriented materials are anisotropic. Orientation can generally be divided into two classes, uniaxial and biaxial.

orthotropic

Having three mutually perpendicular planes of elastic symmetry.

outgassing

Release of solvents and moisture from composite parts under vacuum. Also occurs during the normal curing process under vacuum.

out time

The time a prepreg is exposed to ambient temperature, namely, the total amount of time the prepreg is out of the freezer. The primary effects of out time are to decrease the drape and tack of the prepreg while also allowing it to absorb moisture from the air.

ovaloid

A surface of revolution symmetrical about the polar axis that forms the end closure for a filament-wound cylinder.

oven dry

The condition of a material that has been heated under prescribed conditions of temperature and humidity until there is no further significant change in its mass.

overlay sheet

A nonwoven fibrous mat (of glass, synthetic fiber, and so on) used as the top layer in a cloth or mat lay-up to provide a smoother finish, minimize the appearance of the fibrous pattern, or permit machining or grinding to a precise dimension. Also called surfacing mat.

oxidation

(1) In carbon/graphite fiber processing, the step of reacting the precursor polymer (rayon, PAN, or pitch) with oxygen, resulting in stabilization of the structure for the hot stretching operation. (2) In general use, oxidation refers to any chemical reaction in which electrons are transferred.

P

package

Yarn, roving, and so on in the form of units capable of being unwound and suitable for handling, storing, shipping, and use.

PAN

See polyacrylonitrile.

parallel laminate

(1) A laminate of woven fabric in which the plies are aligned in the same position as originally aligned in the fabric roll. (2) A series of flat or curved cloth-resin layers stacked uniformly on top of each other.

particulate composite

Material consisting of one or more constituents suspended in a matrix of another material. These particles are either metallic or nonmetallic.

particulate reinforced ceramic-matrix composite

A ceramic-matrix composite in which the reinforcing components are particles of equiaxed or platelet geometry (in contrast to whiskers or short fibers).

parting agent

See mold-release agent.

parting line

A mark on a molded piece where the sections of a mold have met in closing.

PAS

See polyarylsulfone.

PBI

See polybenzimidazole.

PC

See polycarbonate.

PEEK

See polyether etherketone.

peel ply

A layer of open-weave material, usually fiberglass or heat-set nylon, applied directly to the surface of a prepreg lay-up. The peel ply is removed from the cured laminate immediately before bonding operations, leaving a clean, resin-rich surface that needs no further preparation for bonding, other than application of a primer where one is required.

peel strength

Adhesive bond strength, as in pounds per inch of width, obtained by a stress applied in a peeling mode.

penetration

The entering of an adhesive into an adherend.

permanence

The property of a plastic that describes its resistance to appreciable changes in characteristics with time and environment.

permanent set

(1) The deformation remaining after a specimen has been stressed a prescribed amount in tension, compression, or shear for a definite time period and released for a definite time period. (2) For creep tests, the residual unrecoverable deformation after the load causing the creep has been removed for a substantial and definite period of time. (3) The increase in length, expressed as a percentage of the original length, by which an elastic material fails to return to original length after being stressed for a standard period of time.

permeability

The passage or diffusion (or rate of passage) of a gas, vapor, liquid, or solid through a barrier without physically or chemically affecting it.

pH

The measure of the acidity or alkalinity of a substance, neutrality being at pH 7. Acid solutions are less than 7, alkaline solutions are more than 7.

phenolic (phenolic resin)

A thermosetting resin produced by the condensation of an aromatic alcohol with an aldehyde, particularly of phenol with formaldehyde. Used in high-temperature applications with various fillers and reinforcements.

phenylsilane resins
: Thermosetting copolymers of silicone and phenolic resins. Furnished in solution form.

physical catalyst
: Radiant energy capable of promoting or modifying a chemical reaction.

PI
: See polyimide.

PIC
: See pressure-impregnation-carbonization.

pick
: An individual filling yarn, running the width of a woven fabric at right angles to the warp. Also called fill, woof, and weft.

pick count
: The number of filling yarns per inch of woven fabric.

pin holes
: Small cavities that penetrate the surface of a cured part.

pit
: A small, regular or irregular crater in the surface of a plastic, usually of a width approximately the same order of magnitude as its depth.

pitch
: A high molecular weight material left as a residue from the destructive distillation of coal and petroleum products. Pitches are used as base materials for the manufacture of certain high-modulus carbon fibers and as matrix precursors for carbon-carbon composites.

plain weave
: A weaving pattern in which the warp and fill fibers alternate; that is, the repeat pattern is warp/fill/warp/fill, and so on. Both faces of a plain weave are identical. Properties are significantly reduced relative to a weaving pattern with fewer crossovers.

planar
: Lying essentially in a single plane.

planar helix winding
: A winding in which the filament path on each dome lies on a plane that intersects the dome, while a helical path over the cylindrical section is connected to the dome paths.

planar winding
: A winding in which the filament path lies on a plane that intersects the winding surface. See also polar winding.

plastic
: (1) A material that contains as an essential ingredient an organic polymer of large molecular weight, hardeners, fillers, reinforcements, and so on; is solid in its finished state; and, at some stage in its manufacture or its processing into finished articles, can be shaped by flow. (2) Made of plastic. A plastic may be either thermoplastic or thermoset.

plastic deformation
: Change in dimensions of an object under load that is not recovered when the load is removed, as opposed to elastic deformation.

plastic flow
: Deformation under the action of a sustained hot or cold force. Flow of semisolids in the molding of plastics.

plasticizer
: (1) A material incorporated in a plastic to increase its workability and flexibility or distensibility. Normally used in thermoplastics. (2) A lower molecular weight material added to an epoxy to reduce stiffness and brittleness, thereby resulting in a lower glass transition temperature for the polymer.

plastic memory

The tendency of a thermoplastic material that has been stretched while hot to return to its unstretched shape upon being reheated.

platens

The mounting plates of a press, to which the entire mold assembly is bolted.

plied yarn

Yarn made by collecting two or more single yarns. Normally, the yarns are twisted together, though sometimes they are collected without twist.

ply

(1) In general, fabrics or felts consisting of one or more layers (laminates, and so on). (2) The layers that make up a stack. (3) Yarn resulting from twisting operations (three-ply yarn, and so on). (4) A single layer of prepreg. (5) A single pass in filament winding (two plies forming one layer).

PMMA

See polymethyl methacrylate.

PMR polyimides

A novel class of high-temperature-resistant polymers. PMR represents in situ polymerization of monomer reactants.

Poisson's ratio

(1) The ratio of the change in lateral width per unit width to change in axial length per unit length caused by the axial stretching or stressing of a material. (2) The ratio of transverse strain to the corresponding axial strain below the proportional limit.

polar boss

In filament winding, a metal end fitting located in the center of each dome that describes the pole about which winding bands are wrapped.

polar winding

A winding in which the filament path passes tangent to the polar opening at one end of the chamber and tangent to the opposite side of the polar opening at the other end. A one-circuit pattern is inherent in the system.

polyacrylonitrile (PAN)

Used as a base material or precursor in the manufacture of certain carbon fibers.

polyamide

A thermoplastic polymer in which the structural units are linked by amide or thio-amide groupings (repeated nitrogen and hydrogen groupings). Many polyamides are fiber-forming.

polyamideimide

A polymer containing both amide (nylon) and imide (as in polyimide) groups; properties combine the benefits and disadvantages of both.

polyamide plastic

See nylon plastics.

polyarylsulfone (PAS)

A high-temperature-resistant thermoplastic with T_g values ranging from 190 to 275 °C (375 to 525 °F). The term is also occasionally used to describe the family of resins that includes polysulfone and polyethersulfone.

polybenzimidazole (PBI)

A condensation polymer of diphenyl isophthalate and 3,3′-diaminobenzidine. Extremely high-temperature resistant. Available as adhesive and fiber.

polycarbonate (PC)

A thermoplastic polymer derived from the direct reaction between aromatic and aliphatic dihydroxy compounds with phosgene, or by the ester exchange reaction with appropriate phosgene-derived precursors. Highest impact resistance of any transparent plastic.

polycondensation

See condensation polymerization.

polyesters, thermoplastic

See thermoplastic polyesters.

polyesters, thermosetting

See thermosetting polyesters.

polyether etherketone (PEEK)
: A linear aromatic crystalline thermoplastic. A composite with a PEEK matrix may have a continuous-use temperature as high as 250 °C (480 °F).

polyetherimide
: An amorphous polymer with good thermal properties, for a thermoplastic. Reported T_g of 215 °C (419 °F) and continuous-use temperature of about 170 °C (338 °F).

polyimide (PI)
: A polymer produced by reacting an aromatic dianhydride with an aromatic diamine. It is a highly heat-resistant resin ≥ 315 °C (600 °F). Similar to a polyamide, differing only in the number of hydrogen molecules contained in the groupings. Suitable for use as a binder or adhesive. May be either thermoplastic or thermoset.

polymer
: A high molecular weight organic compound, natural or synthetic, whose structure can be represented by a repeated small unit, the mer, for example, polyethylene, rubber, and cellulose. Synthetic polymers are formed by addition or condensation polymerization of monomers. Some polymers are elastomers, some are plastics, and some are fibers. When two or more dissimilar monomers are involved, the product is called a copolymer. The chain lengths of commercial thermoplastics vary from near a thousand to over one hundred thousand repeating units. Thermosetting polymers approach infinity after curing, but their resin precursors, often called prepolymers, may be relatively short—6 to 100 repeating units—before curing. The lengths of polymer chains, usually measured by molecular weight, have very significant effects on the performance properties of plastics and profound effects on processibility.

polymerization
: A chemical reaction in which the molecules of a monomer are linked together to form large molecules whose molecular weight is a multiple of that of the original substance. When two or more monomers are involved, the process is called copolymerization.

polymer matrix
: The resin portion of a reinforced or filled plastic.

polymethyl methacrylate (PMMA)
: A thermoplastic polymer synthesized from methyl methacrylate. It is a transparent solid with exceptional optical properties; available in the form of sheets, granules, solutions, and emulsions. Used as facing material in certain composite constructions. See also acrylic plastic.

polyphenylene sulfide (PPS)
: A high-temperature thermoplastic useful primarily as a molding compound. Optimal properties depend on slightly cross-linking the resin. Known for chemical resistance.

polypropylene
: A tough, lightweight thermoplastic made by the polymerization of high- purity propylene gas in the presence of an organometallic catalyst at relatively low pressures and temperatures.

polysulfide
: A synthetic polymer containing sulfur and carbon linkages, produced from organic dihalides and sodium polysulfide. Material is elastomeric in nature, resistant to light, oil, and solvents, and impermeable to gases.

polysulfone
: A high-temperature-resistant thermoplastic polymer with the sulfone linkage, with a T_g of 190 °C (375 °F).

polyurethane
: A thermosetting resin prepared by the reaction of diisocyanates with polyols, polyamides, alkyd polymers, and polyether polymers. See also isocyanate plastics and urethane plastics.

porosity
: A condition of trapped pockets of air, gas, or vacuum within a solid material. Usually expressed as a percentage of the total nonsolid volume to the total volume (solid plus nonsolid) of a unit quantity of material.

postcure
: Additional elevated-temperature cure, usually without pressure, to improve final properties and/or complete the cure, or decrease the percentage of volatiles in the compound. In certain resins, complete

cure and ultimate mechanical properties are attained only by exposure of the cured resin to higher temperatures than those of curing.

postforming

The forming, bending, or shaping of fully cured, C-staged thermoset laminates that have been heated to make them flexible. On cooling, the formed laminate retains the contours and shape of the mold over which it has been formed.

pot life

The length of time that a catalyzed thermosetting resin system retains a viscosity low enough to be used in processing. Also called working life.

PPS

See polyphenylene sulfide.

precision

The closeness of agreement between the results of individual replicated measurements or tests. Precision may be expressed as the standard deviation of the data. Compare with accuracy.

precure

The full or partial setting of a synthetic resin or adhesive in a joint before the clamping operation is complete or before pressure is applied.

precursor

For carbon or graphite fiber, the rayon, PAN, or pitch fibers from which carbon and graphite fibers are derived.

prefit

A process for checking the fit of mating detail parts in an assembly prior to adhesive bonding, to ensure proper bond lines. Mechanically fastened structures are sometimes prefitted to establish shimming requirements.

preform

(1) A preshaped fibrous reinforcement formed by distribution of chopped fibers or cloth by air, water flotation, or vacuum over the surface of a perforated screen to the approximate contour and thickness desired in the finished part. (2) A preshaped fibrous reinforcement of mat or cloth formed to the desired shape on a mandrel or mock-up before being placed in a mold press.

preform binder

A resin applied to the chopped strands of a preform, usually during its formation, and cured so that the preform will retain its shape and can be handled.

pregel

An unintentional, extra layer of cured resin on part of the surface of a reinforced plastic. Not related to gel coat.

preheating

The heating of a compound before molding or casting, to facilitate the operation or reduce the molding cycle.

preimpregnation

The practice of mixing resin and reinforcement and effecting partial cure before use or shipment to the user. See also prepreg.

premix

A molding compound prepared prior to and apart from the molding operations and containing all components required for molding: Resin, reinforcement, fillers, catalysts, release agents, and other ingredients.

premolding

The lay-up and partial cure at an intermediate cure temperature of a laminated or chopped-fiber detail part to stabilize its configuration for handling and assembly with other parts for final cure.

preply

A composite material lamina in the raw- material stage, ready to be fabricated into a finished laminate. The lamina is usually combined with other raw laminae before fabrication. A preply includes a fiber system that is placed in position relative to all or part of the required matrix material to constitute the finished lamina. An organic matrix preply is called a prepreg. Metal-matrix preplies include green tape, flame-sprayed tape, and consolidated monolayers.

prepolymer

A chemical intermediate whose molecular weight is between that of the monomer or monomers and the final polymer or resin.

prepreg

Either ready-to-mold material in sheet form or ready-to-wind material in roving form, which may be cloth, mat, unidirectional fiber, or paper impregnated with resin and stored for use. The resin is partially cured to a B-stage and supplied to the fabricator, who lays up the finished shape and completes the cure with heat and pressure. The two distinct types of prepreg available are (1) commercial prepregs, where the roving is coated with a hot melt or solvent system to produce a specific product to meet specific customer requirements; and (2) wet prepreg, where the basic resin is installed without solvents or preservatives but has limited room-temperature shelf life.

press clave

A simulated autoclave made by using the platens of a press to seal the ends of an open chamber, providing both the force required to prevent loss of the pressurizing medium and the heat required to cure the laminate inside.

pressure bag molding

A process for molding reinforced plastics in which a tailored, flexible bag is placed over the contact lay-up on the mold, sealed, and clamped in place. Fluid pressure, usually provided by compressed air or water, is placed against the bag, and the part is cured.

pressure-impregnation-carbonization (PIC)

A densification process for carbon-carbon composites involving pitch impregnation and carbonization under high temperature and isostatic pressure conditions. This process is carried out in hot isostatic press (HIP) equipment.

pressure intensifier

A layer of flexible material (usually a high-temperature rubber) used to ensure the application of sufficient pressure to a location, such as a radius, in a lay-up being cured.

pressure-sensitive adhesive

A viscoelastic material that, in solvent-free form, remains permanently tacky. Such material will adhere instantaneously to most solid surfaces with the application of very light pressure.

primer

A coating applied to a surface, before the application of an adhesive, lacquer, enamel, and so on, to improve the adhesion performance or load-carrying ability of the bond.

processing window

The range of processing conditions, such as stock (melt) temperature, pressure, shear rate, and so on, within which a particular grade of plastic can be fabricated with optimal or acceptable properties by a particular fabricating process, such as extrusion, injection molding, sheet molding, and so on. The processing window for a particular plastic can vary significantly with design of the part and the mold, with the fabricating machinery used, and with the severity of the end-use stresses.

promoter

A chemical, itself a feeble catalyst, that greatly increases the activity of a given catalyst. See also accelerator.

proof

To test a component or system at its peak operating load or pressure.

proof pressure

The test pressure that pressurized components shall sustain without detrimental deformation or damage. The proof pressure test is used to give evidence of satisfactory workmanship and material quality.

proportional limit

The maximum stress that a material is capable of sustaining without deviation from proportionality of stress and strain (Hooke's law). It is expressed in force per unit area. See also elastic limit.

prototype

A model suitable for use in complete evaluation of form, design, performance, and material processing.

puckers

Areas on prepreg materials where material has locally blistered from the separator film or release paper.

pulp molding

The process by which a resin- impregnated pulp material is preformed by application of a vacuum and subsequently is oven cured or molded.

pultrusion
: A continuous process for manufacturing composites that have a constant cross- sectional shape. The process consists of pulling a fiber-reinforcing material through a resin impregnation bath and through a shaping die, where the resin is subsequently cured.

pyrolysis
: With respect to fibers, the thermal process by which organic precursor fiber materials, such as rayon, polyacrylonitrile (PAN), and pitch, are chemically changed into carbon fiber by the action of heat in an inert atmosphere. Pyrolysis temperatures can range from 800 to 2800 °C (1470 to 5070 °F), depending on the precursor. Higher processing graphitization temperatures of 1900 to 3000 °C (3450 to 5430 °F) generally lead to higher modulus carbon fibers, usually referred to as graphite fibers. During the pyrolysis process, molecules containing oxygen, hydrogen, and nitrogen are driven from the precursor fiber, leaving continuous chains of carbon.

Q

quasi-isotropic laminate
: A laminate approximating isotropy by orientation of plies in several or more directions.

R

random pattern
: A winding with no fixed pattern. If a large number of circuits is required for the pattern to repeat, a random pattern is approached. A winding in which the filaments do not lie in an even pattern.

reaction injection molding (RIM)
: A process for molding polyurethane, epoxy, and other liquid chemical systems. Mixing of two to four components in the proper chemical ratio is accomplished by a high-pressure impingement-type mixing head, from which the mixed material is delivered into the mold at low pressure, where it reacts (cures). Also known as structural reaction injection molding.

reinforced plastics
: Molded, formed, filament- wound, tape-wrapped, or shaped plastic parts consisting of resins to which reinforcing fibers, mats, fabrics, and so on, have been added before the forming operation to provide some strength properties greatly superior to those of the base resin.

reinforced reaction injection molding (RRIM)
: A reaction injection molding with a reinforcement added. See also reaction injection molding.

reinforcement
: A strong material bonded into a matrix to improve its mechanical properties. Reinforcements are usually long fibers, chopped fibers, whiskers, particulates, and so on. The term should not be used synonymously with filler.

relaxation time
: The time required for a stress under a sustained constant strain to diminish by a stated fraction of its initial value.

relaxed stress
: The initial stress minus the remaining stress at a given time during a stress- relaxation test.

release agent
: A material that is applied in a thin film to the surface of a mold to keep the resin from bonding to the mold. Also called parting agent. See also mold-release agent.

release film
: An impermeable layer of film that does not bond to the resin being cured. See also separator.

release paper
: A sheet, serving as a protectant or carrier, or both, for an adhesive film or mass, which is easily removed from the film or mass prior to use.

residual strain
: The strain associated with residual stress.

residual stress

The stress existing in a body at rest, in equilibrium, at uniform temperature, and not subjected to external forces. Often caused by the forming and curing process.

resilience

(1) The ratio of energy returned, on recovery from deformation, to the work input required to produce the deformation (usually expressed as a percentage). (2) The ability to regain an original shape quickly after being strained or distorted.

resin

A solid or pseudosolid organic material, usually of high molecular weight, that exhibits a tendency to flow when subjected to stress. It usually has a softening or melting range, and fractures conchoidally. Most resins are polymers. In reinforced plastics, the material used to bind together the reinforcement material; the matrix. See also polymer.

resin content

The amount of resin in a laminate expressed as either a percentage of total weight or total volume.

resin film infusion (RFI)

A variant of the resin transfer molding process in which a layer of solid resin film is placed along with a dry preform in a matched die. During the autoclave cure cycle, the resin film melts and flows to impregnate the dry preform.

resinoid

Any class of thermosetting synthetic resins, either in their initial temporarily fusible state or in their final infusible state.

resin pocket

An apparent accumulation of excess resin in a small, localized section visible on cut edges of molded surfaces, or internal to the structure and nonvisible. See also resin- rich area.

resin-rich area

Localized area filled with resin and lacking reinforcing material. See also resin pocket.

resin-starved area

Localized area of insufficient resin, usually identified by low gloss, dry spots, or fiber showing on the surface.

resin system

A mixture of resin and ingredients such as catalyst, initiator, diluents, and so on, required for the intended processing and final product.

resin transfer molding (RTM)

A process whereby catalyzed resin is transferred or injected into an enclosed mold in which the fiberglass reinforcement has been placed. See also resin film infusion and vacuum-assisted resin transfer molding.

resistivity

The ability of a material to resist passage of electrical current either through its bulk or on a surface.

resite

See preferred term C-stage.

resitol

See preferred term B-stage.

resole

See preferred term A-stage.

reverse helical winding

In filament winding, as the fiber delivery arm traverses one circuit, a continuous helix is laid down, reversing direction at the polar ends, in contrast to biaxial, compact, or sequential winding. The fibers cross each other at definite equators, the number depending on the helix. The minimum region of crossover is three.

reverse impact test

A test in which one side of a sheet of material is struck by a pendulum or falling object, and the reverse side is inspected for damage.

RFI

See resin film infusion.

rheology

The study of the flow of materials, particularly plastic flow of solids and the flow of non-Newtonian liquids. The science treating the deformation and flow of matter.

rib

A reinforcing member designed into a plastic part to provide lateral, horizontal, hoop, or other structural support.

RIM

See reaction injection molding.

rise time

In urethane foam molding, the time between the pouring of the urethane mix and the completion of foaming.

Rockwell hardness

A value derived from the increase in depth of an impression as the load on an indenter is increased from a fixed minimum value to a higher value and then returned to the minimum value. Indenters for the Rockwell test include steel balls of several specific diameters and a diamond cone penetrator having an included angle of 120° with a spherical tip having a radius of 0.2 mm (0.0070 in.). Rockwell hardness numbers are always quoted with a prefix representing the Rockwell scale corresponding to a given combination of load and indenter, for example, HRC 30.

room-temperature curing adhesive

An adhesive that sets (to handling strength) within an hour at temperatures from 20 to 30 °C (68 to 86 °F) and later reaches full strength without heating.

room-temperature vulcanizing (RTV)

Vulcanization or curing at room temperature by chemical reaction; usually applies to silicones and other rubbers.

roving

A number of yarns, strands, tows, or ends collected into a parallel bundle with little or no twist.

roving ball

The supply package offered to the winder, consisting of a number of ends or strands wound to a given outside diameter onto a length of cardboard tube. Usually designated by either fiber weight or length in yards.

roving cloth

A textile fabric, coarse in nature, woven from rovings.

R-ratio (*R*-factor)

In cyclic fatigue testing, the ratio of applied minimum stress to maximum stress. When $R = -1$, the cycle is equally compressive and tensile.

RRIM

See reinforced reaction injection molding.

RTM

See resin transfer molding.

RTV

See room-temperature vulcanizing.

rubber

Cross-linked polymers having glass transition temperature below room temperature that exhibit highly elastic deformation and have high elongation.

rule of mixtures

When two materials are mixed together, it is normally the case that the properties of the mixture are an average of the properties of the constituents according to the proportion of each in the mixture. This applies, for example, to particulate reinforced composites and fillers in resins.

rupture

(1) A cleavage or break resulting from physical stress. (2) Work of rupture. (3) The integral of the stress-strain curve between the origin and the point of rupture.

S

safe life

See fatigue life.

sandwich construction

Panels composed of a lightweight core material, such as honeycomb, foamed plastic, and so on, to which two relatively thin, dense, high-strength or high-stiffness faces or skins are adhered.

satin

A type of finish having a satin or velvety appearance, specified for plastics or composites.

satin weave

See harness satin.

S-basis

The S-basis property allowable is the minimum value specified by the appropriate federal, military, SAE, ASTM, or other recognized and approved specifications for the material.

SBS

See short beam shear.

scarf joint

A joint made by cutting away similar angular segments on two adherends and bonding the adherends with the cut areas fitted together. See also lap joint.

scrim

A low-cost reinforcing fabric made from continuous filament yarn in an open-mesh construction. Used in the processing of tape or other B-stage material to facilitate handling. Also used as a carrier of adhesive, to be used in secondary bonding.

sealant

A material applied to a joint in paste or liquid form that hardens or cures in place, forming a seal against gas or liquid entry.

secant modulus

Idealized Young's modulus derived from a secant drawn between the origin and any point on a nonlinear stress-strain curve. On materials whose modulus changes with stress, the secant modulus is the average of the zero applied stress point and the maximum stress point being considered. See also tangent modulus.

secondary bonding

The joining together, by the process of adhesive bonding, of two or more already cured composite parts, during which the only chemical or thermal reaction occurring is the curing of the adhesive itself.

secondary structure

In aircraft and aerospace applications, a structure that is not critical to flight safety.

self-extinguishing resin

A resin formulation that will burn in the presence of a flame but will extinguish itself within a specified time after the flame is removed.

self-skinning foam

A urethane foam that produces a tough outer surface over a foam core upon curing.

selvage

The woven-edge portion of a fabric parallel to the warp.

semicrystalline

In plastics, materials that exhibit localized crystallinity. See also crystalline plastic.

separator

A permeable layer that also acts as a release film. Porous Teflon-coated fiberglass is an example. Often placed between lay-up and bleeder to facilitate bleeder system removal from laminate after cure.

set

(1) The irrecoverable or permanent deformation or creep after complete release of the force producing the deformation. (2) To convert an adhesive into a fixed or hardened state by chemical or physical action, such as condensation, polymerization, oxidation, vulcanization, gelation, hydration, or evaporation of volatile constituents.

set up

To harden, as in curing of a polymer resin.

S-glass

A magnesium aluminosilicate composition that is especially designed to provide very high tensile strength glass filaments. S- glass and S-2 glass fibers have the same glass composition but different finishes (coatings). S-glass is made to more demanding specifications, and S-2 is considered the commercial grade.

shear

(1) An action or stress resulting from applied forces that causes or tends to cause two contiguous parts of a body to slide relative to each other in a direction parallel to their plane of contact. (2) In interlaminar shear, the plane of contact is composed primarily of resin. See also shear strength and shear stress.

shear compliance

See compliance.

shear edge

The cutoff edge of the mold.

shear modulus

The ratio of shearing stress to shearing strain within the proportional limit of the material.

shear strain

The tangent of the angular change, caused by a force between two lines originally perpendicular to each other through a point in a body. Also called angular strain.

shear strength

The maximum shear stress that a material is capable of sustaining. Shear strength is calculated from the maximum load during a shear or torsion test and is based on the original cross-sectional area of the specimen.

shear stress

The component of stress tangent to the plane on which the forces act.

sheet molding compound (SMC)

A composite of fibers, usually a polyester resin, and pigments, fillers, and other additives that have been compounded and processed into sheet form to facilitate handling in the molding operation.

shelf life

The length of time a material, substance, product, or reagent can be stored under specified environmental conditions and continue to meet all applicable specification requirements and/or remain suitable for its intended function.

shell tooling

A mold or bonding fixture consisting of a contoured surface shell supported by a substructure to provide dimensional stability.

shoe

A device for gathering filaments into a strand, in glass fiber forming.

Shore hardness

A measure of the resistance of material to indentation by a spring-loaded indenter. The higher the number, the greater the resistance. Normally used for rubber materials.

short beam shear (SBS)

A flexural test of a specimen having a low test span-to-thickness ratio (for example, 4:1), such that failure is primarily in shear.

short shot

Injection of insufficient material to fill the mold.

shot capacity

The maximum weight of material an injection machine can provide from one forward motion of the ram, screw, or plunger.

shrinkage

The relative change in dimension from the length measured on the mold when it is cold to the length of the molded object 24 h after it has been taken out of the mold.

silicon carbide

Reinforcement, in whisker, particulate, and fine or large fiber, that has application as metal-matrix reinforcement because of its high strength and modulus, density equal to that of aluminum, and comparatively low cost. As a whisker or particulate, it gives the composite isotropic properties.

silicone plastics

Plastics based on resins in which the main polymer chain consists of alternating silicon and oxygen atoms, with carbon-containing side groups. Derived from silica (sand) and methyl chlorides and furnished in different molecular weights, including liquids and solid resins and elastomers.

single-circuit winding

A winding in which the filament path makes a complete traverse of the chamber, after which the following traverse lies immediately adjacent to the previous one.

sink mark

A shallow depression or dimple on the surface of an injection-molded part due to collapsing of the surface following local internal shrinkage after the gate seals. An incipient short shot.

sintering

The bonding of powders by solid-state diffusion, resulting in the absence of a separate bonding phase. The process is generally accompanied by an increase in strength, ductility, and, occasionally, density.

size

Any treatment consisting of starch, gelatin, oil, wax, or other suitable ingredient applied to yarn or fibers at the time of formation to protect the surface and aid the process of handling and fabrication or to control the fiber characteristics. The treatment contains ingredients that provide surface lubricity and binding action, but unlike a finish, contains no coupling agent. Before final fabrication into a composite, the size is usually removed by heat cleaning, and a finish is applied.

sizing content

The percent of the total strand weight made up by the sizing; usually determined by burning off or dissolving the organic sizing; known as loss on ignition.

skein

A continuous filament, strand, yarn, or roving, wound up to some measurable length and usually used to measure various physical properties.

skin

The relatively dense material that may form the surface of a cellular plastic or of a sandwich.

skirt

The extension of a motorcase from the tangency plane, used for interstage connections, usually wound or laid up as an integral part of the case.

slenderness ratio

The unsupported effective length of a uniform column divided by the least radius of gyration of the cross-sectional area.

slip

The relative collinear displacement of the adherends on either side of the adhesive layer in the direction of the applied load.

slip angle

The angle at which a tensioned fiber will slide off a filament-wound dome. If the difference between the wind angle and the geodesic angle is less than the slip angle, fiber will not slide off the dome. Slip angles for different fiber-resin systems vary and must be determined experimentally.

slippage

Undesired movement of the adherends with respect to one another during the bonding process.

sliver

A number of staple or continuous-filament fibers aligned in a continuous strand without twist. Pronounced “slyver.” See also strand.

slurry preforming

Method of preparing reinforced plastic preforms by wet processing techniques similar to those used in the pulp molding industry. For example, glass fibers suspended in water are passed through a screen that passes the water but retains the fibers in the form of a mat.

SMC

See sheet molding compound.

S-*N* diagram

(1) A plot of stress (*S*) against the number of cycles to failure (*N*) in fatigue testing. A log scale is normally used for *N*. For *S*, a linear scale is often used, but sometimes a log scale is used here, too. (2) A

representation of the number of alternating stress cycles a material can sustain without failure at various maximum stresses.

softening range

The range of temperatures in which a plastic changes from a rigid to a soft state. Actual values will depend on the test method. Sometimes erroneously referred to as softening point.

solvation

The process of swelling, gelling, or dissolving a resin by a solvent or plasticizer.

specific gravity

The density (mass per unit volume) of any material divided by that of water at a standard temperature.

specific heat

The quantity of heat required to raise the temperature of a unit mass of a substance 1° under specified conditions.

specific properties

Material properties divided by the material density.

SPF

See superplastic forming.

splay

A fanlike surface defect near the gate on a part.

splice

The joining of two ends of glass fiber yarn or strand, usually by means of an air- drying adhesive.

sprayed-metal molds

Molds made by spraying molten metal onto a master until a shell of predetermined thickness is achieved. The shell is then removed and backed up with plaster, cement, casting resin, or other suitable material. Used primarily as a mold in the sheet- forming process.

spray-up

Technique in which a spray gun is used as an applicator tool. In reinforced plastics, for example, fibrous glass and resin can be simultaneously deposited in a mold. In essence, roving is fed through a chopper and ejected into a resin stream that is directed at the mold by either of two spray systems. In foamed plastics, fast-reacting urethane foams or epoxy foams are fed in liquid streams to the gun and sprayed on the surface. On contact, the liquid starts to foam.

spread

The quantity of adhesive per unit joint area applied to an adherend, usually expressed in pounds of adhesive per thousand square feet of joint area.

spring constant

The number of pounds required to compress a spring or specimen 25 mm (1 in.) in a prescribed test procedure.

sprue

A single hole through which thermoset molding compounds are injected directly into the mold cavity.

spun roving

A heavy, low-cost glass or aramid fiber strand consisting of filaments that are continuous but doubled back on themselves.

stabilization

In carbon fiber forming, the process used to render the carbon fiber precursor infusible prior to carbonization.

stabilized core

Honeycomb cores in which the cells have been filled with a specified reinforcing material.

stacking sequence

A description of a laminate that details the ply orientations and their sequence in the laminate.

staging

Heating a premixed resin system, such as in a prepreg, until the chemical reaction (curing) starts, but stopping the reaction before the gel point is reached. Staging is often used to reduce resin flow in subsequent press molding operations.

staple fibers

Fibers of spinnable length manufactured directly or by cutting continuous filaments to short lengths (usually 12.7 to 50 mm, or 1/2 to 2 in. long; 1 to 5 denier).

starved area

An area in a plastic part that has an insufficient amount of resin to wet out the reinforcement completely. This condition may be due to improper wetting, impregnation, or resin flow; excessive molding pressure; or improper bleeder cloth thickness.

starved joint

An adhesive joint that has been deprived of the proper film thickness of adhesive due to insufficient adhesive spreading or to the application of excessive pressure during the lamination process.

static fatigue

Failure of a part under continued static load. Analogous to creep rupture failure in metals testing, but often the result of aging accelerated by stress.

static modulus

The ratio of stress to strain under static conditions. It is calculated from static stress-strain tests, in shear, compression, or tension. Expressed in force per unit area.

static stress

A stress in which the force is constant or slowly increasing with time, for example, test to failure without shock.

stiffness

(1) A measure of modulus. (2) The relationship of load and deformation. (3) The ratio between the applied stress and resulting strain. (4) A term often used when the relationship of stress to strain does not conform to the definition of Young's modulus. See also stress-strain.

stitching

A method of three-dimensional (translaminar) reinforcement in which a needle is used to insert a reinforcing thread (usually aramid or glass) through a two-dimensional laminate. Both dry preforms and prepreg laminates have been stitched.

stops

Metal pieces inserted between die halves. Used to control the thickness of a press- molded part. Not a recommended practice, because the resin will receive less pressure, which can result in voids.

storage life

The period of time during which a liquid resin, packaged adhesive, or prepreg can be stored under specified temperature conditions and remain suitable for use. Also called shelf life.

storage modulus

A quantitative measure of elastic properties in polymers, defined as the ratio of the stress, in phase with the strain, to the magnitude of the strain. The storage modulus may be measured in tension, flexure, compression, or shear.

strain

Elastic deformation due to stress. Measured as the change in length per unit of length in a given direction, and expressed in percentage or mm/mm (in./in.).

strain, axial

See axial strain.

strain gage

Device to measure strain in a stressed material based on the change in electrical resistance.

strain, initial

See initial strain.

strain relaxation

Reduction in internal strain over time. Similar molecular processes occur as in creep, except that the body is constrained.

strain, residual

See residual strain.

strain, shear

See shear strain.

strain, transverse

See transverse strain.

strain, true
See true strain.
strand
Normally an untwisted bundle or assembly of continuous filaments used as a unit, including slivers, tows, ends, yarn, and so on. Sometimes a single fiber or filament is called a strand.
strand count
The number of strands in a plied yarn. The number of strands in a roving.
strand integrity
The degree to which the individual filaments making up the strand or end are held together by the applied sizing.
strand tensile test
A tensile test of a single resin-impregnated strand of any fiber.
strength, compressive
See compressive strength.
strength, flexural
See flexural strength.
strength, shear
See shear strength.
strength, tensile
See tensile strength.
strength, wet
See wet strength.
strength, yield
See yield strength.
stress
The internal force per unit area that resists a change in size or shape of a body. Expressed in force per unit area.
stress concentration
On a macromechanical level, the magnification of the level of an applied stress in the region of a notch, void, hole, or inclusion.
stress-concentration factor
The ratio of the maximum stress in the region of a stress concentrator, such as a hole, to the stress in a similar strained area without a stress concentrator.
stress corrosion
Preferential attack of areas under stress in a corrosive environment, where such an environment alone would not have caused corrosion.
stress crack
External or internal cracks in a plastic caused by tensile stresses less than that of its short-time mechanical strength, frequently accelerated by the environment to which the plastic is exposed. The stresses that cause cracking may be present internally or externally or may be combinations of these stresses. See also crazing.
stress cracking
The failure of a material by cracking or crazing some time after it has been placed under load. Time-to-failure may range from minutes to years. Causes include molded-in stresses, postfabrication shrinkage or warpage, and hostile environment.
stress, fracture
See fracture stress.
stress, initial (instantaneous)
See initial (instantaneous) stress.
stress, nominal
See nominal stress.
stress, normal
See normal stress.
stress relaxation

The decrease in stress under sustained, constant strain. Also called stress decay.

stress, relaxed
: See relaxed stress.

stress, residual
: See residual stress.

stress, shear
: See shear stress.

stress-strain
: Stiffness at a given strain.

stress-strain curve
: Simultaneous readings of load and deformation, converted to stress and strain, plotted as ordinates and abscissae, respectively, to obtain a stress-strain diagram.

stress, tensile
: See tensile stress.

stress, torsional
: See torsional stress.

stress, true
: See true stress.

structural adhesive
: Adhesive used for transferring required loads between adherends exposed to service environments typical for the structure involved.

structural bond
: A bond that joins basic load- bearing parts of an assembly. The load may be either static or dynamic.

structural reaction injection molding
: See reaction injection molding.

structural sandwich construction
: A laminar construction comprising a combination of alternating dissimilar simple or composite materials assembled and intimately fixed in relation to each other so as to use the properties of each to attain specific structural advantages for the whole assembly.

superplastic forming (SPF)
: A strain rate sensitive metal forming process that uses characteristics of materials exhibiting high elongation-to-failure.

surface preparation
: Physical and/or chemical preparation of an adherend to make it suitable for adhesive bonding.

surface treatment
: A material (size or finish) applied to fibrous material during the forming operation or in subsequent processes. For carbon fiber surface treatment, the process used to enhance bonding capability of fiber to resin.

surfacing mat
: A very thin mat, usually 180 to 510 μm (7 to 20 mil) thick, of highly filamentized fiberglass, used primarily to produce a smooth surface on a reinforced plastic laminate, or for precise machining or grinding.

symmetrical laminate
: A composite laminate in which the sequence of plies below the laminate midplane is a mirror image of the stacking sequence above the midplane.

syntactic foams
: Composites made by mixing hollow microspheres of glass, epoxy, phenolic, and so on, into fluid resins (with additives and curing agents) to form a moldable, curable, lightweight, fluid mass, as opposed to foamed plastic, in which the cells are formed by gas bubbles released in the liquid plastic by either chemical or mechanical action.

synthetic resin
: A complex, substantially amorphous, organic semisolid or solid material (usually a mixture) built up by chemical reaction of comparatively simple compounds, approximating the natural resins in luster, fracture, comparative brittleness, insolubility in water, fusibility or plasticity, and some degree of

rubberlike extensibility, but commonly deviating widely from natural resins in chemical constitution and behavior with reagents.

T

tabs
: Extra lengths of composite or other material at the ends of a tensile specimen to promote failure away from the grips.

tack
: Stickiness of an adhesive or filament-reinforced resin prepreg material.

tack range
: The period of time in which an adhesive will remain in the tacky-dry condition after application to the adherend, and under specified conditions of temperature and humidity.

tangent modulus
: The slope of the line at a predefined point on a static stress-strain curve, expressed in force per unit area per unit strain. This is the tangent modulus at that point in shear, tension, or compression, as the case may be. See also secant modulus.

tape
: Unidirectional prepreg fabricated in widths up to 305 mm (12 in.) for carbon and 75 mm (3 in.) for boron. Woven broad goods carbon and glass tapes up to 1250 or 1500 mm (50 or 60 in.) wide are available commercially.

tape wrapped
: Fabric tape is heated and wrapped onto a rotating mandrel and subsequently cooled to firm the surface for the next tape layer application.

Tedlar
: Trade name (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) for polyvinylfluoride (PVF) used as a waterproof film on some composites.

template
: A pattern used as a guide for cutting and laying plies.

tenacity
: The term generally used in yarn manufacture and textile engineering to denote the strength of a yarn or of a filament of a given size. Numerically, it is the grams of breaking force per denier unit of yarn or filament size. Grams per denier is expressed as gpd.

tensile compliance
: See compliance.

tensile modulus
: See Young's modulus.

tensile strength
: The maximum load or force per unit cross-sectional area, within the gage length, of the specimen. The pulling stress required to break a given specimen.

tensile strength, ultimate
: See ultimate tensile strength.

tensile stress
: The normal stress caused by forces directed away from the plane on which they act.

tenth-scale vessel
: A filament-wound material test vessel based on a one-tenth subscale of the prototype.

terpolymer
: A polymeric system that contains three monomeric units.

tex
: A unit for expressing linear density equal to the mass or weight in grams of 1000 meters of filament, fiber, yarn, or other textile strand.

textile fibers
: Fibers or filaments that can be processed into yarn or made into a fabric by interlacing in a variety of methods, including weaving, knitting, and braiding.

T_g

See glass transition temperature.

TGA

See thermogravimetric analysis.

thermal conductivity

(1) Ability of a material to conduct heat. (2) The physical constant for the quantity of heat that passes through a unit cube of a substance in unit time when the difference in temperature of two faces is 1°.

thermal endurance

The time at a selected temperature for a material or system of materials to deteriorate to some predetermined level of electrical, mechanical, or chemical performance under prescribed conditions of test.

thermal expansion molding

A process in which elastomeric tooling details are constrained within a rigid frame to generate consolidation pressure by thermal expansion during the curing cycle of the autoclave molding process.

thermal stress cracking

Crazing and cracking of some thermoplastic resins, resulting from overexposure to elevated temperatures. See also stress cracking.

thermoforming

Forming a thermoplastic material after heating it to the point where it is soft enough to be formed without cracking or breaking reinforcing fibers.

thermogravimetric analysis (TGA)

The study of the mass of a material under various conditions of temperature and pressure.

thermoplastic

Capable of being repeatedly softened by an increase of temperature and hardened by a decrease in temperature. Applicable to those materials whose change upon heating is substantially physical rather than chemical and that in the softened stage can be shaped by flow into articles by molding or extrusion.

thermoplastic polyesters

A class of thermoplastic polymers in which the repeating units are joined by ester groups. The two important types are (1) polyethylene terephthalate (PET), which is widely used as film, fiber, and soda bottles; and (2) polybutylene terephthalate (PBT), primarily a molding compound.

thermoset

A plastic that, when cured by application of heat or chemical means, changes into a substantially infusible and insoluble material.

thermosetting polyesters

A class of resins produced by dissolving unsaturated, generally linear, alkyd resins in a vinyl-type active monomer such as styrene, methyl styrene, or diallyl phthalate. Cure is effected through vinyl polymerization using peroxide catalysts and promoters or heat to accelerate the reaction. The two important commercial types are (1) liquid resins that are cross linked with styrene and used either as impregnants for glass or carbon-fiber reinforcements in laminates, filament-wound structures, and other built-up constructions, or as binders for chopped-fiber reinforcements in molding compounds, such as sheet molding compound (SMC), bulk molding compound (BMC), and thick molding compound (TMC); and (2) liquid or solid resins cross linked with other esters in chopped-fiber and mineral-filled molding compounds, for example, alkyd and diallyl phthalate.

thick adherend test

A test method for film adhesives using thick metallic adherends that allows the true shear stress, strain, and modulus of the adhesive to be determined for stress analysis of bonded joints.

thixotropic (thixotropy)

Concerning materials that are gel-like at rest but fluid when agitated. Having high static shear strength and low dynamic shear strength at the same time. To lose viscosity under stress.

thread

See fiber.

thread count

The number of yarns (threads) per inch in either the lengthwise (warp) or crosswise (fill or weft) direction of woven fabrics.

tolerance
: The specified permissible deviation from the specified nominal value of a component characteristic at standard or stated environmental conditions.

tooling resin
: Resins that have applications as tooling aids, coreboxes, prototypes, hammer forms, stretch forms, foundry patterns, and so on. Epoxy and silicone are common examples.

tool side
: The side of the part that is cured against the tool (mold or mandrel).

torsion
: Twisting stress.

torsional stress
: The shear stress on a transverse cross section caused by a twisting action.

toughness
: A measure of the ability of a material to absorb work, or the actual work per unit volume or unit mass of material that is required to rupture it. Toughness is proportional to the area under the load-elongation curve from the origin to the breaking point.

tow
: An untwisted bundle of continuous filaments. Commonly used in referring to man- made fibers, particularly carbon and graphite, but also glass and aramid. A tow designated at 140K has 140,000 filaments.

towpreg
: A tow of fibers that has been preimpregnated with a resin and is typically used in either filament winding or fiber placement operations.

TPI
: See turns per inch.

tracer
: A fiber, tow, or yarn added to a prepreg for verifying fiber alignment and, in the case of woven materials, for distinguishing warp fibers from fill fibers.

transfer molding
: Method of molding thermosetting materials in which the plastic is first softened by heat and pressure in a transfer chamber and then forced by high pressure through suitable sprues, runners, and gates into the closed mold for final shaping and curing.

transition, first order
: See first-order transition.

transition temperature
: The temperature at which the properties of a material change. Depending on the material, the transition change may or may not be reversible.

transversely isotropic
: Term describing a material exhibiting a special case of orthotropy in which properties are identical in two orthotropic dimensions but not the third. Having identical properties in both transverse directions but not in the longitudinal direction.

transverse strain
: The linear strain in a plane perpendicular to the loading axis of a specimen.

true strain
: The natural logarithm of the ratio of gage length at the moment of observation to the original gage length for a body subjected to an axial force.

true stress
: The stress along the axis calculated on the actual cross section at the time of observation instead of the original cross-sectional area. Applicable to tension and compression testing.

turns per inch (TPI)
: A measure of the amount of twist produced in a yarn, tow, or roving during its processing history. Also, the lead rate of a hoop layer at a specified band width. See also twist.

twist

The spiral turns about its axis per unit of length in a yarn or other textile strand. Twist may be expressed as turns per inch (TPI), and so forth. *S* and *Z* refer to direction of twist, in reference to whether the twist direction conforms to the middle-section slope of the particular letter.

twist, balanced

See balanced twist.

typical-basis

The typical property value is an average value. No statistical assurance is associated with this basis.

U

ultimate elongation

The elongation at rupture.

ultimate tensile strength

The ultimate or final (highest) stress sustained by a specimen in a tension test. Rupture and ultimate stress may or may not be the same.

ultrasonic testing

A nondestructive test applied to materials for the purpose of locating internal flaws or structural discontinuities by the use of high-frequency reflection or attenuation (ultrasonic beam).

ultraviolet (UV)

Zone of invisible radiations beyond the violet end of the spectrum of visible radiations. Since UV wavelengths are shorter than visible wavelengths, their photons have more energy, enough to initiate some chemical reactions and to degrade most plastics, particularly aramids.

ultraviolet (UV) stabilizer

Any chemical compound that, when admixed with a thermoplastic resin, selectively absorbs UV rays.

unbond

An area within a bonded interface between two adherends in which the intended bonding action failed to take place, or where two layers of prepreg in a cured component do not adhere to each other. Also used to denote specific areas deliberately prevented from bonding in order to simulate a defective bond, such as in the generation of quality standards specimens.

undercure

A condition of the molded article resulting from the allowance of too little time and/or temperature or pressure for adequate hardening of the molding.

undercut

A protuberance or indentation that impedes the withdrawal of a molded part from a two-piece, rigid mold. Any such protuberance or indentation, depending on the design of the mold.

uniaxial load

A condition whereby a material is stressed in only one direction along the axis or centerline of component parts.

unidirectional laminate

A reinforced plastic laminate in which substantially all of the fibers are oriented in the same direction.

unsaturated compounds

Any compound having more than one bond between two adjacent atoms, usually carbon atoms, and capable of adding other atoms at that point to reduce it to a single bond.

unsymmetric laminate

A laminate having an arbitrary stacking sequence without midplane symmetry.

urethane plastics

Plastics based on resins made by condensation of organic isocyanates with compounds or resins that contain hydroxyl groups. The resin is furnished as two component liquid monomers or prepolymers that are mixed in the field immediately before application. A great variety of materials are available, depending upon the monomers used in the prepolymers, polyols, and the type of diisocyanate employed. Extremely abrasion and impact resistant. See also isocyanate plastics and polyurethane.

UV

See ultraviolet.

V

vacuum-assisted resin transfer molding (VARTM)

A variant of the resin transfer molding process that uses only vacuum pressure to impregnate the dry preform during cure. The advantages of this process are that because only vacuum pressure is used, the tooling does not have to withstand high pressures, and only single-sided tooling is required because a vacuum bag arrangement is used on the top side.

vacuum bag molding

A process in which a sheet of flexible transparent material plus bleeder cloth and release film are placed over the lay-up on the mold and sealed at the edges. A vacuum is applied between the sheet and the lay-up. The entrapped air is mechanically worked out of the lay-up and removed by the vacuum, and the part is cured with temperature, pressure, and time. Also called bag molding.

vacuum hot pressing (VHP)

A method of processing materials (especially powders) at elevated temperatures and consolidation pressures, and low atmospheric pressures.

vacuum infusion

A resin injection technique, derived from resin transfer molding, in which the resin injection tank and inlet port are at ambient pressure and the pressure gradient is created by vacuum on the outlet port.

vapor-liquid-solid (VLS) process

A process using vapor feed gases and a liquid catalyst, and producing solid crystalline whisker growth. Used to produce silicon carbide whiskers.

VARTM

See vacuum-assisted resin transfer molding.

veil

An ultrathin mat similar to a surface mat, often composed of organic fibers as well as glass fibers.

vent

A small hole or shallow channel in a mold that allows air or gas to exit as the molding material enters.

vent cloth

A layer or layers of open-weave cloth used to provide a path for vacuum to “reach” the area over a laminate being cured, such that volatiles and air can be removed. Also causes the pressure differential that results in application of pressure to the part being cured. Also called breather cloth.

venting

In autoclave curing of a part or assembly, turning off the vacuum source and venting the vacuum bag to the atmosphere. The pressure on the part is then the difference between pressure in the autoclave and atmospheric pressure.

vermiculite

A granular material mixed with resin to form a filler of relatively high compressive strength.

VHP

See vacuum hot pressing.

vinyl esters

A class of thermosetting resins containing esters of acrylic and/or methacrylic acids, many of which have been made from epoxy resin. Cure is accomplished, as with unsaturated polyesters, by copolymerization with other vinyl monomers, such as styrene.

virgin filament

An individual filament that has not been in contact with any other fiber or any other hard material.

viscoelasticity

(1) A property involving a combination of elastic and viscous behavior in the application of which a material is considered to combine the features of a perfectly elastic solid and a perfect fluid. (2) Phenomenon of time-dependent, in addition to elastic, deformation (or recovery) in response to load.

viscosity

The property of resistance to flow exhibited within the body of a material, expressed in terms of relationship between applied shearing stress and resulting rate of strain in shear. Viscosity is usually taken to mean Newtonian viscosity, in which case the ratio of shearing stress to the rate of shearing strain is constant. In non-Newtonian behavior, which is the usual case with plastics, the ratio varies with the shearing stress. Such ratios are often called the apparent viscosities at the corresponding shearing

stresses. Viscosity is measured in terms of flow in Pa · s (P), with water as the base standard (value of 1.0). The higher the number, the less flow.

VLS process

See vapor-liquid-solid process.

void content

Volume percentage of voids, usually less than 1% in a properly cured composite. The experimental determination is indirect, that is, calculated from the measured density of a cured laminate and the "theoretical" density of the starting material.

voids

Air or gas that has been trapped and cured into a laminate. Porosity is an aggregation of microvoids. Voids are essentially incapable of transmitting structural stresses or nonradiative energy fields.

volatile content

The percent of volatiles that are driven off as a vapor from a plastic or an impregnated reinforcement.

volatiles

Materials, such as water and alcohol, in a sizing or a resin formulation, that are capable of being driven off as a vapor at room temperature or at a slightly elevated temperature.

volume fraction

Fraction of a constituent material based on its volume.

volume resistance

(1) The volume resistance between two electrodes in contact with or embedded in a specimen is the ratio between the direct voltage applied to them and that portion of the current between them that is distributed through the volume of the specimen. (2) The electrical resistance between opposite faces of a 1 cm (0.40 in.) cube of insulating material. Also called specific insulation resistance.

vulcanization

A chemical reaction in which a rubber is cured by reaction with sulfur or other suitable agents.

W

wafer

A reinforcement for motorcase port openings.

warp

The yarn running lengthwise in a woven fabric. A group of yarns in long lengths and approximately parallel. A change in dimension of a cured laminate from its original molded shape.

warpage

Dimensional distortion in a composite part.

water absorption

Ratio of the weight of water absorbed by a material to the weight of the dry material.

water break

The appearance of a discontinuous film of water on a surface signifying nonuniform wetting and usually associated with a surface contamination.

water break test

A test to determine if a surface is chemically clean by the use of a drop of water, preferably distilled water. If the surface is clean, the water will break and spread; a contaminated surface will cause the water to bead.

waterjet

Water emitted from a nozzle under high pressure (70 to 410 MPa, or 10 to 60 ksi or higher). Useful for cutting organic materials. See also abrasive waterjet.

weathering

Exposure of plastics to the outdoor environment.

weathering, artificial

See artificial weathering.

weave

The particular manner in which a fabric is formed by interlacing yarns. Usually assigned a style number.

weeping

Slow leakage manifested by the appearance of water on a surface.

weft

The transverse threads or fibers in a woven fabric. Those fibers running perpendicular to the warp. Also called fill, filling yarn, or woof.

Weibull modulus (β)

A statistical constant that relates strength to survival probability. The smaller the value of β, the greater the range of strength values for a material.

weld line

The mark visible on a finished part made by the meeting of two flow fronts of plastic material during molding. Also called weld mark or flow line.

weld mark

See flow line.

wet installation

A bolted joint in which sealant is applied to the head and shank of the fastener so that after assembly a seal is provided between the fastener and the elements being joined.

wet lay-up

A method of making a reinforced product by applying the resin system as a liquid when the reinforcement is put in place.

wet-out

The condition of an impregnated roving or yarn in which substantially all voids between the sized strands and filaments are filled with resin.

wet strength

(1) The strength of an organic matrix composite when the matrix resin is saturated with absorbed moisture, or is at a defined percentage of absorbed moisture less than saturation. (Saturation is an equilibrium condition in which the net rate of absorption under prescribed conditions falls essentially to zero). (2) The strength of an adhesive joint determined immediately after removal from a liquid in which it has been immersed under specified conditions of time, temperature, and pressure.

wetting

The spreading, and sometimes absorption, of a fluid on or into a surface.

wet winding

In filament winding, the process of winding glass on a mandrel in which the strand is impregnated with resin just before contact with the mandrel. See also dry winding.

whisker

A short single crystal fiber or filament used as a reinforcement in a matrix. Whisker diameters range from 1 to 25 μm (40 to 980 μin.), with aspect ratios between 100 and 15,000.

wind angle

The angular measure in degrees between the direction parallel to the filaments and an established reference. In filament-wound structures it is the convention to measure the wind angle with reference to the centerline through the polar bosses, that is, the axis of rotation.

winding pattern

(1) The total number of individual circuits required for a winding path to begin repeating by laying down immediately adjacent to the initial circuit. (2) A regularly recurring pattern of the filament path after a certain number of mandrel revolutions, leading eventually to the complete coverage of the mandrel.

winding tension

In filament winding or tape wrapping, the amount of tension on the reinforcement as it makes contact with the mandrel.

woof

See weft.

work hardening

(1) Increase in resistance to further deformation with continuing distortion. (2) Hardening and strengthening of a metal or alloy caused by the strain energy absorbed from prior deformation.

working life

The period of time during which a liquid resin or adhesive, after mixing with catalyst, solvent, or other compounding ingredients, remains usable. See also gelation time and pot life.

woven fabric

A material (usually a planar structure) constructed by interlacing yarns, fibers, or filaments to form such fabric patterns as plain, harness satin, or leno weaves.

woven fabric composite

A major form of advanced composite in which the fiber constituent consists of woven fabric. A woven fabric composite normally is a laminate comprised of a number of laminae, each of which consists of one layer of fabric embedded in the selected matrix material. Individual fabric laminae are directionally oriented and combined into specific multiaxial laminates for application to specific strength and stiffness requirements.

woven roving

A heavy glass fiber fabric made by weaving roving or yarn bundles.

wrinkle

A surface imperfection in laminated plastics that has the appearance of a crease or fold in one or more outer sheets of the paper, fabric, or other base, which has been pressed in. Also occurs in vacuum bag molding when the bag is improperly placed, causing a crease.

X

x-axis

In composite laminates, an axis in the plane of the laminate that is used as the 0° reference for designating the angle of a lamina.

xy-plane

In composite laminates, the reference plane parallel to the plane of the laminate.

Y

yarn

An assemblage of twisted filaments, fibers, or strands, either natural or manufactured, to form a continuous length that is suitable for use in weaving or interweaving into textile materials.

yarn bundle

See bundle.

yarn, plied

See plied yarn.

y-axis

In composite laminates, the axis in the plane of the laminate that is perpendicular to the *x*-axis. Contrast with *x*-axis.

yield point

(1) The first stress in a material, less than the maximum attainable stress, at which the strain increases at a higher rate than the stress. (2) The point at which permanent deformation of a stressed specimen begins to take place. Only materials that exhibit yielding have a yield point.

yield strength

(1) The stress at the yield point. (2) The stress at which a material exhibits a specified limiting deviation from the proportionality of stress to strain. (3) The lowest stress at which a material undergoes plastic deformation. Below this stress, the material is elastic; above it, the material is viscous. Often defined as the stress needed to produce a specified amount of plastic deformation (usually a 0.2% change in length).

Young's modulus

The ratio of normal stress to corresponding strain for tensile or compressive stresses less than the proportional limit of the material. See also modulus of elasticity.

Z

z-axis

In composite laminates, the reference axis normal to the plane of the laminate.

zero bleed

A laminate fabrication procedure that does not allow loss of resin during cure. Also describes prepreg made with the amount of resin desired in the final part, such that no resin has to be removed during cure.

10. “Standard Terminology Relating to Textiles,” ASTM D 123, *Annual Book of ASTM Standards,* Vol 07.01

11. S.W. Horstman, “Composites and Metal Bonding Glossary,” Aerospace Information Report (AIR) 4844, SAE International, 2000

12. *The Composite Materials Handbook,* MIL- HDBK-17, Department of Defense (DoD) release: Vol 1E, Materials Sciences Corporation, University of Delaware, and Army Research Laboratory, 2000

Abbreviations, Symbols, and Tradenames

Abbreviations and Symbols

a
: crack length

A
: ampere

A
: alkali (glass fiber designator)

A
: area; ratio of the alternating stress amplitude to the mean stress

Å
: angstrom

ABS
: acrylonitrile-butadiene-styrene

ac
: alternating current

AE
: acoustic emission

AES
: Auger electron spectroscopy

AESO
: acrylated epoxidized soybean oil

AFRL
: Air Force Research Laboratory

AGATE
: Advanced General Aviation Transport Experiments

AMS
: Aerospace Materials Specification

ANOVA
: analysis of variance

ANSI
: American National Standards Institute

AO
: atomic oxygen

APB
: aminophenoxy benzene

ARC
: accelerated rate calorimeter

AS
: designation for surface-treated fiber

ASR
: automobile

ASTM
: American Society for Testing and Materials

at.%
: atomic percent

ATL
: automated tape layer

atm

atmosphere (pressure)
AU
designation for untreated fiber
B
width of faces; test section length and width
BET
Brunauer-Emmett-Teller
BF3
boron trifluoride
BJSFM
bolted-joint stress field model
BMC
bulk molding compound
BMI
bismaleimide (resin)
BPA
bisphenol A
Btu
British thermal unit
BVID
barely visible impact damage
C
Kozeny constant
c
composite specific heat (c_p = constant pressure, c_v = constant volume)
CACRC
Commercial Aircraft Composite Repair Committee
CAD/CAM
computer-aided design/computer-aided manufacturing
CAE
computer aided engineering
CAI
compression after impact
CAS
calcium aluminosilicate
CAT
computer-aided tomography
C-C
carbon-carbon
CDCA
cyclohexane dicarboxylic anhydride
CFCC
continuous fiber ceramic composite
CFRC
carbon fiber reinforced composite
CFRM
continuous filament random mat
CFRP
carbon fiber reinforced plastic
CIP
cold isostatic pressing
cm
centimeter
CMC

ceramic-matrix composite
CME
coefficient of moisture expansion
CMM
coordinate measuring machine
CMOD
crack mouth opening displacement
CNC
computer numeric control
CP
commercially pure
cpm
cycles per minute
cps
cycles per second
CSAI
compression strength after impact
CSM
chopped-strand mat
CTE
coefficient of thermal expansion
CV
coefficient of variation PENDING AQ confirmation
CVD
chemical vapor deposition
CVI
chemical vapor infiltration
CVN
Charpy V-notch (impact test or specimen)
d
an operator used in mathematical expressions involving a derivative (denotes rate of change)
d
depth; diameter
da/dn
crack growth rate
dB
decibel
DABA
diallylbisphenol A
DAP
diallyl phthalate
DBTT
ductile-brittle transition temperature
dc
direct current
DCB
double-cantilever beam
DCPD
dicyclopentadiene
DDA
dynamic dielectric analysis
DEA
dielectric analysis
DERA

Defence Evaluation and Research Agency (United Kingdom)
DETA
diethylene triamine
DFMA
design for manufacture and assembly
DGEBA
diglycidyl ether of bisphenol A
DGEBF
diglycidyl ether of bisphenol F
diam
diameter
DIC
differential interference contrast
DMA
dynamic mechanical analysis
DMAC
dimethylacetamide
DMF
dimethylformamide
DMLCC,E
design and manufacturing of low-cost composites for engines
DoD
Department of Defense
DOE
Department of Energy
DOF
degrees of freedom
DRA
discontinuously reinforced aluminum
DRTi
discontinuously reinforced titanium
DSC
differential scanning calorimetry
DTA
differential thermal analysis
DTUL
deflection temperature under load
e
natural log base, 2.71828
E
electrical (designator for glass)
E
modulus of elasticity; Young's modulus
EB
electron beam
EC
eddy current
ECR
special-purpose glass fiber characterized by high corrosion resistance
EEW
epoxy per equivalent weight
EMI/RFI
electromagnetic interference/radio-frequency interference
ENF

end-notched flexure
Eq
equation
et al.
and others
ESCA
electron spectroscopy for chemical analysis
ESD
electrostatic discharge
ETD
elevated temperature, dry
ETW
elevated temperature, wet
f
fiber
F
force; strength
FAA
Federal Aviation Administration
FALN
failure analysis logic network
FE
finite element
FEM
finite element model
FAW
fiber areal weight
FCG
fatigue crack growth
FEA
finite element analysis
FEP
fluorinated ethylene propylene
FG
fiberglass
FOD
foreign object damage
FOS
factor of safety
FP
polycrystalline alumina fiber
FPL
Forest Products Laboratory
FRC
fiber reinforced composites
FRP
fiber-reinforced plastic
ft
foot
FTIR
Fourier transform infrared
g
gram
G

shear modulus
G′
storage modulus
G″
loss modulus
G_{Ic}
interlaminar fracture toughness (mode I, peel; mode II, shear; mode III, scissor shear)
gal
gallon
GFRP
glass-fiber-reinforced plastic
GMT
glass mat thermoplastics
GL/EP
glass/epoxy
GPa
gigapascal
GPC
gel permeation chromatography
gpd
grams per denier
gr
grain
GRP
glass reinforced plastic
h
hour
h
height
H
height
HAZ
heat-affected zone
HDT
heat-deflection temperature
HEPA
high-efficiency particulate air
HERF
high-energy-rate forging
HEXA
hexamethylenetetramine
HIP
hot isostatic pressing
HLU
hand lay-up
HM
high modulus
HO/MA
hydroxylated oil, maleinized
HPC
high-performance compound
HPLC
high-performance liquid chromatography
HS

high-strength
HSO/MA
hydroxylated soybean oil, maleinated
HT
high tensile
Hz
hertz
I
moment of inertia
ICP
inductively coupled plasma
ID
inside diameter
IFT
interlaminar fracture toughness
IM
intermediate modulus
IMC
in-mold coating
IMC
intermetallic-matrix composite
IR
infrared (radiation)
ISO
International Standards Organization
ISS
interlaminar shear strength
J
joule
k
notch sensitivity factor
k
thermal conductivity
K
Kelvin
K
bulk modulus
K
coefficient of thermal conductivity; bulk modulus of elasticity
K_c
plane-stress fracture toughness
K_I
stress-intensity factor
K_{Ic}
plane-strain fracture toughness; mode I critical stress-intensity factor
K_{Id}
dynamic fracture toughness
K_{Iscc}
threshold stress intensity for stress-corrosion cracking
K_t
stress-concentration factor
K_{th}
threshold crack tip stress-intensity factor
kg

kilogram
km
kilometer
kPa
kilopascal
ksi
kips (1000 lb) per square inch
kV
kilovolt
l
length
L
liter; longitudinal direction
L
length
lb
pound
LCF
low cycle fatigue
LEFM
linear-elastic fracture mechanics
LEO
low earth orbit
LFG
long fiber granulate
LFT
long fiber thermoplastics
LM
low modulus
LMC
laminated metal composite
ln
natural logarithm (base *e*)
LOM
laminated object manufacture
LS
low shrink
LSE
low-styrene emission
LVID
low velocity impact damage
m
matrix
M
modulus (glass fiber designator)
M
moment
MAS
magnesium aluminosilicate
MDA
methylenedianiline
MEK
methyl ethyl ketone
Mg

megagram
min
minute; minimum
MJ
megajoule
mL
milliliter
mm
millimeter
MMA
methyl methacrylate
MMC
metal-matrix composite
MOL
material operational limit
mol%
mole percent
MPa
megapascal
mph
miles per hour
MSDS
materials safety data sheet
MTE
medium-toughness epoxy
MVT
moisture vapor transmission
N
Newton
N
fatigue life (number of cycles)
NA
not applicable
NASA
National Aeronautics and Space Administration
NC
numerical control
NDE
nondestructive evaluation
NDI
nondestructive inspection
NDT
nondestructive testing
NGV
natural gas vehicle
nm
nanometer
NMP
N-methyl pyrrolidinone
NMR
nuclear magnetic resonance
NOL
Naval Ordnance Laboratory
No

. number
NPG
neopentyl glycol
OD
outside diameter
OEM
original equipment manufacturer
OHC
open-hole compression
OHV
overhead valve
OMC
organic-matrix composite
OMS
orbital maneuvering system
OSHA
Occupational Safety and Health Administration
oz
ounce
p
particulate
P
applied load; pressure
Pa
pascal
PA
polyamide
PAI
polyamide-imide
PAN
polyacrylonitrile
PAS
polyarylsulfone
PBI
polybenzimidazole
PBT
polybutylene terephthalate
PC
polycarbonate
PCB
printed circuit board
PEI
polyetherimide
PEEK
polyetheretherketone
PES
polyether sulfone
PET
polyethylene terephthalate
PF
phenol formaldehyde
phr
parts per hundred parts resin
PI

polyimide
PIC
pressure-impregnation-carbonization
PIP
polymer infiltration and pyrolysis
pl
platelet
P/M
powder metallurgy
PMC
polymer-matrix composite
PMMA
polymethyl methacrylate
PMR
in situ polymerization of monomer reactants
PP
polypropylene
ppb
parts per billion
PPE
polyphenylene ether
ppm
parts per million
PPS
polyphenylene sulfide
Pr
Prandtl number
PRF
phenol resorcinal formaldehyde
PR-MMC
particle-reinforced metal-matrix composites
PS
polysulfone
psi
pounds per square inch
psia
pounds per square inch absolute
psid
pounds per square inch differential
psig
pounds per square inch gage
PTFE
polytetrafluoroethylene
PUR
polyurethane
PVA
polyvinyl alcohol
PVAC
polyvinyl acetate
PVC
polyvinyl chloride
PVD
physical vapor deposition
PVDF

polyvinylidene fluoride
PVF
polyvinyl fluoride
PZT
lead-zirconium titanate
r
radius
r
rate of reaction
R
radius; ratio of the minimum stress to the maximum stress; load ratio
RA
reduction of area
Ref
reference
RFI
resin-film infusion
RGA
residual gas analysis
RH
relative humidity
RI
refractive index
RIM
reaction injection molding
RMS
root mean square
ROM
rule of mixtures; rough order of magnitude
RP
rapid prototyping
rpm
revolutions per minute
RRIM
reinforced reaction injection molding
RT
room temperature
RTD
room temperature, dry
RTM
resin transfer molding
RTW
room temperature, wet
RTV
room temperature, vulcanizing
RVE
representative volume element
s
second
s
symmetry of stacking about the midplane
S
strength (glass fiber designator)
SACMA

Suppliers of Advanced Composite Materials Association
SAE
Society of Automotive Engineers
SaRTM
solvent-assisted resin transfer molding
SAVE
structural analysis using variable-order elements
SBS
short beam shear
SCRIMP
Seeman composite resin infusion molding process
SD
standard deviation
SEM
scanning electron microscope or microscopy
SHS
self-propagating high-temperature synthesis
SI
Systeme International d'Unites
SIMS
secondary ion mass spectroscopy
SLA
stereolithography
SLS
selective laser sintering
SM
standard modulus
SMC
sheet molding compound
SMC-C
sheet molding compound-continuous
SMC-R
sheet molding compound-random
S-N
stress-number of cycles
SOMG/MA
soybean oil monoglyceride, maleinated
SPC
statistical process control
SPF
superplastic forming
sp gr
specific gravity
SRIM
structural reaction injection molding
SSB
small-scale bridging
SSY
small-scale yielding
t
thickness; time
T
transverse direction
T

temperature; tenacity
Tm
melting temperature
tan
equal to ratio of the loss modulus to the storage modulus
TEM
transmission electron microscope or microscopy
TFE
tetrafluoroethylene
T_g
glass transition temperature
TGA
thermogravimetric analysis
TLC
thin-layer chromatography
T_m
melting temperature
TMA
thermomechanical analysis
TMC
thick molding compound
TMC
titanium-matrix compsite
TMF
thermal mechanical fatigue
TPI
turns per inch
TS
thermoset
TTU
through-transmission ultrasonics
U
velocity
UD
unidirectional
UDC
unidirectional composite
UHM
ultrahigh modulus
UL
Underwriters' Laboratory
UP, UPE
unsaturated polyester
USAF
United States Air Force
UTS
ultimate tensile strength
UV
ultraviolet
VARI
vacuum-assisted resin injection
VARTM
vacuum-assisted resin transfer molding
v

viscosity

v

void

V

velocity

V

volume fraction

V_f

volume fraction of fiber

VCXPS

voltage contrast x-ray photoelectron spectroscopy

VHP

vacuum hot pressing

VLS

vapor-liquid-solid

V_m

volume fraction of matrix

V_v

volume fraction of void content

VOC

volatile organic compound

vol

volume

vol%

volume percent

w

whisker

W

watt

W

width

WPE

weight per epoxide

WR

woven roving

wt%

weight percent

XPS

x-ray photoelectron spectroscopy

YAG

yttrium-aluminum-garnet

yr

year

ZTA

zirconia-toughened alumina

1-D

one dimensional

2-D

two dimensional

3-D

three dimensional

3DP

three-dimensional printing

°

	angular measure; degree
°C	degree Celsius (centigrade)
°F	degree Fahrenheit
0°	fiber direction
90°	perpendicular to fiber direction
α	angle; coefficient of thermal expansion
Δ	change in quantity; an increment; a range
η	viscosity
ϵ	strain
$\dot{\epsilon}$	strain rate
ϵ-N	strain life, strain-number of cycles
γ	shear strain; surface tension; surface energy
$\dot{\gamma}$	shear strain rate
μin.	microinch
μm	micrometer (micron)
ν	Poisson's ratio
π	pi (3.141592)
ω	excitation frequency
ψ	damping
ρ	density
σ	tensile stress
τ	shear stress
θ	angle
±θ	angle plies
φ	porosity
⇔	direction of reaction
÷	divided by
=	

	equals
^	circumflex
≈	approximately equals
≠	not equal to
≡	identical with
>	greater than
>>	much greater than
≥	greater than or equal to
∞	infinity
α	is proportional to; varies as
∫	integral of
<	less than
<<	much less than
≤	less than or equal to
±	maximum deviation
-	minus; negative ion charge
×	diameters (magnification); multiplied by
·	multiplied by
Ω	ohm
/	per
%	percent
+	plus; positive ion charge
√	square root of
~	approximately; similar to

Greek Alphabet

A, α	alpha
B, β	beta

Γ, γ
gamma
Δ δ
delta
Ε, ϵ
epsilon
Ζ, ζ
zeta
Η, η
eta
Θ, θ
theta
Ι, ι
iota
Κ, κ
kappa
Λ, λ
lambda
Μ, μ
mu
Ν, ν
nu
Ξ, ξ
xi
Ο, ο
omicron
Π, π
pi
Ρ, ρ
rho
Σ, σ
sigma
Τ, τ
tau
ϒ, υ
upsilon
Χ, χ
chi
Ψ, ψ
psi
Ω, ω
omega
